BACKGROUND: Healthcare quality is frequently described with composite measures representing the overall performance. Despite growing attention to overuse in healthcare, there is little experience with composite measures of overuse. Overuse can be defined as use of a service in the absence of a clear medical basis for its use, or when the risk of harm exceeds its likely benefit. Our goal was to create a composite measure of overuse useable with claims data. We therefore aimed to identify a set of potentially overused medical procedures (indicators), operationalize these to be measureable with administrative claims, aggregate these indicators into a single indicator of overuse, and test whether the index is associated with higher costs and worse clinical outcomes, which would be the proof of principle that the measure is detecting regional overuse.

METHODS: This was an observational study, using 5 % of Medicare claims from 2008 (Parts A and B), of older patients in the U.S. receiving healthcare services in hospitals or outpatient settings. Via an environmental scan, we identified published descriptions of overused procedures. We assessed each procedure's feasibility for measurement with claims data and developed algorithms for occurrences of procedures in patients unlikely to benefit. We calculated summary statistics to illustrate variance in use across hospital referral regions (HRRs) and selected 20 for inclusion in the Johns Hopkins Index of Overuse (JHOI). We started with an initial analysis of each of the 20 indicators (denote by P). As such, we regressed P_{ijk} as $P_{ijk} = \beta X_i + \Phi_{jk} + \varepsilon_{ijk}$ where X_i is a vector of patient specific factors, Φ_{jk} is a set of regional fixed effects for j procedures across the k HRRs. From this model, the Φ_{jk} is a risk-adjusted measure indicating if region k overuses procedure j more or less than expected. The $JHOI_k$ was estimated as an average of the Φ_{jk} . Thus, in this version of the JHOI each indicator contributes equally to the index. With Spearman's correlation, we assessed the correlation of this regional measure, presumptively a measure of systematic overuse, with regional measures of total costs, risk-adjusted mortality, 30-day mortality, and total mortality.

RESULTS: 613 procedures were identified as overused. Twenty had abundant frequency and variance to be possible measures of systematic overuse, including 13 diagnostic tests, 2 tests for screening, 1 for monitoring, and 4 therapeutic procedures. Usage varied markedly across HRRs. Among 1,451,142 beneficiaries, 14 % had at least one overuse event. The index was positively correlated with 30-day inpatient mortality ($r=0.27$, $p=<0.0001$), and positively correlated with total costs ($r=0.39$, $p<0.0001$). It was similarly positively correlated with inpatient days (0.22, $p<0.0001$) and intensive care unit days ($r=0.32$, $p<0.0001$), but not with total mortality.

CONCLUSIONS: We identified a set of overused procedures that demonstrate significant variance in their usage. This study provides proof of principle that systematic overuse exists and is measurable. We need to identify the best combination of indicators for the index, which may require inclusion of procedures prevalent in younger people, and to validate the index when applied to panel data.

THE MEANINGFUL USE OF ELECTRONIC HEALTH RECORDS AND HEALTHCARE UTILIZATION Lisa M. Kern; Alison M. Edwards; Rainu Kaushal. Weill Cornell Medical College, New York, NY. (*Tracking ID #1937856*)

BACKGROUND: Since 2011, the federal government has been investing \$20 billion in incentives for adoption and meaningful use of interoperable electronic health records (EHRs). The effect of “Meaningful Use” (MU) of EHRs on health care utilization is not known. We sought to determine the effects of MU on health care utilization, compared to typical use of EHRs without MU.

METHODS: We conducted a longitudinal cohort study of primary care physicians in the Hudson Valley region of New York over 2 years (2010–2011). We divided physicians, all of whom were using EHRs, into 2 study groups, based on whether they had achieved MU in 2011 or not. We used negative binomial regression to determine associations between study group and 7 different utilization outcomes (primary care visits, specialist visits, laboratory tests, radiology tests, emergency department visits, hospital admissions and 30-day readmissions), adjusting for 11 physician characteristics (membership in an independent practice association, gender, age, degree, specialty, rural county, practice size, Patient-Centered Medical Home status, panel size, case mix and plan mix).

RESULTS: We included 213 physicians and 127,353 patients. Of the physicians, 107 (50 %) had achieved MU and 106 (50 %) had not. For every 100 patients whose physicians achieved MU, there were 17 fewer primary care visits and 61 fewer laboratory tests, compared to patients whose physicians did not achieve MU ($p<0.05$ for each adjusted comparison). There were no significant differences for the other outcomes.

CONCLUSIONS: Achieving Stage 1 MU was associated with a decrease in primary care visits and laboratory tests. This suggests that effects of MU on health care utilization are distinct from the effects of typical EHR use without MU.

THE MEDICATION METRONOME: A HEALTH IT SYSTEM TO IMPROVE MEDICATION MANAGEMENT AND LABORATORY MONITORING FOR CHRONIC DISEASES Steven J. Atlas¹; Michael Jernigan¹; Jeffrey M. Ashburner¹; Jaime Chang¹; Leila H. Borowsky¹; Yuchiao Chang¹; Richard W. Grant².

¹Massachusetts General Hospital, Boston, MA; ²Kaiser Permanente Northern California, Oakland, CA. (*Tracking ID #1938604*)

BACKGROUND: Lack of timely medication intensification and inadequate safety monitoring are two prevalent and potentially modifiable barriers to effective and safe chronic care. To test a model of chronic disease management in which medication initiation or dose adjustment orders are explicitly and immediately linked to future planned laboratory monitoring, we developed a novel health information technology (IT) tool (Medication Metronome) designed to support non-visit based medication management. Integrated into an existing electronic health record (EHR), the tool enabled primary care physicians (PCPs) to schedule future laboratory monitoring when initiating or adjusting doses of medications for diabetes, hypertension, and/or hyperlipidemia management. We hypothesized that scheduling follow-up laboratory monitoring (e.g. HbA1c 3 months after starting metformin) would support a cycle of laboratory monitoring and iterative medication dose adjustment resulting in more effective and safer chronic disease care.

METHODS: Physicians from two sites within a primary care network were randomized to intervention ($n=22$) or control ($n=22$) groups. During a 1-year intervention, PCPs allocated to the intervention had an additional feature in their electronic medication prescription interface that enabled them to schedule future laboratory tests when ordering new prescriptions or adjusting doses to treat type 2 diabetes, hypertension, or hyperlipidemia. This process initiated automated patient reminders that included a mailed letter and lab slip 1 week before the test was due and (if necessary) a second letter and lab slip 1 week after the test due date if no result was found. Notification of persistently overdue lab results (>3 weeks after due date) was added to a physician “Watchlist” of test results within the EHR. Control physicians had access to the same EHR but without the added Medication Metronome interface. Efficacy labs were defaulted to order, while

safety monitoring needed to be actively turned on by intervention physicians. The primary effectiveness outcome was the percentage of follow-up time that a patient was at or below risk factor goal (HbA1c $\leq 7\%$ among diabetics prescribed hypoglycemic agents; LDL-cholesterol ≤ 130 mg/dl for patients with hyperlipidemia without cardiovascular risk and ≤ 100 mg/dl for patients with cardiovascular risk) using a mixed effects model. The primary safety outcome was the percentage of safety monitoring laboratory tests (creatinine after initiating drugs for hypertension and diabetes, and liver function testing after initiating statins) completed within 4 weeks of the medication order using logistic regression models. Models accounted for clustering by PCP and adjusted for patient age, gender, race/ethnicity, primary language spoken and baseline lab value.

RESULTS: During the study period, there were 2991 eligible medications orders among 2031 patients of intervention PCPs and 2420 orders among 1590 patients of control PCPs. In the intervention group, 659 prescriptions (22 %) used the Metronome interface to initiate laboratory follow-up (521 [79 %] efficacy, 138 [21 %] safety). Patient characteristics were similar among intervention and control groups except slightly more intervention patients were non-Hispanic whites (84.3 % vs. 80.5 %, $p=0.02$) and spoke English (95.4 % vs. 92.8 %, $p=0.001$), and had lower LDL levels (118.2 vs. 125.6 mg/dl, $p=0.002$). The adjusted percentage of time that a patient was at or below the effectiveness outcome goal over 3 months after a medication order did not differ among patients of intervention and control PCPs for diabetes (30.9 % vs. 29.1 %, $p=0.72$) or hyperlipidemia (51.6 % vs. 46.7 %, $p=0.2$) (see Table). Similarly, the performance of safety monitoring labs within 4 weeks of a medication order for hypertension, diabetes or hyperlipidemia did not differ among intervention or control groups (data not shown).

CONCLUSIONS: A visit-independent, health IT tool to support a cycle of laboratory monitoring and iterative medication dose adjustment following the initiation or change of chronic disease medications during an office-based visit did not increase goal attainment or safety monitoring rates compared to usual care. New models for reimbursing providers for health care services may be needed before adoption of innovative tools that support visit-independent medication management.

Mean proportion of time at or below goal in intervention and control groups

	Intervention		Control		Difference	95 % CI
	N	Adjusted Mean %	N	Adjusted Mean %		
Diabetes: HbA1c ≤ 7	308	30.9 %	268	29.1 %	1.8 %	-8.4–12.1 %
Intervention group limited to those with Metronome order	120	32.5 %	268	29.1 %	3.5 %	-8.6–15.5 %
Hyperlipidemia: LDL at goal	674	51.6 %	391	46.7 %	4.9 %	-1.6–11.4 %
Intervention group limited to those with Metronome order	227	53.0 %	391	46.7 %	6.3 %	-1.4–14.0 %

THE QUALITY AND IMPORTANCE OF FEEDBACK IN PROFESSIONAL DEVELOPMENT OF INTERNS AND RESIDENTS Ryan Graddy; Panagis Galiatsatos; Colleen Christmas. Johns Hopkins Bayview Medical Center, 913 Baylis Street, MD. (*Tracking ID #1939327*)

BACKGROUND: The receipt of high quality feedback during medical education is likely a key component of learner development of professional skills, knowledge, and identity. Available literature demonstrates that physicians are often poor at self-assessing their own strengths and weaknesses as clinicians and educators, suggesting that receipt of outside feedback throughout one’s career is crucial to continuing professional development. Nonetheless, a paucity of data exists on learner attitudes toward feedback as both recipient and provider.

METHODS: We conducted a structured online survey of internal medicine residents and interns at a moderate-sized academic residency program (Johns Hopkins Bayview Medical Center) to assess the perceived role and importance of feedback in trainees' professional development. Survey questions were developed with a Likert scale model that focused on self-assessed value of several modes of teaching including directed feedback, confidence in giving feedback to individuals at varying levels of training, and importance assigned to feedback giving and receipt in one's future career path.

RESULTS: 19 interns and 15 upper level residents completed the survey. 89.4 % (17) of interns deemed one-on-one feedback with faculty members as "useful" or "very useful" for professional development; over 50 % of respondents rated this as "very useful." Teaching on rounds, small group sessions, online reference materials, teaching conferences, a module-based internet learning center, and self-directed learning all received lower ratings. In contrast, residents rated online reference materials most consistently as "useful" or "very useful" (100 %, 15), while 73.6 % (11) of upper level residents rated one-on-one feedback as such. Both interns and residents rated a module-based internet learning resource as the least useful tool in their development. Interns consistently reported a high degree of confidence in providing feedback to students (73.7 % agreed or strongly agreed), but generally felt less confidence in providing feedback to fellows and faculty (36.8 % each). Residents felt confident in providing feedback to medical students and interns in 73.3 % of cases (11 for each), but only 13.3 % (2) felt confident providing feedback to fellows and 26.7 % (4) to attending physicians. Across the board, the importance of giving and receiving feedback during one's future career was greatly valued; 73.7 % (14) of interns and 80.0 % (12) of residents strongly agreed that receipt of high quality feedback is important to the doctor they aspire to be in 10 years, while 57.9 % (11) of interns and 71.4 % (10) of residents strongly agreed that giving high quality feedback is important to the doctor they aspire to be.

CONCLUSIONS: High quality feedback is consistently recognized as playing an important role in professional development among interns and residents, particularly during intern year. While trainees are highly confident in providing feedback to more junior learners, they report low confidence in providing feedback to more senior team members, suggesting that navigation of the cultural hierarchy of medicine remains challenging. Given the importance of feedback to lifelong professional development, further efforts are needed to improve resident training in this skill area.

THE RELATION BETWEEN ANTIHYPERTENSIVE MEDICATION AND SEXUAL FUNCTION IN WOMEN: BASELINE DATA FROM THE SPRINT STUDY Holly N. Thomas^{1,2}; Gregory W. Evans³; Dan Berlowitz^{4,5}; Denise E. Bonds⁶; Glenn M. Chertow⁷; Molly B. Conroy¹; Capri Foy⁸; Stephen Glasser⁹; Cora E. Lewis⁹; William T. Riley¹⁰; Laurie Russell⁸; Olubunmi Williams¹¹; Rachel Hess¹.

¹University of Pittsburgh, Pittsburgh, PA; ²VA Pittsburgh Healthcare System, Pittsburgh, PA; ³Wake Forest University, Winston-Salem, NC; ⁴Bedford VA Hospital, Bedford, MA; ⁵Boston University School of Medicine, Boston, MA; ⁶University of Virginia School of Medicine, Charlottesville, VA; ⁷Stanford University School of Medicine, Palo Alto, CA; ⁸Wake Forest University School of Medicine, Winston-Salem, NC; ⁹University of Alabama at Birmingham School of Medicine, Birmingham, AL; ¹⁰National Institute of Mental Health, Bethesda, MD; ¹¹Emory University, Atlanta, GA. (Tracking ID #1937990)

BACKGROUND: Treatment of hypertension results in substantial reductions in cardiovascular risks, yet patients often discontinue antihypertensive medications due to side effects. Studies have suggested an association between antihypertensives and sexual dysfunction in men, but the relationship between these medications and sexual dysfunction in women is less well understood. We used a cross-sectional cohort of older women to examine the relations among different classes of antihypertensives and sexual function.

METHODS: The Systolic Blood Pressure Intervention Trial (SPRINT) is a randomized controlled trial of high-risk (presence of cardiovascular disease, chronic kidney disease, or 10-year Framingham risk score $\geq 15\%$) individuals aged 50 and older comparing the effect of standard (systolic < 140 mmHg) and lower (systolic < 120 mm Hg) blood pressure control targets on a variety of clinical outcomes. Baseline data were used for this analysis. A randomly selected subset of participants completed questionnaires on quality of life

(QoL), including sex. Self-reported sexual function was assessed using a modified version of the Female Sexual Function Index (FSFI), a validated instrument. A score of < 27 indicates sexual dysfunction. Antihypertensive class was defined by medications participants were taking at the start of the trial. Only women who engaged in any kind of sexual activity in the prior 4 weeks were included in the analysis (FSFI scores cannot be calculated in inactive women). Descriptive statistics were used to compare sexually active and inactive women. A multivariable linear regression model including class of medication and potential confounding variables (demographic factors, level of blood pressure, and comorbidities) was used to examine the relation between medication class and FSFI score while adjusting for other variables. Two-mean comparison tests were used to determine the power our sample had to detect at least a moderate clinical difference in FSFI score (Cohen's $d=0.5$) for women taking a given medication versus women not taking that medication.

RESULTS: Of 690 women who participated in the QoL portion of SPRINT, 183 (26.5 %) were sexually active. Inactive women were more likely to be older, less educated, live alone, and have medical comorbidities. The mean age for sexually active women was 63.4 (SD 9.1) and 41.5 % were white. Among sexually active women, FSFI scores were low overall, with the mean (25.3) falling below the cutoff for dysfunction. Scores were similar for different antihypertensive classes (Table 1). The mean FSFI was significantly higher for women not taking any antihypertensives (28.0, unadjusted $P=0.041$), but this difference did not persist in multivariable analysis ($P=0.35$). Neither class of medication, nor any of the potential confounders, was significantly associated with FSFI score on multivariable analyses (Table 2). This analysis had 82.6 % (85.4, 92.0, 90.2) power to detect a moderate difference in FSFI scores between beta-blocker (calcium-channel blocker, diuretic, angiotensin converting enzyme inhibitor/angiotensin receptor blocker) users and non-users.

CONCLUSIONS: Similar to prior studies of older women, FSFI scores were overall low in this cohort. We found no association between any antihypertensive class and sexual dysfunction in women in this cross-sectional sample. Larger, longitudinal studies are necessary to fully understand the relation between antihypertensive medications and sexual function in women.

FSFI scores among sexually active women in SPRINT

	N (%)	Mean FSFI score	SD
All sexually active women	183 (100.0)	25.3	6.0
Women on no antihypertensives	19 (10.4)	28.0	4.7
Beta-blocker users	45 (24.6)	24.6	6.7
Calcium channel blocker users	50 (27.3)	25.4	6.4
Diuretic users	95 (51.9)	24.8	6.5
ACE/ARB users	115 (62.8)	24.9	5.7

ACE/ARB = angiotensin-converting enzyme inhibitor/angiotensin-receptor blocker

Baseline characteristic	Fully adjusted beta for FSFI score (95 % CI)	P-value
Not taking antihypertensives (vs. any)	1.83 (-2.02, 5.68)	0.35
Beta-blocker use (vs. not)	-0.58 (-2.77, 1.62)	0.61
Calcium channel blocker use (vs. not)	0.2 (-1.8, 2.2)	0.84
Diuretic use (vs. not)	-1.39 (-3.3, 0.52)	0.153
ACE/ARB use (vs. not)	-0.99 (-2.86, 0.87)	0.29
Systolic blood pressure (per 10 mm Hg increase)	0.07 (-0.73, 0.87)	0.86
Diastolic blood pressure (per 10 mm Hg increase)	0.67 (-0.47, 1.81)	0.25
Presence of chronic kidney disease (vs. not)	0.07 (-2.34, 2.48)	0.95
Presence of hyperlipidemia (vs. not)	1.13 (-0.7, 2.96)	0.22
Presence of cardiovascular disease (vs. not)	0.0 (-2.77, 2.76)	1.00

Multivariable predictors of FSFI score among sexually active women in SPRINT
Adjusted for age, race, education status, living with others, use of antidepressants, use of hormone therapy

THE RELATIONSHIP BETWEEN ATTRIBUTES OF PATIENT-CENTERED MEDICAL HOMES, PATIENT ENGAGEMENT, AND OUTCOMES OF CARE AMONG INDIVIDUALS LIVING WITH DIABETES Allyson G. Hall¹; Fern J. Webb²; David Wood²; Jeffrey S. Harman¹. ¹University of Florida, Gainesville, FL; ²University of Florida, College of Medicine, Jacksonville, FL. (*Tracking ID #1937694*)

BACKGROUND: Successful diabetes management requires coordination of multiple modalities, support for patients' participation in self-management activities, and paying attention to diverse cultural attitudes and beliefs. Patient-centered medical homes (PCMHs) are a conceptualization of how to provide care to individuals living with diabetes. How primary care sites implement key attributes of the medical home may be directly associated with how patients with diabetes experience care, engage in their care, and ultimately their health outcomes. This study examines: 1) how experiences with care and patient engagement (as measured by the Patient Activation Measure (PAM)) varies across four PCMHs; 2) the relationship between patients' ratings of their medical homes and level of engagement in their care; and 3) the relationship between patient engagement and self-reported outcomes of care.

METHODS: 1,300 randomly selected adult patients with diabetes seen at 4 National Committee for Quality Assurance Level 3 accredited academic primary care practices participated in a telephone survey. Survey items included the PAM and questions on experiences with their medical home. Ordered logistic regression analysis (controlling for race/ethnicity, marital status, education, health status, and age) was used to determine the relationship between a medical home practice and the extent to which patients were more engaged in their care; the relationship between patient ratings of their medical home and their PAM score; and relationship between their PAM score and the degree to which patients report following their diet as prescribed, and whether they check their feet for cracks and calluses. In-depth interviews with staff provided information on how each clinic operated.

RESULTS: The qualitative interviews showed that despite all 4 clinics achieving NCQA accreditation, there are differences in the manner in which key components of the PCMH model are implemented. For example, clinicians at site A had undergone intensive specialized training in diabetes care and provided a comprehensive disease management program to its patients. The survey showed that a higher proportion of patients at location A reported positive experiences with care. Ordered logistic regression analysis confirmed that patients at Location A were significantly more likely to have higher PAM scores compared to patients at the other three clinics. Regression analysis also demonstrated that patients with higher medical home domain ratings were more likely to have higher PAM scores; and that higher PAM scores are associated with reports of following their diet as prescribed and checking feet for cracks and calluses.

CONCLUSIONS: Despite receiving similar NCQA ratings, how medical homes offer and provide services can vary. This variation may lead to differing patient experiences with care and ultimately a difference in how patients can perceive their ability to manage and engage in their care.

THE RELATIONSHIP BETWEEN NEIGHBORHOOD FOOD ACCESS AND FOOD INSECURITY IN AN URBAN ENVIRONMENT Victoria L. Mayer¹; Amy Hillier²; Marcus A. Bachhuber^{1,3}; Judith A. Long^{1,3}. ¹Perelman School of Medicine at the University of Pennsylvania, Philadelphia, PA; ²School of Design, University of Pennsylvania, Philadelphia, PA; ³Philadelphia Veterans Affairs Medical Center, Philadelphia, PA. (*Tracking ID #1939936*)

BACKGROUND: Approximately 17.6 million households are estimated to be food insecure in the United States, meaning they do not have enough food for an active, healthy life. Programs to augment food access (i.e., neighborhood availability of healthy foods) are increasingly widespread, but the relationship between food access and food insecurity is unknown.

METHODS: We analyzed the 2008, 2010, and 2012 Southeastern Pennsylvania Household Health Survey. Our outcome was food insecurity, defined by skipping or reducing meal size because of budget. Logistic regression models included food access variables, including ease of finding fruits and vegetables and perceived quality of grocery stores in the neighborhood, as well as individual and neighborhood level covariates.

RESULTS: Of 11,599 respondents, 16.7 % of respondents reported food insecurity. Of those who reported food insecurity, 79.4 % found it easy or very easy to find fruits and vegetables and 60.6 % reported excellent or good quality grocery stores in their neighborhood. In the fully adjusted model, compared to those who reported very easy access to fruits and vegetables, those who reported easy, difficult or very difficult access were more likely to report food insecurity (OR 1.18: 95 % CI 1.00–1.38, 2.21: 95 % CI 1.70–2.88, and 3.57: 95 % CI 2.50–5.09). Compared to those who reported excellent stores, those who reported good, fair, and poor quality stores were more likely to report food insecurity (OR 1.35: 95 % CI 1.12–1.62, 1.87: 95 % CI 1.50–2.37, and 2.32: 95 % CI 1.69–3.19).

CONCLUSIONS: Neighborhood food access plays a role in food insecurity. However, many food insecure individuals already have local access to healthy foods. Interventions aimed at improving diet in communities with a high prevalence of food insecurity should focus not only on availability, but also on affordability.

THE RELATIONSHIP BETWEEN TELEPHONE VISITS AND USE OF OUTPATIENT CARE DURING THE VA MEDICAL HOME INITIATIVE David A. Katz^{1,2}; Kimberly McCoy¹; Mary Vaughan Sarrazin¹. ¹University of Iowa, Iowa City, IA; ²University of Iowa Carver College of Medicine, Iowa City, IA. (*Tracking ID #1939083*)

BACKGROUND: Increased use of telephone visits and other non-face-to-face contacts is widely advocated as a key strategy for VA medical homes to improve access and efficiency. The objective of this study is to determine whether telephone visits are associated with fewer in-person primary care visits and fewer ED visits during the Patient Aligned Care Team (PACT) initiative.

METHODS: We conducted a cross-sectional analysis of VA outpatients with at least one chronic condition (HTN, DM, COPD, CAD, CHF, depression/anxiety) who were assigned to a VA primary care provider (PCP) and had at least one primary care visit each year with physicians or physician extenders during FY2010-13 ($N=100,383$). To do this, we linked data in the 2010 Patient Care Management Module (PCMM) to VA outpatient data; patients of resident providers, nursing home residents, and those who received home telehealth were excluded. Clinic stop codes were used to identify telephone visits with nurses and providers, primary care visits, and ED visits, which were tabulated during FY2012-13. We used generalized estimating equations (GEE) with overdispersed Poisson models to assess number of primary care visits, and multivariable logistic regression models to predict any ED use. In a longitudinal analysis, we assessed whether patients who received telephone visits during the

6 months following the initial clinic visit in FY2012 (months 0–6) were more likely to visit the primary care clinic and the ED during the subsequent 3 month period (months 7–9), compared to patients who did not receive any telephone visits during months 0–6. All regression models controlled for demographics, disability status, 22 chronic medical and psychiatric conditions [Romano, 1993; Abrams, 2009], as well as number of primary care clinic visits and prior VA hospitalization (all calculated from baseline FY2010–11 data); robust sandwich variance estimates were used to account for clustering at the level of patients' usual site of care.

RESULTS: During FY2012–13, study patients had a mean of 4.8 primary care visits and 19 % had visited the ED; 44 and 2 % received at least one telephone visit from a primary care nurse and a PCP, respectively. In multivariable models, patients who received 1 and 2+ nurse telephone visits had greater use of primary care visits: IRR (95 % CI)=1.10 (1.07, 1.13) and 1.30 (1.23, 1.37), respectively. Patients who received 1 and 2+ nurse telephone visits were also more likely to visit the ED during follow-up: OR (95 % CI)=2.5 (1.8, 3.5) and 4.5 (2.8, 7.2), respectively. In longitudinal analysis, patients who received nurse telephone visits during 6-month follow-up had more primary care visits and were more likely to visit the ED during the subsequent 3 months than those who did not receive telephone visits from a nurse: IRR (95 % CI)=1.16 (1.11, 1.20) and OR (95 % CI)=1.7 (1.3, 2.2), respectively. Similar results were observed for providers, except that the results for ED use were not statistically significant.

CONCLUSIONS: Although the use of telephone visits is an important strategy for improving access to care, telephone visits have the potential to generate more outpatient visits and ED referrals, as previously unrecognized problems are brought to the attention of primary care team members. More effective telephone care strategies may obviate the increased need for face-to-face visits.

THE ROLE OF EVOLUTIONARY CONCEPTS IN MEDICAL EDUCATION, 10 YEARS LATER

Brandon H. Hidaka¹; Anila Asghar³; Randolph M. Nesse⁵; Katelyn Bennett^{4,2}; Matthew Beyrouty^{2,4}; Nicole Skursky^{2,4}; Mark D. Schwartz^{2,4}.

¹University of Kansas Medical Center, Kansas City, KS; ²NYU School of Medicine, New York, NY; ³McGill, Montreal, QC, Canada; ⁴VA New York Harbor Healthcare System, New York, NY; ⁵Arizona State University, Tempe, AZ. (Tracking ID #1938046)

BACKGROUND: Understanding evolutionary biology deepens medical knowledge and expands our explanatory models for research, education, and practice. A 2003 survey revealed how, and why, little evolution is taught in medical school. The current survey assessed the current situation and changes since the prior study.

METHODS: We surveyed curriculum deans of all 153 Canadian and US medical schools. Respondents rated the curricular coverage (4-point scale from not covered to covered in depth) and importance (4-point scale from not important to essential) of 12 core evolutionary principles (e.g. somatic selection in cancer, tradeoffs, hygiene hypothesis, and antibiotic resistance). We described the gap between importance and coverage of these principles and compared coverage in 2003 and 2013. We measured the association between mean coverage with school characteristics, resources devoted to teaching evolution, potential controversy, and mean importance. Respondents rated the usefulness of 13 teaching resources that could facilitate teaching evolution. Open-ended questions sought further insight into benefits of and barriers to infusing

evolution into medical education. Qualitative responses were sorted into themes by three independent researchers.

RESULTS: Of the 60 (39 %) responding schools, 90 % were from the US, 62 % were public, 27 % from the top NIH quartile, 42 % placed high priority on training future researchers, and 48 % felt that teaching evolution could arouse controversy among students, faculty, legislators, or donors. Schools reported a median (IQR) of 0 (0–2) faculty with a PhD in Evolution, 0 (0–2) faculty doing research based in evolution, 6 (4–16) hours teaching evolutionary topics in the curriculum, and 5 (2–15) hours teaching applications of evolutionary principles to specific medical problems. Figure 1 illustrates the proportion of importance and coverage of the 12 evolutionary principles. Table 1 compares current survey results with those from the 2003 survey. A school's mean coverage of evolution principles was associated with the number of faculty with a PhD in evolutionary biology ($r=0.29$, $p=0.07$), the number of faculty whose research is based in evolutionary biology ($r=0.38$, $p=0.02$), having an evolutionary medicine student interest group ($p=0.04$), and the school's mean rating of importance of evolutionary topics ($r=0.75$, $p<0.0001$). The 3 teaching resources ranked as most useful were: model test questions and answers with explanations, case studies with facilitator guides, and model curricula for adding evolution content to existing courses and rotations. Qualitative responses revealed barriers to teaching evolution in medical school: competition in already overfull curricula, anticipated religious controversy, low perceived value, and lack of resources, especially faculty.

CONCLUSIONS: North American medical schools have increased the content of evolutionary principles in their curriculum over the past decade. Curriculum deans view many evolutionary principles as important, but report minimal coverage of many topics ranked as important. Their responses suggest that bridging the gap will best be accomplished by bolstering faculty expertise in evolutionary biology, and developing education resources that can augment their effectiveness in teaching the basic principles of evolutionary biology that are useful in medicine.

Table 1

	2003 survey	2013 survey	Difference
% Having evolutionary biologist on faculty	16	49	+33

THE ROLES OF COST AND QUALITY INFORMATION IN MEDICARE ADVANTAGE PLAN ENROLLMENT DECISIONS Rachel O. Reid¹; Partha Deb⁴; Benjamin L. Howell²; William Shrunk³. ¹Brigham and Women's Hospital, Boston, MA; ²Center for Medicare & Medicaid Services, Baltimore, MD; ³Brigham and Women's Hospital, Boston, MA; ⁴Hunter College, New York, NY. (Tracking ID #1933518)

BACKGROUND: To facilitate informed decision making in the Medicare Advantage marketplace, the Centers for Medicare & Medicaid Services publishes information about Medicare Advantage plans via the Medicare Plan Finder website, including costs, benefits, and quality ratings provided on a 1-to-5 star scale. Little is known about how beneficiaries weigh costs versus quality when making enrollment choices. In this study, we assess the variation in Medicare Advantage enrollment attributable to plan attributes and willingness to pay for quality.

METHODS: We conducted a nationwide, beneficiary-level cross-sectional analysis of the 2011 Medicare Advantage and Prescription Drug (MAPD) plan choices of beneficiaries enrolling in Medicare Advantage for the first time ever in 2011 who were not eligible for the low-income subsidy. Matching beneficiaries with their choice-sets of MAPD plans by county, we used conditional logistic regression to estimate associations between plan attributes and enrollment, to assess both the proportion of explained enrollment variation attributable to plan attributes and willingness to pay for quality. The model accounted for 5-star quality ratings, costs (premiums and average estimated out-of-pocket costs), benefits (plan structure; deductibles; coinsurance; hearing, vision, dental benefits; and prescription gap coverage), and lagged county-level sponsor organization (i.e., brand) market share. Because willingness to pay for quality may vary at different rating levels, the model included both the 5-star quality rating itself and its quadratic transform. We assessed differential willingness to pay by beneficiary characteristics (age, sex, race, and urban versus rural residence) by interacting these covariates with quality and cost covariates.

RESULTS: The study cohort included 847,069 first-time Medicare Advantage enrollees who selected an eligible MAPD plan in 2011. Relative to the total variation explained by the model, market share accounted for 35.3 % of variation in plan choice, premiums for 25.7 %, estimated out-of-pocket costs for 11.6 %, and 5-star quality ratings for 13.6 %. Mean cumulative willingness to pay for a plan in total annual combined premiums and out-of-pocket costs varied from \$4,154.93 for a 2.5-star plan to \$5,698.66 for a 5-star plan. Increases in willingness to pay diminished at

higher 5-star quality ratings: \$549.27 (95 % CI \$541.10 to \$557.44) to go from a 2.5-star plan to a 3-star plan and \$68.22 (95 % CI \$61.44 to \$75.01) to go from a 4.5-star plan to a 5-star plan. Beneficiaries aged 64–65 years were more willing to pay for plans with higher quality ratings than other age groups; black and rural beneficiaries were less willing to pay for plans with higher quality ratings.

CONCLUSIONS: Medicare Advantage enrollees prefer plans with higher quality ratings and lower costs; however, market share's contribution to plan choice suggests that word-of-mouth and brand recognition are also influential. Key subgroups' differential willingness to pay for quality and market share's influence argue for continued efforts to advance communication of plan attributes to improve marketplace efficiency. If increased enrollment in plans with the highest quality ratings is a goal, the diminishing marginal utility for quality observed supports policy interventions to make achievement of the highest ratings desirable for insurers and enrollment in the highest-rated plans attractive and accessible to beneficiaries.

THE USE OF PANEL MANAGEMENT ASSISTANTS TO IMPROVE SMOKING CESSATION AND HYPERTENSION MANAGEMENT BY VA PRIMARY CARE TEAMS: A CLUSTER RANDOMIZED CONTROLLED TRIAL Mark D. Schwartz^{1,2}; Ashley E. Jensen^{1,2}; Binhuang Wang^{1,2}; Katelyn Bennett^{1,2}; Anne Dembitzer^{1,2}; Sheila Strauss³; Antoinette Schoenthaler²; Colleen Gillespie²; Scott Sherman^{1,2}. ¹VA New York Harbor Healthcare System, New York, NY; ²NYU School of Medicine, New York, NY; ³NYU College of Nursing, New York, NY. (Tracking ID #1937793)

BACKGROUND: Panel Management (PM), a set of tools and processes applied to populations of patients, can expand prevention and chronic illness management beyond the office visit, but there is limited evidence for its effectiveness or guidance on how to incorporate it into clinical practice. To test the effectiveness of incorporating PM into clinical practice, we randomly assigned Panel Management Assistants (PMAs) to primary care teams with and without panel management education.

METHODS: We conducted an 8-month, cluster-randomized controlled trial at two campuses of the VA New York Harbor Healthcare System. A total of 20 primary care (PC) teams were randomized, which consisted of 51 physicians and 18 nurses serving 8,153 patients with hypertension and/or smoking. Twelve teams were randomized to

receive support from a PMA, a college graduate with no clinical training who underwent a one-month orientation that covered basic clinical issues in hypertension and smoking, skill development in panel management, VA's electronic medical record and administrative tools, and motivational interviewing and Brief Action Planning. PMAs systematically reviewed panel data for their assigned teams to identify patients with specific gaps in care. They joined biweekly team meetings to review lists of identified patients and propose PM strategies using a toolkit developed for the study and then conducted patient outreach by phone and mail. Six of the 12 intervention teams also received PM education consisting of five, 20-minute PM education sessions during team meetings. These case-based sessions addressed working in multidisciplinary teams, practicing PM, and leveraging the clinical microsystem. The eight control teams received only monthly data on their smoking and hypertensive patients. Primary outcomes were assessed from the medical record and by patient survey: mean systolic and diastolic blood pressure (BP), proportion of patients with controlled BP, self-reported quit attempts, nicotine replacement therapy (NRT) prescriptions, and referrals to disease management services. PC staff was surveyed before and after the intervention.

RESULTS: Regression analysis, controlling for baseline BP and clustering, revealed no significant differences among study arms in mean systolic or diastolic BP values post-intervention. Following the intervention, 90 % of smokers reported quitting for at least 1 day and 64 % reported quitting for at least a week. However, there were no significant differences in smoking rates or quit attempts by study group. Patients on intervention teams were more likely to receive NRT for smoking ($OR=1.4$; 95 % CI 1.2–1.6), to enroll in the VA's weight management ($OR=1.2$; 95 % CI 1.1–1.6) or, Telehealth programs ($OR=1.7$, 95 % CI 1.4–2.1), than patients on control teams. Most staff (80 %) assigned to an intervention team felt the PMA was a useful resource for their team and 73 % wanted to continue working with a PMA. Only 26 % said the PMA took too much of their time. Only 40 % said they would continue using PM strategies when the PMA left the team.

CONCLUSIONS: PM support and education for PC teams improved process, but not outcomes among veterans with hypertension and smoking. This study has important limitations, as it included only veterans, implementation lasted only 8 months with post-intervention data collection interrupted by Hurricane Sandy, and primary care teams were newly formed at study outset. However, incorporating PMAs into PC teams was feasible and highly valued by the clinical staff, and warrants further study.

THE VALUE OF STUDENT-RUN CLINICS FOR THE PREMEDICAL STUDENT: A MULTI-INSTITUTIONAL STUDY Kaylin Pennington¹; Ian Tong¹; Cindy Lai²; Patricia S. O'Sullivan²; Leslie Sheu². ¹Stanford University, Stanford, CA; ²University of California, San Francisco, San Francisco, CA. (Tracking ID #1938624)

BACKGROUND: Over 40,000 students apply to US medical schools each year. While the majority of premedical students participate in clinical experiences prior to medical school matriculation, the skills and abilities gained from these widely variable experiences are not well known. In student-run clinics (SRCs), premedical students take on authentic roles in patient care—acting as interpreters, patient navigators, patient advocates, and health educators. While research has shown that SRCs are ideal experiential learning arenas for medical students, the subjective benefit of SRCs on premedical students has not yet been explored. This study is a first attempt to characterize the impact of the SRC experience on the premedical student who later matriculates to medical school.

METHODS: We conducted a retrospective cohort study involving first-year medical students at five California medical schools. Participants completed an anonymous one-time online survey that included demographic information, premedical activities, and Likert scale questions (from not (1) to extremely (4) important) related to SRC participation. We calculated descriptive statistics and used chi-squared and t-tests to compare groups. We used SPSS for all tests and set significance at 0.05.

RESULTS: Two-hundred eighty-seven responses were collected between September and November 2013 (48.2 % response rate, ranging from 30 to 71 % by school). Across all five schools, 50 students in total (17.4 % of respondents) reported volunteering in an SRC and 24 students served as leaders. For those participating in SRCs, major activities included taking patient histories and vital signs; serving as interpreters, patient advocates, or receptionists; case management; and supporting operational activities. Students' greatest motivations to volunteer were a desire to work with patients and underserved populations (means 3.88 (SD 0.39) and 3.84 (SD 0.37), respectively), and students believed that they gained the most skills in these areas (means 3.67 (SD 0.63) and 3.74 (SD 0.57), respectively). Most students (56 %) found one or more mentors through their SRC experience; 67.8 % identified medical student mentors. Students found their SRC experience to be among their most

meaningful premedical experiences (mean score 8.60 out of 10 (SD 1.36)), with those students who served in leadership positions or identified mentors finding the experience more meaningful than those who did not ($p<0.02$).

CONCLUSIONS: Nearly one-fifth of first-year medical students surveyed volunteered in SRCs prior to their medical school matriculation. Students identified SRCs as meaningful venues for developing leadership, teamwork, and patient interaction skills. Medical schools could build on the skills these students have as part of a systems-based practice curriculum. One major limitation to our study is our low survey response rate, which may introduce bias to our results. Nevertheless, we hope that this attempt to understand premedical clinical experiences will serve as fertile ground for future research including comparing premedical SRC experiences to other clinical experiences and understanding how premedical SRC experiences may meet early competency milestones (particularly patient care, interpersonal and communication skills, and systems-based practice).

THE VARYING IMPACT OF CHRONIC DISEASES ON PHYSICAL AND MENTAL HEALTH-RELATED QUALITY OF LIFE: IMPLICATIONS FOR A NOVEL MEASURE OF MULTIMORBIDITY Melissa Y. Wei^{1,2}; Ichiro Kawachi³; Olivia Okereke^{4,2}; Kenneth Mukamal¹. ¹Beth Israel Deaconess Medical Center/Harvard Medical School, Boston, MA; ²Harvard School of Public Health, Boston, MA; ³Harvard School of Public Health, Boston, MA; ⁴Brigham and Women, Boston, MA. (Tracking ID #1928886)

BACKGROUND: More adults have multimorbidity, the coexistence of two or more chronic conditions, than have one chronic disease. Multimorbidity is associated with decreased health-related quality of life (HRQOL) and greater healthcare utilization and cost. However, heterogeneity in the impact of chronic conditions is not well-characterized and has limited consistent and systematic efforts to study multimorbidity. We aimed to 1) quantify the impact of a broad range of individual chronic diseases on both physical and mental HRQOL, and 2) determine whether a multimorbidity index of diseases weighted by their associated HRQOL differs from a simple count of the number of diseases.

METHODS: The Nurses' Health Study (NHS) is a prospective cohort of 121,700 female nurses aged 30–55 years when data collection began in 1976. In 2000, participants completed a questionnaire on 50 physician-diagnosed chronic diseases and conditions and the Short Form (SF)-36, including its Physical Component Summary (PCS) and Mental Component Summary (MCS). These summary scores are scaled 0–100 from lowest to highest functioning, and differences of 5–10 points (0.5–1 standard deviations) are typically considered clinically meaningful. We used multiple linear regression to measure the effect of individual morbidities on HRQOL after adjusting for age and other morbidities.

RESULTS: Of 94,839 women who returned questionnaires on chronic disease, we included 61,206 women who also completed the SF-36. Their mean age was 70 years (SD 7.1). The mean PCS score was 46.5 (SD 10.7), and mean MCS score was 54.6 (SD 7.7), close to general population norms. The most common chronic diseases were hypercholesterolemia, hypertension, osteoarthritis, benign breast disease, cataracts, and others shown in Table 1. The impact of common conditions on either PCS or MCS varied widely (PCS: median -1.31, range -6.89 to 0.64; MCS: median -0.80, range -7.24 to 0.33). Osteoarthritis had the greatest adverse impact on PCS, while atrial fibrillation and diabetes also reduced PCS by 2–4 points. While hypercholesterolemia was most prevalent, its impact on PCS was small and non-significant. Diseases with the greatest adverse impact on PCS were multiple sclerosis, Parkinson's disease, ALS, osteoarthritis, rheumatoid arthritis, lung cancer, emphysema, and congestive heart failure, respectively, but with the exception of osteoarthritis were generally less prevalent (0.03 % for ALS to 3.7 % for rheumatoid arthritis). The conditions with the largest adverse effect on MCS were depression, Parkinson's disease, lung cancer, inflammatory bowel disease, interstitial cystitis, lupus, hip fracture, and stroke. Although PCS and MCS were not meaningfully correlated across individuals (Pearson's correlation coefficient $r=0.02$), the magnitude of impact of various conditions on PCS was positively correlated with that on MCS ($r=0.26$). A multimorbidity index of the most common conditions weighted by their impacts on PCS was positively but far from uniformly correlated with a simple corresponding count of diseases ($r=0.67$).

CONCLUSIONS: In this study of over 60,000 women who reported both comorbidities and HRQOL, individual conditions varied widely in their effects on HRQOL, with some conditions associated with several-fold greater impact than others. Even common conditions varied widely in their associations with HRQOL. Across conditions, the impact on physical HRQOL correlated positively but moderately with mental HRQOL. Our results suggest that simple counts of diseases

for multimorbidity are unlikely to capture their true impact on health, and that methods weighted to HRQOL or other validated measures are both feasible and promising.

Table 1. Change in Physical Component Summary and Mental Component Summary scores for the most prevalent chronic diseases and conditions in the Nurses' Health Study in 2000

Chronic disease or condition	Prevalence, %	Physical Component Summary			Mental Component Summary		
		Change in PCS	Standard error	P-value	Change in MCS	Standard error	P-value
Elevated cholesterol	36.0	-0.012	0.08	0.88	-0.28	0.07	<0.0001
High blood pressure	35.0	-1.79	0.08	<0.0001	-0.06	0.07	0.43
Osteoarthritis	25.6	-6.89	0.09	<0.0001	0.85	0.07	<0.0001
Fibrocystic/benign breast disease	19.4	0.46	0.09	<0.0001	-0.009	0.08	0.91
Cataract	19.0	-0.82	0.10	<0.0001	-0.14	0.08	0.09
Osteoporosis	14.7	-0.23	0.11	0.03	-0.55	0.09	<0.0001
Depression	8.6	-2.60	0.13	<0.0001	-7.24	0.11	<0.0001
Basal cell cancer	7.6	0.64	0.14	<0.0001	0.33	0.12	0.005
Atrial fibrillation	7.2	-2.29	0.14	<0.0001	-0.32	0.12	0.007
Diabetes mellitus	5.9	-4.11	0.16	<0.0001	-0.56	0.13	<0.0001

PCS: Physical Component Summary; MCS: Mental Component Summary

THINKING OUTSIDE THE BOX: MEDICAL TRAINEE PERSPECTIVES ON THE SOCIAL DETERMINANTS OF HEALTH Maggie K. Benson¹; Thuy Bui¹; Janet Arida²; Paula Leslie²; Martha Terry². ¹University of Pittsburgh Medical Center, Pittsburgh, PA; ²University of Pittsburgh, Pittsburgh, PA. (*Tracking ID #1931771*)

BACKGROUND: The social, political, environmental and economic contexts of peoples' lives tremendously impact their health. Research shows that factors such as housing, education, income, neighborhood safety, transportation, food availability and social support are strongly correlated with health outcomes and contribute to overall health status more than traditional medical care. The World Health Organization is focusing attention on the "social determinants of health" (SDH) and is challenging governments, providers, and community leaders to do likewise. Medicine has traditionally focused on a biological model emphasizing pathophysiology and discreet medical and surgical interventions to improve health and prevent disease. However, physicians are increasingly called upon to investigate and act upon the social factors impacting their patients' health. Literature exists on training in health advocacy, cultural competence, communication and health literacy, but little is known about how the SDH are approached in education or how trainees conceptualize the SDH in the context of patient care. We sought: 1. To understand how medical trainees conceptualize the SDH; 2. To explore how medical trainees believe the SDH relate to the care that physicians provide to patients; 3. To identify how medical education approaches the SDH.

METHODS: We conducted focus group discussions with third and fourth year medical students and second and third year internal medicine residents at an urban academic medical center. Participants were recruited via the medical school and residency email lists. Focus groups were stratified by training level: two groups with medical students and two with internal medicine residents. The focus groups were guided by a facilitator experienced in qualitative methodology. Seven open-ended questions were developed by the investigative team to probe how participants conceptualize the SDH and how participants learned about them during their medical education. Each focus group was held over a 60 min period with 4–6 participants. Discussions were audio-recorded and transcribed. Two coders independently read and coded each transcript to elicit primary themes.

RESULTS: In qualitative analysis, the following themes emerged: 1. Medical trainees conceptualize the "social determinants of health" to include a broad range of patient characteristics and experiences. Trainees mentioned socioeconomic status, cultural background, education attainment and health literacy, a history of adverse life events as well as prior personal and family member experience with the healthcare system as elements of the SDH. One student defined the SDH broadly as "everything outside your exact biology." 2. Medical trainees believe the SDH relate to the care that physicians provide to patients both positively and negatively. Trainees described experiences where physician consideration of the SDH positively impacted the care provided to patients by allowing health care providers to be more mindful of the cost of interventions or transportation difficulties. Conversely, they also discussed experiences where patients' care was negatively impacted by providers' preconceptions about a patient based on his socioeconomic status. 3. Trainees have learned about the SDH through both formal and informal educational interventions, however there was agreement that clinical experiences were more meaningful than classroom

didactics. Trainees stated that learning about the SDH in the context of "real" patients either through the care of patients in clinical settings or inviting patients to speak in more formal settings made a greater and more lasting impact. Trainees acknowledged that while simulated exercises have good intention in raising awareness about the SDH, they felt such activities could be perceived as "insulting to the real problems actually faced" by patients. There was a strong belief that currently, learning about the SDH "has to be sought out" by those interested, and might not be of interest to all medical trainees. They expressed concern that until the SDH are considered a routine and essential part of traditional medical care, it will be a challenge for medical educators to address it successfully amongst a broad range of medical trainees.

CONCLUSIONS: This is the first study that sought to ask medical trainees about their perceptions and preferred learning strategies related to the social, political, economic and environment factors that impact health. Participants expressed that educational experiences in this domain need to be factored in across the continuum in a clinical context and not as separate modules or "electives" that only serve those already interested and knowledgeable. In this focus group study, medical trainees provided valuable input as to why SDH training is important, where it fails and how to address it more successfully in the future.

TIME IN TRAINING AND CLINICAL SKILLS AS MEASURED BY UNANNOUNCED STANDARDIZED PATIENTS Colleen Gillespie; Kathleen Hanley; Lisa Altshuler; Adina Kalet; Jaclyn Fox; Sondra Zabar. NYU SoM, New York, NY. (*Tracking ID #1937691*)

BACKGROUND: The ACGME's Next Accreditation System uses outcomes to determine readiness to practice, reflecting growing awareness that simply completing required years of training may not guarantee competence. Measuring those outcomes, however, continues to be a challenge for Residency Programs. Unannounced Standardized Patient visits—standardized clinical scenarios played by highly trained actors integrated, incognito, into providers' clinical schedule—represent a very promising method for assessing "true" competence. In the context of exploring time—vs competency-based determination of physician preparation, we report on the relationship between time in training and clinical skills as assessed by USPs in a sample of Primary Care Internal Medicine Residents.

METHODS: 4 USP cases were developed to represent common primary care challenges: Educating a patient about her diagnosis (Education); Teaching a patient to take medications correctly (Medication); Assessing underlying reasons for a non-specific complaint (Tiredness); and Counseling on health maintenance and behavior change (Health Promotion). Visits were fielded with Primary Care residents in a small residency program ($n=24$) over 5 years. Thirty-five residents treated the "Education" USP (22 PGY1, 6 PGY2, 7 PGY3); 34 residents treated the "Medication" USP (22 PGY1, 5 PGY2, 7 PGY3); 35 treated the "Tiredness" case (18 PGY1, 9 PGY2, 8 PGY3); and 36 residents treated the "Health Promotion" case (20 PGY1, 7 PGY2, 9 PGY3). Behaviorally anchored checklists were used by USPs to rate performance in: Communication, assessment, physical examination, education/counseling, management plan, and patient activation (4–11 items/domain). Scores were calculated as % items rated well done (vs. not or partly); internal consistency was >.70 for all. Time in training was assessed by PGY and as cumulative months of training. Independent samples Kruskal-Wallis tests were used to determine if the distribution of competence

scores differed by PGY; correlations assessed the relationship between months of training and competence scores; and hierarchical regressions explored the influence of months of training after controlling for residents' scores on a PGY1 OSCE (baseline competence).

RESULTS: The distribution of competence scores did not consistently differ by PGY for any of the 4 USP visits (Kruskal-Wallis tests $p>.05$). Only 4/24 possible correlations between time in training (months) and competence score (4 cases \times 6 domains) were significant (Pearson's r ; $p<.05$): In the Medication case, assessment and physical exam scores were negatively correlated with time in training ($r=-.58$ and $-.41$); patient activation scores were positively correlated with time in training in the Tiredness ($r=.42$) and Education ($r=.28$) cases. Similar results were obtained after controlling for "baseline" (PGY1) OSCE performance: Months of training accounted for small amounts of variance in assessment scores for the Medication and Health Promotion case (R^2 range $.09\text{--}.16$; Std Betas= $-.27$ and $-.34$); in exam scores for the Medication case ($R^2=.17$; Std Beta= $-.32$); and in Patient Activation scores for the Tiredness and Education cases (R^2 range $.08\text{--}.12$; Std Betas= $.20$ and $.25$).

CONCLUSIONS: If USP visits are valid and reliable assessments of "true" clinical competence, then time in training does not appear to be a good indicator of competence. However, our exploratory study was powered to detect only fairly substantial effects. In addition, our checklist may be subject to expertise reversal effects as evidenced by negative associations between training and assessment and examination, where highly skilled physicians may omit less relevant information gathering. Our results, however, do suggest that clinical competence is not simply a product of time in training.

TIME PREFERENCE, OBESITY, AND RESPONSE TO CALORIE LABELING Kelly A. Kyanko; Brian Elbel. NYU School of Medicine, New York, NY. (Tracking ID #1936183)

BACKGROUND: Behavioral economics, or applying psychological insights to traditional economic decision making, suggests that individuals do not always make choices that maximize their long-term well-being. Few studies have addressed how these principles may influence food choice and obesity. In particular, time preference, how once values the immediate want to consume healthy food versus the more distant potential health consequences, could be particularly important. We sought to explore the relationship between time preference in obesity and one policy approach meant to influence obesity, calorie labeling.

METHODS: Data were collected from a random digit dial telephone survey of 2926 adults in two cities: one that implemented menu calorie labeling (Philadelphia) and one that did not (Baltimore), both before and after labeling began. Two measures of time preference were used: The choice of a lottery payout of \$1000 now or \$1500 a year from now measured present bias or time discounting, and financial planning horizon (a few months or greater than a few months) measured planning ability and self-control. Multivariable logistic regression was used to assess factors related to self-reported obesity and the whether the respondent reported noticing and being influenced by calorie labeling, adjusting for age, sex, race, education, income, and health status.

RESULTS: Obese individuals were more likely than non-obese to have a short financial planning horizon (OR=1.33, 95% CI: 1.11–1.60), but did not demonstrate differences in time discounting compared to non-obese individuals. Though obesity was predictive of being influenced by calorie labeling (OR obese vs. under or normal weight=3.29, 95% CI: 1.86–5.82; OR severely obese vs. under or normal weight=2.57, 95% CI: 1.40–4.70), measures of time discounting and financial planning were not.

CONCLUSIONS: Differences in planning ability are associated with and may play a role in the development of obesity. While behavioral economics principles may help target obesity interventions, in this study time preference did not change individuals' behavior in response to menu calorie labeling.

TIME TRENDS OF CLINICAL OUTCOME AND SPENDING OF CARE FOR ACUTE MYOCARDIAL INFARCTION HOSPITALIZATIONS IN THE UNITED STATES, 2001–2011 Takehiro Sugiyama^{1,2}; Kohei Hasegawa^{3,4}; Osamu Takahashi⁵; Tsuguya Fukui⁵; Yusuke Tsugawa⁶. ¹The University of Tokyo, Tokyo, Japan; ²National Center for Global Health and Medicine, Tokyo, Japan; ³Massachusetts General Hospital, Boston, MA; ⁴Harvard Medical School, Boston, MA; ⁵St. Luke's International Hospital, Tokyo, Japan; ⁶Harvard Interfaculty Initiative in Health Policy, Cambridge, MA. (Tracking ID #1932307)

BACKGROUND: The incidence of acute myocardial infarction (AMI), particularly ST-elevation AMI (STEMI), has decreased in the US during the last decade. The in-hospital mortality due to AMI has also decreased. However, it is unclear whether the time trend of in-hospital mortality differs by cardiovascular intervention performed during hospitalization, percutaneous coronary intervention (PCI) and coronary artery bypass grafting (CABG), and by type of AMI, STEMI and non-STEMI (NSTEMI). Additionally, little is known about the time trend of AMI-associated healthcare spending by intervention performed during hospitalization and type of AMI. We aimed to investigate the time trends in in-hospital mortality and hospital charge and cost per discharge for AMI hospitalization, by intervention performed during hospitalization and type of AMI in the US.

METHODS: We performed a serial cross-sectional study using the Nationwide Inpatient Sample from 2001 to 2011. We included all hospital discharges for those who hospitalized with the primary diagnosis of AMI aged 30 years or older. Primary outcome measures were in-hospital mortality as well as hospital charge and cost per discharge adjusted for inflation. We classified AMI hospitalizations into 6 subgroups: by intervention performed during hospitalization (no PCI/CABG, PCI without CABG, and CABG with or without PCI) and by type of AMI (STEMI and NSTEMI). We investigated time trends of outcomes for each subgroup, adjusting for patient characteristics, patient comorbidities, and hospital characteristics. We used logistic regression for in-hospital mortality, whereas we used linear regressions for log-scale hospital charge and cost, estimating percent changes of geometric means.

RESULTS: Between 2001 and 2011, we identified a total of 1,504,462 discharges of AMI in the US, corresponding to a weighted estimate of 7,373,282 discharges. The rate of AMI hospitalizations decreased from 4.6 per 1,000 populations in 2001 to 3.3 per 1,000 populations in 2011. Adjusted in-hospital mortality decreased, particularly in NSTEMI without interventions (OR of 2011 with reference to 2001: 0.59, 95%CI: 0.53–0.66) and NSTEMI with CABG (OR of 2011 with reference to 2001: 0.39, 95%CI: 0.26–0.60). By contrast, hospital charge per discharge increased during 11 years in all subgroups ranging from a 38.5% (95%CI: 30.1%–47.4%) increase in NSTEMI without interventions to an 82.5% (58.2%–110.6%) increase in STEMI with CABG. Hospital cost per discharge increased during 11 years in all strata, ranging from 8.2% (3.2%–13.5%) increase for NSTEMI without interventions to 32.2% (21.3%–44.2%) increase for STEMI with CABG.

CONCLUSIONS: In nationally representative samples, we found that in-hospital mortality for AMI hospitalizations decreased significantly during the last decade. By contrast, hospital charge and cost per discharge increased in all subgroups; the time trends of hospital charge and cost differed by intervention performed during hospitalization and type of AMI. While we succeeded in improving clinical outcomes of AMI in the US in the last decade, the spending of care especially for those who underwent interventions has been increasing substantially.

TIMING IS EVERYTHING: STUDYING INSULIN ADMINISTRATION IN THE INPATIENT SETTING Valentina Rodriguez; Benjamin Levin; Joseph Mermelstein; Marelle Yehuda; Robert E. Graham. Lenox Hill Hospital, Manhattan, NY. (Tracking ID #1939304)

BACKGROUND: Hyperglycemia in hospitalized patients is a common, serious, and costly health care problem that is dependent on multiple factors including food consumption, exercise, and types of insulin used. Variables in insulin action (e.g., onset, peak, and duration) must be considered. Most diabetes experts have recommended checking finger stick glucose level, administering rapid acting insulin, and starting a meal all within 30 min. We have evaluated the timing of these intervals to assess for adherence to these recommendations.

METHODS: At an academic hospital in an urban setting, the times between finger stick glucose testing, rapid acting insulin administration, and meal delivery for general internal medicine patients were directly observed and recorded over the course of several weeks between June and August 2013. Inclusion criteria included any medicine inpatient receiving rapid acting insulin (not limited to diabetic patients). Patients who were NPO, receiving tube feeds, or who refused finger stick checks or insulin, were excluded. To account for variation and volume of staff, data was collected on separate weekdays (including weekends); in addition, 2 separate general medical floors were observed. In order to directly observe nursing staff collection of finger stick glucose levels, administration of insulin, and delivery of meals, 4 residents and 2 medical students participated in data collection.

RESULTS: Of the 122 patients studied, 6 were NPO and thus excluded. Of the remaining 116 patients, only 44 patients (38%) received their meal within 30 min of their finger stick glucose check. Sixty-one of the 116 patients (53%) required pre-meal insulin; of these patients, only 16 of the patients (26%) received insulin within

15 min of their meal. Eleven patients (18 %) received insulin within 30 min of having their finger stick glucose checked.

CONCLUSIONS: For a large percentage of patients, the times from finger stick glucose check to meal and from meal to insulin were each in excess of 30 min. It is clear from our data that we are not adhering to current recommendations. In addition, our hospital as well as similar institutions would likely benefit from staff education. While not examined in this study, this deficiency has the potential to result in hypo/hyperglycemic events and affect patient satisfaction.

TO BUY OR NOT TO BUY: USE OF EXTRAMURAL AMBULATORY CARE CURRICULA AMONG PEDIATRIC, INTERNAL MEDICINE, & MED-PEDS PROGRAMS Jaideep S. Talwalkar^{1,2}; D'Juanna Satcher³; Teri Turner^{3,4}; Stephen Sisson⁵; Ada M. Fenick². ¹Yale School of Medicine, New Haven, CT; ²Yale School of Medicine, New Haven, CT; ³Baylor College of Medicine, Houston, TX; ⁴Baylor College of Medicine, Houston, TX; ⁵Johns Hopkins University School of Medicine, Baltimore, MD. (*Tracking ID #1929225*)

BACKGROUND: The sharing of curricular resources is becoming an increasingly common phenomenon among medical educators, as residency programs implement “extramural curricula,” those which have been developed by other institutions for the purpose of sharing. Existing extramural curricula have been designed to improve education on important topics in ambulatory care for children and adults. Current rates of implementation among pediatric, internal medicine, and combined med-peds training programs are unknown. The purpose of this study was to assess the usage rates of extramural ambulatory care curricula among pediatric, internal medicine, and combined med-peds residency programs.

METHODS: Two independent surveys designed to characterize various aspects of the continuity clinic experience were sent to pediatric and combined med-peds program directors respectively in the spring of 2012. Each survey contained an item asking respondents about their use of extramural ambulatory care curricula. No similar recent data were available for internal medicine. In order to determine current usage rates among internal medicine programs, we queried the editors of the Yale Office Based Medicine Curriculum and the Johns Hopkins Internet Learning Center Internal Medicine Curriculum, the two extramural curricula commonly known to be widely used by internal medicine training programs. To verify the accuracy of this data collection method for comparison purposes to the survey data from pediatric and med-peds programs, we also collected subscription rate information for the Yale Primary Care Pediatrics Curriculum and Johns Hopkins Pediatrics Ambulatory Care Curriculum through direct query. Data were analyzed with SAS 9.3 to conduct the two-proportion tests. Significance was defined as $p<0.05$.

RESULTS: Surveys were returned by 111 of 198 (56 %) pediatric and 63 of 79 (80 %) med-peds programs. Of the med-peds survey respondents, 60 answered the item related to extramural ambulatory care curricula. Responses from pediatric programs indicated that 48 of 111 (43 %) were using an extramural curriculum, compared with 39 of 60 (65 %) med-peds programs ($p=0.007$). Most pediatric programs utilizing an extramural curriculum indicated using the Yale (23/48, 48 %) or Johns Hopkins (22/48, 46 %) curricula. One program indicated utilizing both curricula. The editors of the Yale Primary Care Pediatrics Curriculum and Johns Hopkins Pediatrics Ambulatory Care Curriculum indicated that 42 and 48 pediatric residency programs had active subscriptions in 2012, collectively representing 45 % of the 201 pediatric programs in the ERAS database. The editors of the Yale Office Based Medicine Curriculum and Johns Hopkins Internal Learning Center Internal Medicine Curriculum indicated that 130 and 170 internal medicine residency programs had active subscriptions in 2012, collectively representing 75 % of the 402 categorical internal medicine programs in the ERAS database. Numbers of med-peds program subscriptions were unavailable from all curricular editors. The collective subscription rate of internal medicine programs was greater than the subscription rate of pediatric programs ($p<0.001$).

CONCLUSIONS: Training programs in pediatrics, internal medicine, and combined med-peds utilize extramural curricula to guide education in ambulatory care, but internal medicine and med-peds programs employ these curricula at greater rates than pediatric programs. The difference in utilization rates among these parallel training environments has not been previously identified. Given the similarities in training structure, pediatric programs may wish to look to educational solutions that have been used successfully for internal medicine training. Combined training programs may be in a unique position to bring educational solutions to their categorical counterparts. Our future research will examine the factors that impact subscription decisions among program types.

TOTAL TIME SPENT WITH PHYSICIANS IN OFFICE-BASED SETTINGS BY HISPANIC AND NON-HISPANIC WHITE INDIVIDUALS ANNUALLY IN THE UNITED STATES Lyndonna M. Marrast¹; Leah Zallman^{2,1}; David Bor¹; David Himmelstein³; Steffie Woolhandler³; Danny McCormick¹. ¹Cambridge Health Alliance, Cambridge, MA; ²Cambridge Health Alliance, Cambridge, MA; ³City University of New York at Hunter School of Public Health, New York, NY. (*Tracking ID #1939259*)

BACKGROUND: Hispanics in the U.S. experience worse healthcare outcomes across a wide range of conditions and settings compared with non-Hispanic whites (subsequently referred to as “whites”). During outpatient visits, physicians must form partnerships with patients, address complex medical and psychosocial problems, ensure informed decision making that respects patients’ needs and preferences and, for primary care physicians, provide preventive care and coordinate care with specialists. Prior studies have indicated that more time spent with a physician during an outpatient visit is associated with better quality of care for some measures, better medication adherence and higher levels of patient satisfaction; however little is known about the total amount of time that Hispanics spend with physicians in the U.S. annually.

METHODS: We analyzed data from the 2010 National Ambulatory Medical Care Survey (NAMCS) and used Census Bureau figures as population denominators to estimate rates. The NAMCS is an annual visit-based cross-sectional survey that provides nationally representative estimates of visits to office-based physicians. It collects data on visit duration, patient demographics and health conditions. We used the NAMCS to estimate the mean visit duration and the average number of office visits annually for Hispanic and white patients. We estimated the frequency of visits for each group by dividing the number of visits by the corresponding U.S. population estimate. We calculated the total annual average number of minutes spent in office visits for each group by multiplying visit duration by visit frequency. We also compared visit duration and frequency as well as total time spent with providers according to specialty. In addition, to partially account for potential differences in need for time spent with a physician, we compared total annual time spent with a physician after age standardization.

RESULTS: The average age of patients making outpatient visits was 34.6 years for Hispanic and 49.0 years for white individuals. Most visits made by Hispanics occurred in the West and South while most visits by whites were made in the South and Midwest. Overall mean visit duration was 6.4 % longer for Hispanic than white individuals (20.5 min vs. 21.5 min). Hispanic-white differences in visit duration varied substantially by physician specialty, with Hispanic individuals having shorter visit duration than whites for psychiatric visits (28.3 vs. 33.3 min respectively) but longer visit duration for primary care visits (24.3 vs. 19.7 min). Whites made 732 million visits to outpatient practices while Hispanics made 114 million visits. Overall, Hispanics made 35.1 % fewer visits to physicians than whites (2.4 vs. 3.7 per person per year) and spent 32.6 % fewer total minutes per person per year than whites (50.5 vs. 74.9 min per person). Age standardization had little impact on these findings.

CONCLUSIONS: While Hispanic individuals have slightly longer visits with physicians, the mean annual total time spent with a physician is markedly lower for Hispanics than whites, even after accounting for differences in age. Reducing these disparities in visits to and minutes with providers might help decrease Hispanic-white disparities in clinical outcomes.

TRANSITIONAL CARE INTERVENTIONS TO PREVENT READMISSIONS FOR PEOPLE WITH HEART FAILURE: A SYSTEMATIC REVIEW AND META-ANALYSIS Cynthia K. Feltner^{1,2}; Christine D. Jones³; Crystal W. Cene¹; Zhi-Jie Zheng⁴; Carla A. Sueta¹; Marina Arvanitis¹; Kathleen N. Lohr⁴; Jennifer C. Middleton²; Daniel E. Jonas^{1,2}. ¹University of North Carolina- Chapel Hill, Chapel Hill, NC; ²UNC, Cecil G. Sheps Center for Health Services Research, Chapel Hill, NC; ³University of Colorado, Denver, CO; ⁴RTI International, Research Triangle Park, NC. (*Tracking ID #1937563*)

BACKGROUND: Up to 25 % of patients hospitalized with heart failure (HF) are readmitted within 30 days. To reduce rehospitalization of Medicare patients, CMS recently began lowering reimbursements to hospitals with excessive risk-standardized readmission. This policy incentivizes hospitals to develop transition programs to reduce readmission rates. Despite advances in the quality of acute and chronic HF disease management, knowledge gaps remain about effective interventions to support the transition of care for people with HF. The purpose of this review is to assess the comparative effectiveness of transitional care interventions to reduce early readmissions and mortality for adults hospitalized with HF.

METHODS: We searched MEDLINE®, Cochrane Library, CINAHL®, and clinical trial registries (January 1, 1990 to late October, 2013). We required that studies recruit subjects during or within 1 week of an index hospitalization for HF and compare a transitional care intervention with another eligible intervention or with usual care. We required that interventions include one or more of the following components: education to patient or caregiver (or both), discharge planning, appointment scheduling before discharge, planned outpatient clinic visits (primary care, multidisciplinary HF), home visits, telemonitoring, telephone support, or interventions to increase provider continuity. We required studies to report a readmission rate, mortality rate, or the composite outcome (all-cause readmission or mortality). We included outcomes occurring no longer than 6 months following an index hospitalization. Two investigators independently selected, extracted data from, and rated risk of bias of included studies. We grouped studies of similar interventions for our evidence synthesis based on the mode and environment of delivery. We used random-effects models to estimate pooled effects. We stratified analyses for each intervention category by outcome timing. We calculated the number needed to treat (NNT) for readmission and mortality outcomes when appropriate. We graded strength of evidence (SOE) based on established guidance.

RESULTS: We included 47 trials. Most included people with moderate to severe HF; mean ages were in the 70s. Few trials reported 30-day readmission rates. At 30 days, high intensity home-visiting programs reduced all-cause readmission and the composite endpoint (all-cause readmission or death) (low SOE). Over 3 to 6 months, home-visiting programs reduced all-cause readmission, HF-specific readmission, and the composite endpoint (moderate SOE). Multidisciplinary (MDS)-HF clinic interventions reduced all-cause readmission (moderate SOE). Structured Telephone Support (STS) interventions reduced HF-specific readmission (moderate SOE) but not all-cause readmissions (moderate SOE). Home-visiting programs, MDS-HF clinic and STS interventions produced a mortality benefit. Neither telemonitoring nor primarily educational interventions reduced readmissions or mortality.

CONCLUSIONS: Home-visiting programs and MDS-HF clinic interventions reduced all-cause readmission and mortality; STS reduced HF-specific readmission and mortality. These interventions should receive the greatest consideration by systems or providers seeking to implement transitional care interventions for people with HF.

TRANSLATING A HEART DISEASE LIFESTYLE INTERVENTION FOR USE IN SOUTH ASIAN IMMIGRANT COMMUNITIES: PRELIMINARY RESULTS OF A PILOT RANDOMIZED CONTROLLED TRIAL Namratha R. Kandula¹; Swapna S. Dave¹; Yasin Patel¹; Paola E. Seguil¹; Peter John D. De Chavez²; Santosh Kumar³; Himali Barucha³; David W. Baker¹; Bonnie Spring²; Juned Siddique². ¹Northwestern University, Chicago, IL; ²Northwestern University, Chicago, IL; ³Metropolitan Asian Family Services, Chicago, IL. (*Tracking ID #1937567*)

BACKGROUND: South Asians (Asian Indians and Pakistanis) are the second fastest growing ethnic group in the United States (US) and have an increased risk of atherosclerotic cardiovascular disease (ASCVD) compared to other populations. Although lifestyle interventions have shown effectiveness at reducing ASCVD risk in non-Hispanic Whites, evidence suggests that program reach has been limited in South Asian populations. Over 90 % of US South Asians are immigrants, and there is often a mismatch between the conceptual underpinning of most lifestyle interventions and South Asians' social and cultural context. Through a community-academic partnership, we pilot-tested a culturally-salient, community-based healthy lifestyle intervention and compared it with print health education materials to reduce ASCVD risk factors in a medically underserved South Asian immigrant community.

METHODS: South Asians in Chicago, 30–59 years, were recruited through a community organization that provides social services to medically underserved South

Asians. Participants received community-based screening, and those with at least one ASCVD risk factor (hypertension, hypercholesterolemia, pre-diabetes, type 2 diabetes, or overweight/obesity) were randomized into the South Asian Heart Lifestyle Intervention (SAHELI) study and followed for 6 months. The SAHELI intervention group ($n=31$) attended 6 interactive group sessions that incorporated the deep (values, beliefs, explanatory models) and surface (language) structures of South Asian culture. Classes were led by trained, multilingual health educators and focused on simple health messages, skills-building and self-monitoring related to increasing physical activity, eating a healthful diet, portion control, and stress management and coping. Intervention participants also received biweekly support using motivational interviewing via telephone. The control group ($n=32$) received translated print education materials containing standard clinical information about ASCVD risk factors and healthy behaviors. Both groups were referred to primary care providers. Outcomes, including weight, blood pressure, cholesterol, hemoglobin A1c, health behaviors, knowledge, coping, and exercise confidence were measured at baseline and 3, and 6 months.

RESULTS: Participants' average age was 50 ($SD\pm 8$) years, 63 % were female, 46 % had less than or equal to a high school education, one-third were limited English proficient, and two-thirds had no health insurance. At baseline, mean BMI was 30 kg/m² ($SD\pm 4.9$), hemoglobin A1c 6.3 ($SD\pm 1.2$), total cholesterol 185 ($SD\pm 32$), and systolic blood pressure 129 ($SD\pm 17$). Compared to the control group, the SAHELI intervention group lost significantly more weight (-3.2 lb, p -value=0.04) and had a greater sex-adjusted decrease in hemoglobin A1c (-0.43 %, p -value <0.01) at 6 months. Changes in blood pressure and cholesterol did not differ between the treatment groups. We also observed a significant increase in both intervention and control groups' knowledge and coping.

CONCLUSIONS: A lifestyle intervention incorporating the socio-cultural context of underserved South Asian immigrants and delivered in a community setting was more effective at improving ASCVD risk factors than print health education materials. Analyses of accelerometer and 24-hour dietary recall data are underway. A future study will evaluate the long-term effect of SAHELI in a larger sample of US South Asians.

TRANSLATION INTO PRACTICE OF COMPARATIVE EFFECTIVENESS OF DEPRESSION MEDICATIONS: THE DEPRESSION MEDICATION CHOICE DECISION AID TRIAL Annie LeBlanc¹; Nilay Shah¹; Jeph Herrin²; Megan Branda¹; Mark Williams¹; Jonathan Inselman¹; Victor M. Montori¹. ¹Mayo Clinic, Rochester, MN; ²Yale University, New Haven, CT. (*Tracking ID #1940132*)

BACKGROUND: Depression care often demands primary care clinicians' and patients' discerning among medication regimens of different efficacy, safety, cost, and burden to the patient, as documented in comparative effectiveness research (CER). Decision aids, shared decision making tools, offer CER evidence in a format that is accessible to both patients and their clinicians such that a treatment decision can be made that best fits both the clinical situation, and patient's values, preferences, and goals. The objective of the study was to determine the effectiveness of a decision aid to translate CER on antidepressants into practice.

METHODS: We used a patient-centered participatory action research approach involving a multidisciplinary team and stakeholders to develop Depression Medication Choice, a decision aid for use during clinical encounters. We then conducted a clustered, practice-based randomized trial in 10 rural, suburban, and urban primary practices, enrolling clinicians and their patients suffering from moderate or severe depression, to assess the impact of the use of Depression Medication Choice in clinical encounters on clinician and patient involvement in decision-making, decision making quality, and patient measures of medication adherence and mood outcomes, compared to usual depression care. Measures of patients' and clinicians' decision making quality (decisional conflict, knowledge, and satisfaction) were completed following the encounter whereas patient involvement in decision-making was assessed through the review of video-recordings of the encounters. Six-month medication adherence was assessed through a composite of pharmacy records, survey, and review of patient electronic records. Mood outcome was measured using the Patient Health Questionnaire (PHQ-9) at the initial visit and at 6 months post visit.

RESULTS: Twenty four stakeholders from 12 organizations (patients, health systems, buyer action groups, psychiatrists, care managers, family physicians) contributed to the development of the decision aid, that is comprised of issue cards that organize information on antidepressants around cost, weight change, sleep, sexual dysfunction, discontinuation syndrome, information patients should know, and particular considerations. We then enrolled 10 primary care practices, 117 clinicians and 301 patients [67 % women; age, mean (SD): 44 (15); PHQ-9, mean (SD): 15 (4)] in the trial. The use of the decision aid (DA), compared to usual care (UC), was shown to significantly improve patients decision making quality (decisional conflict: DA=20 % vs. UC=25 %, p =.02; knowledge: DA=64 % vs. UC=56 %, p =.03;

satisfaction: DA=78 % vs. UC 60 %, $p=.002$, clinicians decision making quality (decisional conflict: DA=20 % vs. UC 32 %, $p=.01$; satisfaction: DA=87 % vs. UC=67 %, $p<.001$), and patient involvement: DA=47 % vs. UC=33 %, $p<.001$. There was no difference in 6-months medication adherence (average percent days covered: DA=50 vs. UC=58, $P=0.16$). Patients in the DA arm had significantly higher 6 month response rate (defined as >50 % improvement in PHQ-9) compared to usual care (DA=51 % vs. UC=32 %, $p=.04$) in their mood outcomes.

CONCLUSIONS: Through this trial, we were able to successfully engage patients, clinicians, and stakeholders in the development and evaluation of the Depression Medication Choice, a shared decision making tool translating CER of antidepressants, and designed for use by patients and clinicians during clinical encounters. Compared to usual care, patients participating in encounters using Depression Medication Choice decision aid were more comfortable with their decision, were more knowledgeable and satisfied with the information sharing, were more engaged in the decision making process, and showed greater improvement in their depression outcomes. Thus, we have developed and evaluated the efficacy of the decision aid Depression Medication Choice as a novel patient-centered translational tool for CER in depression treatment that can help patients and their clinicians identify and implement the kind of effective treatment that best fits patient's values, preferences, and goals, a true path to high quality healthcare.

TRENDS IN USE OF MECHANICAL VENTILATION BY OLDER PATIENTS WITH AND WITHOUT DEMENTIA Tara Lagu^{1,2}; Jennifer Tjia⁴; Marya Zilberman³; Penelope S. Pekow^{1,5}; Meng-Shiou Sheih¹; Mihaela S. Stefan^{1,2}; Peter K. Lindenauer^{1,2}. ¹Baystate Medical Center, Springfield, MA; ²Baystate Medical Center, Springfield, MA; ³EviMed Research Group, LLC, Goshen, MA; ⁴University of Massachusetts Medical School, Worcester, MA; ⁵University of Massachusetts Medical School, Amherst, MA. (*Tracking ID #1934944*)

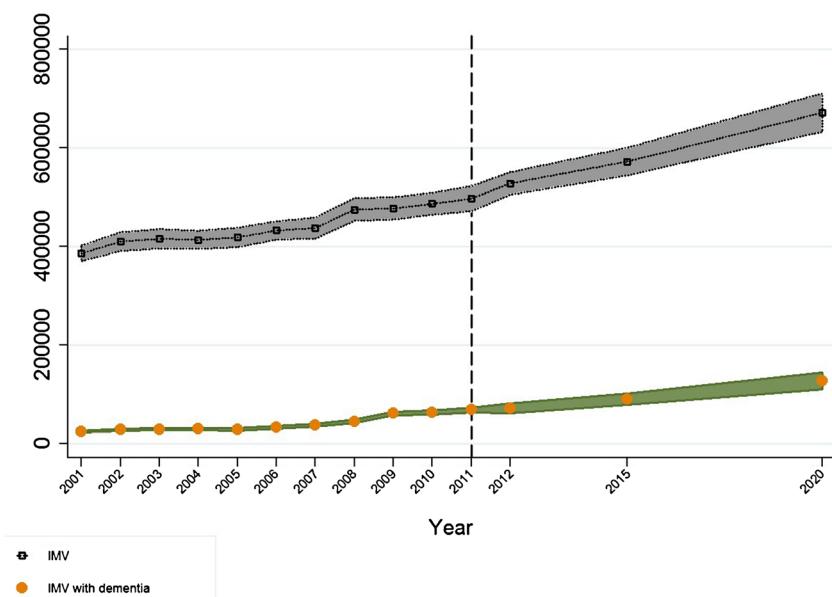

BACKGROUND: Patients with dementia receiving invasive mechanical ventilation (IMV) are at high risk for delirium, functional decline, and excess mortality, but the number of elderly patients with dementia who receive IMV is unknown. We aimed to

examine temporal trends in IMV use by older patients with and without dementia and to predict future use.

METHODS: We used data from the 2001–2011 Nationwide Inpatient Sample, which contains a 20 % stratified sample of short-term, non-federal, and non-rehabilitation hospitals. We included hospitalizations for patients aged ≥ 65 years who received IMV (ICD-9 CM procedure code: 96.70; 96.71; 96.72). Within this group, we examined admissions with and without a diagnosis code for dementia. Primary outcomes included changes in the number of hospitalizations receiving IMV over time. Using population estimates from the US Census Bureau, we calculated age- and sex-specific rates of IMV for 2001 through 2011. We used linear regression to estimate a trend for each age-sex group and then used population estimates for 2015 and 2020 to project the number of cases ventilated per year nationally to 2020.

RESULTS: We identified a total of 4,855,452 (standard deviation [SD]=81,349) hospitalizations in patients ≥ 65 who received IMV; of these, 452,390 (SD=9354) had a diagnosis of dementia. We observed a steady increase of almost 30 % in the number of hospitalizations of older patients who received IMV, rising from 386,364 (SD=8,079) in 2001 to 497,496 (SD=12,929) in 2011 at an annual growth rate of 2.9 % per year. Notably, the percentage of these admissions for patients 85 years or older remained relatively constant from 2001 to 2011 and is expected to decrease over time, from 16 % of all ventilated admissions over 65 years in 2001 to 10 % in 2020. The occurrence of dementia diagnoses among ventilated patients 65 years or older grew at a rate of 11.4 % per year, increasing from 6.4 to 13.8 % between 2001 and 2011. By 2020, we estimate that there will be 671,986 (SD=19,922) admissions in patients ≥ 65 requiring IMV, of whom 20 % will have a diagnosis of dementia (Figure).

CONCLUSIONS: The use of IMV by populations ≥ 65 is expected to double between 2001 and 2020, and growth in hospitalizations for IMV patients with dementia is outpacing, by a factor of 4, those for IMV patients without dementia. Unless changes are made to temper current trends, our health care system faces an upcoming shortage of critical care resources. As general internists, we must promote earlier discussions about end-of-life goals in subpopulations of patients (e.g., patients over 85 years; patients with advanced dementia) who are least likely to benefit from IMV and other critical care therapies.

Projected growth in use IMV by patients ≥ 65 with and without dementia

UNDER-UTILIZATION OF THE ONLINE-PRESCRIPTION DRUG MONITORING PROGRAM (PDMP) IN MASSACHUSETTS Laila Khalid¹; Leonard Young²; Karen E. Lasser^{1,3}; Ziming Xuan^{3,4}; Christopher W. Shanahan¹; Allison Lange¹; Orlaith Heymann¹; Jane M. Liebschutz¹. ¹Boston Medical Center, Boston, MA; ²Massachusetts Department of Public Health, Boston, MA; ³Boston University School of Public Health, Boston, MA; ⁴Boston University School of Public Health, Boston, MA. (*Tracking ID #1938186*)

BACKGROUND: State Prescription Drug Monitoring Programs (PDMPs) are designed to decrease controlled prescription drug misuse by allowing prescribers to identify patients who are going to multiple prescribers and/or multiple pharmacies and thus make better informed prescribing decisions. However, PDMP is only effective if the information is made available to providers and they in turn utilize it. This prompted a 2012 Massachusetts (MA) law requiring all prescribers to join and utilize the MA online-PMP before each controlled

substance prescription. There is lack of research on utilization of state PMPs by providers. We examined the frequency and professional designations of prescribers utilizing the MA online PDMP to understand patterns of use prior to the law's implementation.

METHODS: We analyzed 2011 and 2012 reports of prescriber logins from the MA PMP database. Prescribers included physicians, mid-level providers (nurse practitioners and physician's assistants), podiatrists and dentists. We tabulated the number of log-ins of each enrolled prescriber and defined prescribers in the highest quartile of logins as high frequency users. We also analyzed data according to physician specialty.

RESULTS: There was an increase in the number of prescribers utilizing the PMP in 2012. Among physicians utilizing the PMP, emergency medicine physicians (37.9 % in 2011, 29.3 % in 2012) made up the largest proportion followed by internal medicine (29.7 % in 2011, 31.6 % in 2012) and family medicine physicians (17.3 % in 2011, 18.8 % in 2012). Emergency medicine physicians made up the largest proportion (59.7 % in 2011, 48.3 % in 2012) of high-frequency utilizers followed by internal medicine (19.4 % in 2011, 21.6 % in 2012) and family medicine physicians (9.0 % in 2011, 10.9 % in 2012).

CONCLUSIONS: Enrollment and utilization of the MA online MA PDMP remained low in 2011 and 2012 with under 60 % of the enrollees actually logging on and searching patients. Reasons for low utilization of the PDMP, such as lack of integration with the electronic health records (EHR), and lack of time should be explored further. Utilization data should be matched to PDMP data longitudinally to identify possible effects of utilization on rates of doctor/pharmacy shopping and other prescribing patterns.

Table 1 Utilization of PMP by Prescriber for each year.

	2011 n (%)	2012 n (%)
Total enrolled	1,506	3,505
Prescribers utilizing PMP	781 (51.9)	1,989 (56.7)
MD	609 (78.0%)	1,474 (74.1)
Mid-level Providers	169 (20.4)	476 (24.0)
Dentists	3 (0.4)	36 (18)
Podiatrists	0	3 (0.2)
Mean no. of logins (std)	42.4 (81.7)	52.6 (60.1)

UNDERDIAGNOSIS OF HYPERTENSION IN ADULTS Emeka C. Anyanwu¹; David Kaelber^{1,2}. ¹Case Western Reserve University, Cleveland, OH; ²MetroHealth, Cleveland, OH. (Tracking ID #1897047)

BACKGROUND: Nearly a third of adults in the US are known to be hypertensive. Even after diagnosis, many go on to develop sequelae of hypertension in multiple organ systems. We posit there exists a sizable population of adults that meet the criteria of diagnosis for hypertension that remain undiagnosed despite already having presented with qualifying blood pressure measurements. For these adults complications of hypertension are likely to occur if they continue to go undiagnosed. Furthermore we suspect that there are sociodemographic characteristics that predispose one to go undiagnosed. The objective of this study is to determine the rate of underdiagnosis of hypertension in adults as well as the patient characteristics associated with the underdiagnosis of adult hypertension.

METHODS: We examined all blood pressures in our electronic health record (EpicCare, Epic Corporation, Verona, WI) from patients 18 years and older seen at least two times for a primary care or specialty care outpatient visit between 2010 and 2012 at large academic urban medical system in northeast Ohio. Patients were considered hypertensive, as per the Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure, if the average of at least two blood pressures on two separate visits was greater than 130 mmHg systolic or greater than 90 mmHg. Patients were considered to be undiagnosed if they did not have an ICD-9 code associated with hypertension (401.xx - essential hypertension, 402.9 - elevated blood pressure reading without diagnosis of hypertension and 997.91 - hypertension) in their EHR problem list, past medical history, or encounter diagnoses list during the study period. Patient age, gender, self-reported ethnicity, insurance type, height, weight were also obtained.

RESULTS: 48,712 patients met inclusion criteria for blood pressures consistent with hypertension. Of these only 32,328 (66.3 %) had a diagnosis of hypertension. Logistic regression demonstrated that patients with commercial insurance (OR 1.71 CI 1.65–1.79), of majority ethnicity (Caucasian) (OR 1.88 CI 1.81–1.96), and non-English-speaking (OR 1.13 CI 1.07–1.19) were all more likely to have undiagnosed hypertension, based on blood pressures recorded in their EHR. In contrast, the prevalence of undiagnosed hypertension decreased per 1-y increase over age 18 (OR 0.95 CI 0.95–0.95), with each elevated blood pressure reading (OR 0.79 CI 0.78–0.79), and with each visit during the two year study period (OR 0.96 CI 0.96–0.96).

Gender, height, and weight were not associated with an increase or decrease in hypertension diagnosis.

CONCLUSIONS: Up to a third of adults with hypertension, based on data in EHRs, have not had their hypertension diagnosed. Disparities in the underdiagnosis of hypertension exist based on age, insurance, and ethnicity. This study highlights demographics for whom physicians might provide better diagnosis and treatment.

UNDERSTANDING TRIAGE CHOICES FOR PATIENTS WITH DIABETIC KETOACIDOSIS ADMITTED FROM EMERGENCY DEPARTMENTS IN NEW YORK Isabel Preeshagul¹; Gargi Bajpayee¹; Hannah Wunsch³; Colin R. Cooke⁴; Hayley B. Gershengorn². ¹Beth Israel Medical Center, New York, NY; ²Montefiore Medical Center, Bronx, NY; ³New York Presbyterian/Columbia, New York, NY; ⁴University of Michigan, Ann Arbor, MI. (Tracking ID #1939581)

BACKGROUND: There are no known guidelines directing where in the hospital to admit patients with diabetic ketoacidosis (DKA)—either the general medicine ward or the intensive care unit (ICU). Large variation exists across New York State (NYS) hospitals in how often patients are triaged to the wards versus the ICU. One possible explanation for this variation may be substantial differences in protocols for care and staffing of hospital beds across institutions. We sought to determine the factors that influence emergency department (ED) providers' decisions to triage DKA patients to the general hospital wards as opposed to an ICU.

METHODS: We created a survey consisting of 11 multiple choice questions pertaining to the management and triage practices for patients with DKA. Surveys were developed to be available by email and as a scripted phone survey. We obtained Institution phone numbers via internet search. The same investigator (IP) phoned each hospital and requested answers to the scripted survey from either an ED physician director, charge nurse, ED physician or ED nurses. These providers are responsible for making triage decisions, therefore were presumed to be most knowledgeable about protocols. Standard summary statistics were used to quantify survey results. We targeted hospitals in New York for which risk-adjusted rates of ICU utilization for patients with DKA are known.

RESULTS: We identified and attempted to survey 146 hospitals. For each site, multiple calls were made and we obtained a total of 23 responses (15.8 %). Of the 23 hospitals providing data, nearly all (82 %) had a protocol for DKA management in the ED. Most (82 %) used continuous intravenous (IV) insulin infusions for the mainstay of therapy with a bolus, as opposed to exclusively bolus administration for treatment. All hospitals permitted continuous IV infusions of insulin in the ED and in the ICU. The majority (59 %) of the surveyed institutions had step down units, but less than half of these institutions (41 %) permitted continuous IV insulin infusions in these units. Only 9 % of hospitals surveyed permitted insulin infusions on a telemetry unit and 5 % on general hospital wards. The greater part of the hospitals (55 %) had a protocol for triage of DKA patients. The majority of institutions (64 %) held patients in the ED until closure of their anion gap.

CONCLUSIONS: Our data provides useful insight into the triage and management of DKA patients statewide. Of the institutions surveyed, most had a protocol for DKA triage. The majority did not allow patients to be admitted to non-ICU locations prior to closure of the anion gap. Our data suggest that many EDs indiscriminately triage patients with DKA to the ICU despite prior data suggesting that care for patients with DKA outside of the ICU is safe. Future research examining DKA triage from the ER to the hospital is warranted to understand how to optimize triage protocols, improve resource allocation and most importantly enhance care for DKA patients on the general wards.

UNDERSTANDING VARIATION IN PCP REFERRAL PATTERNS IN A LARGE MULTISPECIALTY PRACTICE GROUP Michael L. Barnett¹; Thomas D. Sequist^{1,2}. ¹Brigham and Women's Hospital, Boston, MA; ²Partners Healthcare System, Boston, MA. (Tracking ID #1937624)

BACKGROUND: Primary care physicians (PCPs) generate the vast majority of specialty referrals, and the decision to refer directly impacts health care quality, patient experiences, and spending. We analyzed referral rates among PCPs to characterize the relative contribution of patient and physician characteristics to the probability of referral, as well as the long term impact on utilization among PCPs with high rates of referral.

METHODS: We analyzed electronic health record data within a large multispecialty group practice that requires electronic referral orders. We enrolled 78,485 patients

18 years and older who visited 142 PCPs during a baseline referral rate measurement period (2005–2006), and then analyzed subsequent specialist referrals among these patients from 2007 to 2011. We collected information on patient age, gender, race, Charlson comorbidity score (2005–2006), and number of subsequent specialist appointments (2007–2011). To calculate PCP referral rates, we estimated a mixed effects logistic regression model using 2005–2006 data adjusted for patient characteristics, using a random intercept term to account for correlation within individual PCPs. We calculated the ratio of the PCP's adjusted referral rate estimated from the fitted random intercept over the expected referral rate estimated with the same model without the random intercept. We multiplied this ratio by the average referral rate in the entire cohort to calculate the case-mix adjusted referral rate for each PCP. We used the c-statistic to assess the relative contribution of patient and physician characteristics in this model. We next categorized PCPs according to their quintile of adjusted referral rate and examined the characteristics of the PCPs and their patient panels, testing for trends using logistic regression. In the period from 2007 to 2011, we estimated the adjusted probability with logistic and negative binomial models that patients with PCPs in the different referral quintiles received any specialty referral, the average number of referrals per patient, and the average number of specialty visits.

RESULTS: From 2007 to 2011, the PCPs placed 102,276 referral orders, representing 74 % of the total referrals for this cohort (additional referrals came from urgent care physicians). The five most commonly referred specialties were orthopedic surgery (23 %), dermatology (15 %), otorhinolaryngology (9 %), gastroenterology (9 %), and general surgery (8 %). Physicians with more female, non-white and younger patients as well as those with fewer comorbidities were more likely to be in the highest referral quintile, as were physicians with fewer patient encounters and smaller panels (all $p < 0.001$, Table). The c-statistic for a logistic regression model to predict referrals using patient characteristics alone was 0.56, while the mixed effects model with a physician-level random intercept alone had a c-statistic of 0.68, which was unchanged after incorporating patient characteristics into the model. The adjusted average rate of referral per 100 patient visits was 5.2, 16.3, 21.0, 25.6, and 36.2 by quintile of referral rate among PCPs, with an overall average of 17.4. Adjusting for age, sex, race, and comorbidities, the average patient with a PCP in the highest quintile of referral rate had a 77 % (95 % CI 76–78) probability of receiving a referral and had 2.2 (95 % CI 2.1–2.3) referrals on average from 2007 to 2011, compared to a 36 % (95 % CI 35–37) chance of receiving a referral and 0.59 (95 % CI 0.57–0.61) average number of referrals in lowest quintile. From 2007 to 2011, in the 12 months subsequent to a referral, patients of PCPs in the highest referral quartile experienced an average of 3.6 (95 % CI 3.4–3.8) follow-up specialist visits versus 0.53 (95 % CI 0.51–0.56) visits among patients of PCPs in the lowest referral quartile.

CONCLUSIONS: We observe wide variation among PCPs in specialty referral rates, which is explained in large part by physician characteristics as opposed to patient characteristics. This variation has substantial long-term implications, with patients seen by PCPs in the highest quintile of referral rates experiencing dramatically more specialist visits over time. Our analyses suggest that physician-level interventions are needed to address this variation which may be due to physician subjectivity in the decision to refer patients.

Table: Patient and Physician Characteristics by Referral Rate Quintile

	Referral Rate Quintile					<i>p</i> -value
	1 (lowest)	2	3	4	5 (highest)	
Physicians						
Referral Rate/100 Visits	5.2	16.3	21.0	25.6	36.2	<0.001

UNNECESSARY LABS AND IMAGING PERCEIVED BY THIRD YEAR MEDICAL STUDENTS DURING THE INTERNAL MEDICINE CLERKSHIP

Amit K. Pahwa¹; Reena Karani²; Amanda Bertram¹; Bimal Ashar¹; Danielle Cayea¹.

¹Johns Hopkins University, Baltimore, MD; ²Mt Sinai, New York, NY. (Tracking ID #1939257)

BACKGROUND: From 1990 to 2007, hospital expenditures increased an average of 7.2 % per year. Medicare fee for service inpatient spending totaled \$114 billion in 2009. While major procedures, evaluation, and management services only increased by approximately 30 % from 2000 to 2009, both imaging and tests increased by 85 % during that same period. Because of this, the AAMC recommends that clinical skills curricula train medical students to select, justify, and interpret clinical tests and imaging. Despite this educational imperative, 60 % of medical students rate their education in medical economics to be inadequate annually. It is likely that students experience this inadequacy not because of poorly executed curriculum but because the curriculum to address these skills is lacking. Currently only 15 % of IM residency programs have a formal curriculum in high value cost-conscious care. To date there has been no assessment of undergraduate medical education in high value cost conscious care and exposure to both high value cost conscious care and unnecessary testing.

METHODS: We conducted a multi institutional study by distributing a survey to third year medical students upon completion of their internal medicine clerkship to assess their exposure to high value cost conscious care and unnecessary care. Questions focused on the frequency of perceived unnecessary testing, reason for unnecessary testing and environmental factors that may lead to unnecessary testing.

RESULTS: To date 28 medical students from two institutions have completed the survey. Seventy eight percent (22 students) noticed at least one instance when labs or imaging tests were ordered that seemed unlikely to impact patient care. Eighty percent (16 students) felt that their patients had unnecessary labs at least once or twice per week. The most common reason unnecessary testing occurred was either physicians practicing defense medicine (65 % or 13 students) or house staff wanting to investigate a potentially rare diagnosis (60 % or 12 students). Most students (50 %) witnessed discussion of costs during work rounds or attending rounds at most twice a month. More often (70 % witnessed at least once or twice per week) teams members were guided to order more testing rather than be praised (50 % were praised at least once or twice week) for not ordering an unnecessary test. However only 30 % of students feel comfortable bringing unnecessary testing to the attention of their supervising house staff or attending.

CONCLUSIONS: This data suggest that medical students are exposed to a fair amount of unnecessary testing on their patients but feel very uncomfortable bringing it to the attention of their supervisors. As faculty we must be more cognizant of how our interventions are perceived by learners. We must also create an environment where learners can feel rewarded for being parsimonious with testing and safely question the value in testing. Limitations include a low sample size but as the year passes, more students will complete the survey. Because third year medical students are developing clinically it is difficult to ascertain if those instances of unnecessary testing were truly unnecessary.

US DECENTNIAL CENSUS DATA NO LONGER ACCURATELY PREDICTS INCOME FOR CONTEMPORARY HEALTH DISPARITIES RESEARCH

Rachel J. Stern¹; Hilary K. Seligman^{1,2}; David Guzman²; Melanie Levy³. ¹UCSF, San Francisco, CA; ²San Francisco General Hospital, San Francisco, CA; ³University of California, Los Angeles, Los Angeles, CA. (Tracking ID #1939573)

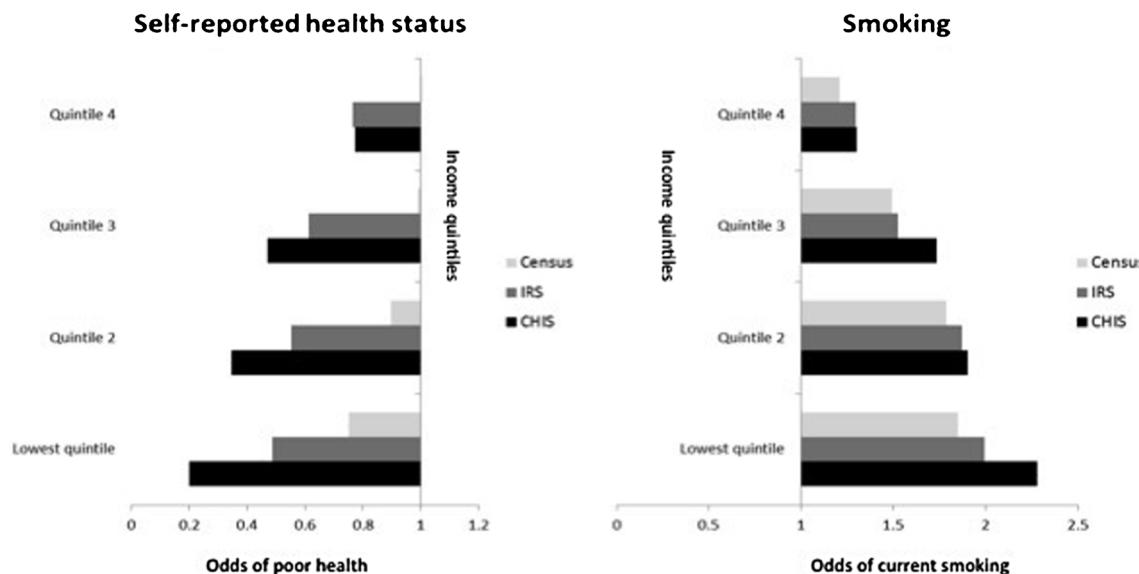

BACKGROUND: When individual-level income data is not available, for example with large, administrative datasets, investigators devise proxy measures to approximate income. In health disparities research, the most common income proxy measure is derived by linking zip code with US Census data for average income. We examined the performance of multiple proxy measures of income (US Census, American Community Survey (ACS) or Internal Revenue Service (IRS)) because 1) there is not clear consensus on the most accurate one (eg, economists use IRS data as a gold-standard proxy), and 2) the US Census stopped collecting income data in 2000.

METHODS: We determined individual-level, self-reported income and health measures for a population-based sample of >40,000 non-institutionalized Californians using the 2003 and 2009 California Health Interview survey (CHIS). We chose two health measures which historically have shown clear income gradients: self-reported health status (very good/excellent vs all other) and current smoking. Using multivariate logistic regression adjusted for age, sex, and race, we examined whether proxy measures of income (US Census 2000, ACS 2009, and IRS 2000 & 2009), linked by patient zip code to the CHIS dataset, replicated gradients observed using individual-level income from CHIS. We divided income into quintiles (common practice in health disparities research) and compared the lowest quintile with each of the measures using kappa statistics for agreement and Spearman's Rank Correlation.

RESULTS: Comparing proxy variables to the CHIS' individual income measurement, the Census 2000 income proxy and IRS 2000 income proxy were weakly

correlated with individual income in 2003 (kappa 0.24 for both; no ACS available). Proxy income in ACS 2009 (kappa 0.24) and IRS 2009 (0.25) was weakly correlated with individual income in CHIS 2009, but better correlated than Census 2000 (0.22, $p < 0.01$) was with CHIS 2009. IRS variables performed incrementally better than census and ACS both years (IRS vs census 0.36 vs 0.34 in 2003, 0.36 vs 0.33 in 2009). In the health outcomes analysis, IRS and Census data both replicated the income gradient in smoking prevalence, but IRS better replicated the income gradient in self-reported health status (Figure 1).

CONCLUSIONS: All proxy measures of income commonly used show only poor to fair correlation with individual income, reinforcing their inferiority to individual-level measures. Differences in the performance of the various proxy measures were small. However, Census 2000 performance deteriorated over time and failed to demonstrate known relationships between income-sensitive health conditions and income by 2009. Census 2000 data should no longer be used to estimate income in contemporary health disparities research. When proxy measures of income are necessary, IRS- or ACS-derived measures of income are superior.

US PHYSICIANS' EXPOSURE TO, KNOWLEDGE AND PRACTICE OF HIGH VALUE CARE DURING TRAINING: RESULTS FROM A NATIONAL SURVEY OF INTERNAL MEDICINE RESIDENTS Kira L. Ryskina^{1,2}; Cynthia D. Smith³; Arlene Weissman³; Jason Post⁴; Constance J. Dine⁵; KeriLyn Gwisdalla⁶; Deborah Korenstein². ¹University of Pennsylvania, Philadelphia, PA; ²University of Pennsylvania, Philadelphia, PA; ³American College of Physicians, Philadelphia, PA; ⁴Mayo Clinic, Rochester, MN; ⁵University of Pennsylvania, Philadelphia, PA; ⁶Banner Good Samaritan Medical Center, Phoenix, AZ. (Tracking ID #1939258)

BACKGROUND: US healthcare costs continue to be unsustainably high, which has led to calls to incorporate cost consciousness and high value care training (that balances benefits of tests or treatments against potential harms and costs) into graduate medical education. In this study, we report findings from a national survey of internal medicine residents about their exposure to costs of care as well as knowledge and practice of high value care during training.

METHODS: A two-page paper survey was administered to all residents taking the Internal Medicine In-Training Examination (ITE) in October 2012. The survey included questions regarding knowledge and practice of high value care, exposure to costs of care during training as well as career plans. Residents from programs outside of the United States were excluded from analysis. Residents were characterized according to their year of training, gender, medical school location, residency program track, career plans, and the Dartmouth Atlas' hospital care intensity (HCI) index of the training hospital. Descriptive statistics were used to report residents' self-reported knowledge and practice of high value care during training. Multivariate logistic regression with clustering at the program level was used to identify resident and program characteristics associated with self-reported practice of high value care (e.g., discussing costs of care with patients or incorporating costs into clinical decisions) during residency.

RESULTS: Of the 21,617 US internal medicine residents, 18,102 (84 %) completed the survey. Of the sample, 34.1 % were PGY1, 34.6 % were PGY2, and 31.3 % were PGY3. Forty-four percent were women. Half of residents (50.9 %) reported that the issues of balancing benefits and harms with costs was the topic of teaching conferences or rounds at least a few times a month. Residents reported receiving education in this area as part of grand rounds (50.8 %), resident lectures (49.1 %), and intern/resident report (45.7 %).

Nearly one in seven residents (14.0 %) reported not receiving any education on providing care that balances the benefits with costs and harms. Residents who trained at a hospital with above average HCI index were more likely to know where to find estimated costs of tests and treatments compared to those who trained at a hospital with below average HCI index (28.0 % vs 24.2 %, $p < 0.001$), but were less likely to report incorporating the costs of tests and treatments into clinical decisions (44.9 % vs. 47.4 %, $p = 0.001$), or incorporating patients' values and concerns into clinical decisions (86.9 % vs. 89.6 %, $p < 0.001$). Residents who trained at a hospital with an above average HCI index were less likely to report discussing costs when caring for patients ($OR = 0.83$, $p = 0.002$, 95 % CI 0.74–0.93) or incorporating costs into clinical decisions ($OR = 0.86$, $p = 0.001$, 95 % CI 0.78–0.94).

CONCLUSIONS: A large proportion of residents received some instruction about balancing benefits, harms, and costs, but less than a third of residents know where to find cost information and less than half incorporate costs into clinical decisions. Residents trained at hospitals associated with high levels of healthcare utilization were less likely to report discussing costs with patients and practicing high value care concepts, though differences were small.

USE OF A PATIENT DECISION AID IN ROUTINE CARE: WHAT IMPACT DOES IT HAVE ON DECISION MAKING ABOUT PROSTATE CANCER SCREENING? Leigh H. Simmons^{1,2}; Sandra Feibelmann¹; Karen R. Sepucha^{1,2}; Lauren Leavitt¹. ¹Massachusetts General Hospital, Boston, MA; ²Harvard Medical School, Boston, MA. (Tracking ID #1937662)

BACKGROUND: Decision aids (DAs) are educational tools that present information about treatment options and outcomes and help patients reflect on goals and treatment preferences. Randomized controlled trials of DAs have been shown to increase patients' knowledge and involvement in treatment decisions, and reduce decisional conflict. However, less is known about the impact of these tools in routine care. The aim of this study was to assess the effectiveness of a prostate cancer screening DA when used in primary care.

METHODS: The DA used is a 20-minute DVD and booklet produced by the Informed Medical Decisions Foundation and Health Dialog. All primary care

providers in practices affiliated with Massachusetts General Hospital are able to order the DA through the electronic medical record. The DA is then mailed with a questionnaire to the patient. One reminder phone call or post card was sent to increase survey response rates. The questionnaire asked patients to indicate their screening intentions before and after watching the program, rate the importance of different goals on a scale from 0 (not at all) to 10 (extremely) important, complete 5 multiple choice knowledge items, and evaluate the DA.

RESULTS: From March 2010-November 2013, 2,588 PSA DAs were mailed to patients and 616 completed the questionnaire (response rate 23.8%). The respondents were 83.4% white, 58.4 years old (SD 8.1 years), and 55.3% reported a college education or more. About half (47.6%) had never had a PSA test, 44.2% had a prior PSA test, and 8.3% did not answer. Most respondents watched all or most of the program (75.8%), slightly fewer read all or most of the booklet (60.4%). Men's screening intentions changed after watching the DA. After viewing the DA, fewer men were not sure about testing (33.6% unsure pre-viewing vs. 17% unsure post viewing, $p < .001$) and more men did not intend to have a PSA test (32% pre-viewing vs. 51% post viewing, $p < .001$). Men who were leaning toward having a PSA test felt it was more important to find cancer early (8.4 vs. 5.0 out of 10, $p < .001$) and to have peace of mind from a negative result (8.2 vs. 4.9 out of 10, $p < .001$) compared to men who were leaning toward not having PSA test. Patients' mean knowledge score was 89.4% (SD 21.7%). A majority understood that most men with prostate cancer die of something other than prostate cancer (84.4%) and that a higher than normal PSA test result does not always mean the man has prostate cancer (87.3%). Most respondents found the DA very or extremely useful in helping them understand what a PSA test is (77.5%), deciding whether or not to have a PSA test (78.2%), and preparing to talk with their provider about the PSA test (71.3%).

CONCLUSIONS: Although the response rate was low, the DA helped men clarify preferences about screening, be well informed, and prepare to discuss PSA screening with primary care providers. These results provide evidence of the effectiveness of DAs in supporting shared decision making in clinical practice.

USE OF A WEB-BASED MODULE FOR FACULTY DEVELOPMENT IN COMMUNICATION AND CHRONIC OPIOID PRESCRIBING Anna K.

Donovan¹; Gordon J. Wood²; Doris Rubio^{1,3}; Patrice Gibbs³; Hollis Day¹; Carla Spagnoletti¹. ¹University of Pittsburgh School of Medicine, Pittsburgh, PA;

²Northwestern Lake Forest Hospital, Midwest Palliative & Hospice CareCenter, Glenview, IL; ³University of Pittsburgh, Center for Research on Health Care, Data Center, Pittsburgh, PA. (Tracking ID #1940095)

BACKGROUND: As prescription opioid use and its complications reach epidemic proportions, internists must effectively communicate with patients with chronic non-malignant pain (CNMP). However, few published curricula focus on communication surrounding opioid prescribing. Results of an informal survey of the internal medicine faculty at the University of Pittsburgh School of Medicine (UPSiOM) called for faculty development in "communicating with patients about opioid use". As such, we implemented a web-based curriculum entitled Collaborative Opioid Prescribing Education-Risk Evaluation and Management Strategy (COPE-REMS®), which was developed at the University of Washington School of Medicine. We hypothesized that this curriculum would increase faculty participants' communication skills knowledge and confidence level, as well as self-reported and actual use of these skills with patients who have CNMP.

METHODS: Eligible participants were the clinician-educator faculty affiliated with the UPSiOM Internal Medicine Residency Program. Participants were also required to care for outpatients given the focus of the module. Of note, this study had an IRB exemption. Funding for this study was provided by the Thomas Nimick, Jr. Competitive Research Fund. Faculty were asked to complete the curriculum, along with pre and post electronic surveys to assess their knowledge, attitudes, and reported use of skills between May and June 2013. A follow-up survey was administered to all participants in December 2013, to assess delayed attitudes and reported uses of skills. Analysis of survey items included summary statistics and repeated measures ANOVA between pre, post, and 6 month responses to survey questions. We used the Bonferroni correction for posthoc analysis. All statistical analysis was done using Stata 13. In addition, 23 of the eligible faculty members were randomly selected to participate in a pre and post-module Observed Structured Clinical Exam (OSCE) during this time to assess change in actual communication skills. Each OSCE was scored with a 16-item checklist completed by one of four standardized patients (SPs) in real time and by a communication expert (CE) who viewed recorded encounters in a blinded fashion. Paired t-tests were used for statistical analysis comparing pre and post-module scores on the knowledge-based test and OSCE.

RESULTS: A total of 62% (33/53) of eligible participants, with a mean of 16.1 years of post-training clinical practice experience, completed the curriculum. They rated their overall baseline physician-patient communication skills as 7.9 (scale 1–10 where 1 = poor and 10 = outstanding). All reported at least some prior faculty-level training in both physician-patient communication and management of patients with CNMP. Participants felt the curriculum was clear (mean 4.7; scale 1–5 were 1 = strongly disagree and 5 = strongly agree) and met its stated learning objectives (mean 4.7). Most felt that the time it took to complete the module was too long (mean 4.5); some faculty reported spending greater than 3 h on completing the module while one participant spent only 24 min. The 25-item knowledge-based test scores improved with completion of the curriculum (pre 75% vs. post 90%, $p < .001$). Compared to the pre-curriculum scores, participants reported improved comfort in managing patients both immediately post-curriculum and at 6 months (3.6 vs. 4.0 vs. 4.1 at pre, post, and 6 month time points respectively, $p = 0.0184$; scale 1–5 where 1 = totally uncomfortable and 5 = totally comfortable), prescribing opioids (3.3 vs. 3.8 vs. 3.9, $p = 0.0061$), and conducting a conversation about discontinuing opioids (2.8 vs. 3.5 vs. 3.9, $p < .001$). Additionally, repeated measures ANOVA between the three timepoints demonstrated an improvement in faculty comfort with teaching residents about managing patients with CNMP (3.5 vs. 3.9 vs. 4.0 for pre, post, and 6 months respectively, $p < 0.0016$). Of the 23 faculty randomized to the OSCE, the OSCE participation rate was 57% (13/23); an additional 4 faculty volunteered to complete at least one OSCE to maximize utilization of the funded SP encounters. When rated by the SPs, the mean pre-OSCE score was 74% vs. post 82% ($p = 0.0344$). When rated by the CE, the scores were 65% and 71% respectively ($p = 0.0767$). The inter-rater reliability between the CE and each of the four SPs was fair to moderate ($k = 0.28$ to 0.66).

CONCLUSIONS: The COPE-REMS® curriculum was feasible to implement among clinician-educator faculty. Despite rating their baseline communication skills highly, this seasoned group of clinicians had improvement in their knowledge and comfort with managing patients with CNMP after participating in the curriculum. Improvement in actual skill was also achieved, and was statistically significant when rated by SPs during the OSCE component of the study. A web-based curriculum such as the COPE-REMS® may be useful for other programs looking to improve their faculty's comfort and skill in managing patients with CNMP.

USE OF ELECTRONIC PATIENT PORTALS - DISPARITIES IN AGE, GENDER, AND RACE Saira Varghese; Ruchira Sengupta; Javier Rodriguez Sanchez; Juan Pablo Domecq Garces; Sudeep D. Thapa; Kimberly Baker-Genaw. Henry Ford Hospital, Detroit, MI. (Tracking ID #1926444)

BACKGROUND: Just as the essentials of daily living have become more readily available via electronic access, so should the access to our own personal health records. Electronic patient portals are online applications that allow patients to electronically access their personal health information and communicate directly with their healthcare providers. Electronic access to health information will empower patients to become more involved in their own health management. In order for such a system to be successful, it must be readily available and offered to every patient, regardless of their age, sex, or ethnicity. It is important to identify barriers that prevent these portals from being used—whether it be on the part of the provider to offer access, or the patient to initiate access. In addition, use of electronic portals satisfies one of the meaningful use criteria as set by the Centers for Medicare & Medicaid Services (CMS) Incentive Programs, leading to further reimbursement. We analyzed the use of MyChart, the electronic portal implemented at Henry Ford Hospital, with respect to patient activation, usage, and rejection of these electronic portals, across different genders, age groups and ethnicities. Our analysis will help us to improve the implementation of electronic health portals, and also help identify patient populations that need more recruitment.

METHODS: The EPIC clarity database was used to obtain MyChart activation and demographics for four resident-operated Internal Medicine clinic sites, namely Main Campus, Sterling Heights, Grosse Pointe and Fairlaine. This was an observational retrospective descriptive study.

RESULTS: Our results revealed that there was no significant difference between males and females across the four sites with respect to activating MyChart accounts. In contrast, when analyzing across ethnic groups we find that the Caucasian population across all clinic sites, were more likely to active rather than not use or decline their activation codes. More importantly, it was noted that the African-American population were universally less inclined to activate or use MyChart across all sites when compared to all other ethnicities. As for disparities among different age groups, it was noted that the elderly above age 65 were less likely to use or activate

MyChart when compared to their middle-aged and younger counterparts.

CONCLUSIONS: Electronic patient portals are an excellent means to improve communication between patients and their physicians, allow patients to have increased autonomy over their own personal health records, and improve overall health care delivery and workflow. However before such portals can be used effectively, it is important to not only to identify which patient populations would be the most active users, but also to elucidate the barriers and reasons why certain other groups may not be able to engage in their healthcare management via these portals. Our study set out to specifically focus on whether there were differences between different age groups, genders and ethnicities in terms of their activation or use of MyChart at certain Henry Ford Clinic sites. Our analysis reveals that it may be worthwhile to focus our attention on the elderly and African American patient populations, as these groups appear to be the least involved in using their electronic health records. Albeit this study has a number of limitations, the overall results are impressive and do warrant a closer look into how certain factors such as socio-economic status, education, and environmental factors correlate with participation in electronic healthcare and in turn would help us to improve the way we offer these tools to certain patient populations to encourage their involvement. Ultimately, the goal of electronic portals is to make it easier for every patient to access, take interest and have a better understanding of their own healthcare and using the results of this study, we hope to improve the use of electronic patient portals, particularly MyChart at HFH, so that more patients can enjoy these benefits.

USE OF EMERGENCY ROOM AFTER MEDICALLY COMPLICATED PREGNANCY: A MEDICAID CLAIMS ANALYSIS Ashley M. Harris¹; Hsien-Yen Chang²; Lin Wang⁵; Martha Sylvia, PhD,³; Donna Neale⁴; David M. Levine¹; Wendy L. Bennett¹. ¹Johns Hopkins Hospital, Baltimore, MD; ²Johns Hopkins School of Public Health, Baltimore, MD; ³Johns Hopkins, Baltimore, MD; ⁴Johns Hopkins Hospital, Baltimore, MD; ⁵Johns Hopkins HealthCare, Glen Burnie, MD. (Tracking ID #1938772)

BACKGROUND: Frequent interaction with the healthcare system in pregnancy and postpartum provides opportunity for engagement in primary care and risk factor modification. Low income women, however, cite multiple barriers to postpartum primary care and studies suggest they may utilize the emergency room (ER) for care. Women with pregnancies complicated by gestational diabetes (GDM) and hypertensive disorders of pregnancy including gestational hypertension, pre-eclampsia, and eclampsia (HDP) are at increased risk of future diabetes, hypertension and cardiovascular disease. The objectives of this study were to: 1) determine if women with pregnancies complicated by GDM or HDP would be more likely to use the ER in the 6 months postpartum than women with uncomplicated pregnancies, and 2) to determine other risk factors for ER use in the 6 months postpartum.

METHODS: This is a retrospective population based cohort study using 2003–2009 administrative claims data from one Maryland Medicaid Managed Care Organization. Claims data were linked with 2000 U.S. Census data by zip code, to obtain neighborhood characteristics. The sample included pregnant women age 12–45, with more than 100 days Medicaid coverage during pregnancy, and at least 90 days postpartum coverage. The primary outcome was one or more ER visits in the 6 months postpartum. To examine the association between ER visits and pregnancies complicated by GDM or HDP, we used logistic regression models that adjusted for maternal age, race, non-pregnancy related co-morbidities (chronic hypertension, type II diabetes, obesity, asthma, substance abuse, mental health disorders), duration of coverage, prenatal care, pregnancy or postpartum primary care use, and neighborhood socioeconomic characteristics.

RESULTS: We identified 26,074 pregnancies of which 20 % ($n=5,340$) were complicated by GDM or HDP, and 80 % ($n=20,734$) were not. In the first 6 months postpartum, 24 % of women had one or more ER visits, ranging from 0 to 40 total visits per woman. In unadjusted analyses, 27 % of women with GDM and/or HDP visited the ER compared with 24 % of women without ($p<0.0001$). In adjusted analyses, women with GDM or HDP were significantly more likely to have at least one ER visit compared to women without these conditions ($OR=1.17$, $p<0.0001$, 95 % CI=0.0800902, 0.2359954). Non-pregnancy related medical co-morbidities were also strongly related to ER use. Women with other medical comorbidities had significantly more ER visits as compared to women without: 33 % vs 20 % respectively ($p<0.0001$), and an OR=1.65 in adjusted analyses ($p<0.0001$, 95 % CI=0.4288324, 0.5676198). Finally, women who attended at least one primary care visit postpartum were more likely to use the ER ($OR=1.49$, $p<0.0001$, 95 % CI=0.3301632, 0.4717708).

CONCLUSIONS: Nearly 25 % of women used the ER regardless of pregnancy complication, but those with recent GDM or HDP pregnancy had higher use. These

results highlight the importance of targeting women with a history of GDM or HDP, and non-pregnancy related medical co-morbidities, for postpartum outreach.

USE OF HEALTH-RELATED INFORMATION & COMMUNICATION TECHNOLOGY (ICT) AMONG PREGNANT AND POSTPARTUM WOMEN: THE TECHMOM STUDY Nymisha Chilukuri¹; Meredith West¹; Wendy L. Bennett^{1,2}.

¹Johns Hopkins University, Baltimore, MD; ²Johns Hopkins University, Baltimore, MD. (Tracking ID #1939249)

BACKGROUND: Pregnancy and the post-partum period provide opportunities to promote health behavior change in women but providers often miss these opportunities. Understanding how low-income, underserved women utilize Internet and Communication Technology (ICT) could inform technology-based interventions to promote behavior change. We examined differences in ICT usage by race/ethnicity and English proficiency to inform the tailoring of ICT-based interventions.

METHODS: The TechMom Study was a cross-sectional survey of 247 women who were pregnant or within one-year post-partum from 4 Johns Hopkins outpatient pediatric and obstetric clinical sites. Descriptive statistics were used to characterize participants. Multivariate logistic regression was performed to determine differences in cell phone/texting, email/internet and social networking usage by race/ethnicity and English proficiency, adjusting for age, income, marital and insurance status.

RESULTS: Most women were pregnant (83.8 %). Proportions of Latino, African-American, Caucasian and women of other races were 28 %, 40 %, 23 % and 9 %, respectively. 51.8 % had Medicaid or Medical Assistance and 59.5 % reported having a PCP. Latinas were more likely to have limited English proficiency compared with non-Latinas (83.8 % vs. 1.13 %, $p=0.000$). We did not detect any statistically significant differences in cell phone or text messaging use between Latino, Caucasian or African American racial/ethnic groups. Latinas (OR 0.30, $p=0.03$) were less likely to use e-mail/internet, but there was no statistically significant difference in use among Caucasians, compared with the reference group of African Americans. Among the Latinas who used the Internet, they were equally as likely to report using social networks as the other racial/ethnic groups (OR 1.409, $p=0.692$). Latinas were less likely to prefer receiving health information via cell phone (OR 0.37, $p=0.07$), equally likely via Internet (OR 0.804, $p=0.742$), and more likely via social networking sites (OR 6.8, $p=0.002$) as African-Americans. Women with limited English proficiency were equally likely to use cell phone (OR 1.1, $p=1.0$) but less likely to use e-mail/Internet (OR 0.18, $p=0.002$) as women with English proficiency. If using these tools, women with limited English proficiency were less likely to prefer receiving health information via a cell phone (OR 0.34, $p=0.05$), but had equal desire for receipt via Internet (OR 0.40, $p=0.20$), and an increased desire for receipt via social network sites (OR 3.0, $p=0.11$).

CONCLUSIONS: In urban, hospital-based outpatient obstetric and pediatric practices, pregnant and post-partum Latinas were equally likely to use texting and cell phones but less likely to use e-mail/internet compared with African-Americans and Caucasians. Women with limited English proficiency were equally likely to use cell phone/texting. These findings support the development of culturally-appropriate health promotional text-messaging focused on improving women's and family's health behaviors to reach out to women of all racial/ethnic groups.

USE OF TEXT MESSAGING TO MOTIVATE EXERCISE IN LATINOS WITH ONE OR MORE ATHEROSCLEROTIC RISK FACTORS: TWO PILOT STUDIES Tracie C. Collins¹; Fanglong Dong¹; Elizabeth Ablah¹; Deborah Parra-Medina⁴; Paula Cupertino²; Nicole Rogers³; Carolyn Ahlers-Schmidt⁵. ¹KU School of Medicine - Wichita, Wichita, MN; ²KU School of Medicine - Kansas City, Kansas City, KS; ³Wichita State University, Wichita, KS; ⁴University of Texas Health Science Center, San Antonio, TX; ⁵KU School of Medicine Wichita, Wichita, KS. (Tracking ID #1938248)

BACKGROUND: Text messaging offers an innovative approach to motivate behavior change and improve control of atherosclerotic risk factors in adult Latinos. We conducted two pilot studies: 1) to determine cell phone and text message usage among Latinos with one or more atherosclerotic risk factors (e.g. age 50–69 years with diabetes mellitus or a history of smoking; hypertension, or hyperlipidemia) and 2) to determine the efficacy of a motivational counseling script, delivered via text messaging, to improve the use of exercise among Latinos with one or more atherosclerotic risk factors.

METHODS: We administered a 15-item survey to Latino adults with one or more atherosclerotic risk factors. For an additional sample of Latino adults with one or more

atherosclerotic risk factors, we conducted a six-week, pre- and post-trial intervention. As part of the six-week trial, we ascertained stage of readiness to engage in exercise, which is a component of the original motivational script -Patient-centered Assessment and Counseling for Exercise (PACE) protocol - and exercise behavior scores (Exercise Behavior Questionnaire). Stage of readiness to exercise is based on the Transtheoretical Model and participants receive a score of one for precontemplation, a score of two to four for contemplation, and a score of five to eight for action/maintenance. Based on a participant's stage of readiness to exercise score, he/she received text messages. Text messages were sent once per day, 5 days per week for 6 weeks.

RESULTS: Among the 82 persons who completed the survey, (mean age 49.2, SD 12.0 years), 96.3 % owned a cellphone, 91.3 % had texting capacity on their cellphones, and 82.1 % had unlimited text messaging. More than 90 % received and sent text messages daily. Further, of those with text messaging capability, 89.2 % received at least one text message daily, and 52.7 % received five or more text messages daily. For the six-week trial, the mean age of the 13 participants was 49.2 years (SD 11.9). All 13 participants received their text messages. At baseline, the mean PACE score was 2.64 (0.67) out of a maximum score of 8 and this increased to 5.36 (0.81) at 6 weeks ($P<0.001$). At baseline, the mean exercise behavior score was 55.91 (55.76) minutes of exercise per week and this increased to 201.82 (61.61) minutes of exercise per week at 6 weeks ($P=0.0003$)

CONCLUSIONS: Use of cell phones and text messaging is common among Latinos with one or more atherosclerotic risk factors. Further, delivering a behavioral change intervention via text messaging is feasible and potentially efficacious to improve stage of readiness to engage in exercise as well as exercise behaviors among Latinos with one or more atherosclerotic risk factors.

USING A POSITIVE APPROACH TO IMPROVE PATIENT SATISFACTION IN PRIMARY CARE *Brittany P. Fenner; Stephanie A. Rose; Brett Capel; Nicholas Jackson; Bharat Kumar; David Rudy. University of Kentucky, Lexington, KY. (Tracking ID #1940244)*

BACKGROUND: Optimizing patient satisfaction is an important goal in healthcare today. Patient satisfaction is measured in several domains and results are utilized to develop strategies for improvement. These commonly involve quality improvement methods where deficits are identified and interventions for correction are initiated. Another method is to discover positive aspects of patient satisfaction and build upon these strengths. To this end we used Appreciative Inquiry to identify positive aspects of patient care in our university-based internal medicine primary care clinic.

METHODS: We conducted appreciative interviews of 50 patients or their family members in our clinic. Subjects were asked to tell a story of a time in their clinic experience that stood out for them when they received, saw, or were part of excellent patient care, who were the individuals involved, what were the positive characteristics of those individuals, and the aspects of the clinic that contributed to this experience. Responses were recorded on a response form. The texts were analyzed for thematic categories independently through qualitative methods by three reviewers. Discrepancies were resolved via consensus.

RESULTS: The predominant themes were: personal attention given by the staff, superior bedside manner, efficient care, patient-staff relationship, consistency in care, and educational environment. Personal attention and bedside manner were overwhelmingly the most common responses, with approximately 60 % of patients citing each of these aspects and every patient mentioning at least one of these two themes.

CONCLUSIONS: Patient responses parallel domains commonly utilized to measure patient satisfaction. Improvements in patient satisfaction may be framed in a positive light such as in the present study or deficits in patient satisfaction may be presented in a "blame and shame" fashion. We believe that presenting providers, staff, and administration with what patients value in their interactions with the health care system and asking for mechanisms to propagate these positive aspects may be an effective means of increasing patient satisfaction. We plan to present our data to all involved in the clinic and seek their input on how to accentuate these positive aspects. Patient satisfaction data will be followed longitudinally.

USING LEARNING STYLE ASSESSMENTS FOR INCOMING INTERNS *Luke Cunningham; Chirayu Shah; Steffanie Campbell; Richard J. Hamill. Baylor College of Medicine, Houston, TX. (Tracking ID #1937866)*

BACKGROUND: General Internists are increasingly becoming the experts in teaching both inpatient and outpatient skills to residents. With duty hour restrictions for resident training and increasing patient care demands, there is increasing need to optimize learning. Moving towards a learner-centered approach, it is important to understand the learning preferences of the housestaff. We attempted to assess learning

style preferences of incoming interns and compare the results to their perceived learning style. In addition, we assessed the impact of this exercise during orientation. **METHODS:** During the Department of Medicine orientation at Baylor College of Medicine in June 2013, a paper-based VARK (Visual, Auditory, Read/Write, Kinesthetic) instrument was given to all incoming interns. On a voluntary and anonymous basis, the interns submitted a separate page that included their scores and additional survey questions. Studying strategies were discussed for each of the learning styles and the interns received a handout about how to incorporate their learning style. All analysis was done using descriptive statistics.

RESULTS: There were 97 interns at orientation. The response rate was 90 % (87/97). Two responses were removed because of incomplete information. 56.5 % of interns had a multimodal learning style. The interns' perceived learning preference was 54 % visual, 21 % auditory, 53 % read/write, and 51 % kinesthetic. The VARK learning preferences were 62 % kinesthetic, 60 % read/write, 55 % auditory, and 54 % visual. When comparing their perceived learning style to the results of the VARK, 21 % were the same, 68 % with partial matches, and 11 % with completely different results. The interns reported this exercise was either very helpful or somewhat helpful by 93 % (79/85). 53 % (45/85) were going to try another learning strategy based on the results of their VARK assessment.

CONCLUSIONS: The majority of interns have multimodal learning preferences with the predominant being kinesthetic and read/write. General Internists should evaluate their current teaching methods to determine if a multimodal approach is being used. Offering the VARK assessment to learners will help attendings tailor their teaching based on the learner's preferences. In addition, the VARK assessment tool was considered a helpful exercise by most interns and over half planned to utilize a different learning strategy guided by the results. Learning style assessments should be considered for incoming trainees during orientation.

USING PATIENT FEEDBACK TO EXPLORE AND IMPROVE DIABETES CONTROL COMMUNICATION *Anjali Gopalan^{1,2}; Kevin H. McDonough⁴; Katherine Kellom⁵; Marilyn M. Schapira^{1,3}. ¹Philadelphia VA Medical Center, Philadelphia, PA; ²Perelman School of Medicine at the University of Pennsylvania, Philadelphia, PA; ³Perelman School of Medicine at the University of Pennsylvania, Philadelphia, PA; ⁴University of Pennsylvania, Philadelphia, PA; ⁵Perelman School of Medicine at the University of Pennsylvania, Philadelphia, PA. (Tracking ID #1937786)*

BACKGROUND: Only 25 % of patients with diabetes accurately understand the meaning of hemoglobin A1C values (A1C). This is of concern given that an understanding of diabetes management targets, specifically glycemic goals, is associated with better disease outcomes. However, A1C may not be how patients assess their current diabetes control. The purpose of this study was to learn about the metrics patients with diabetes use to gauge whether or not they are meeting their diabetes management goals, and to explore alternative communication formats that might be more effective at conveying information on glycemic control to patients.

METHODS: We conducted semi-structured interviews with patients with diabetes seen at University of Pennsylvania internal medicine practices. The first part of interviews covered the following: basic demographics, personal diabetes history, the participant's understanding of diabetes and diabetes control, diabetes-related goals, assessment of personal control, and a review of the A1C value and barriers to understanding this value. In the second part of the interview participants reviewed alternative formats designed to communicate glycemic control. Potential alternative communication formats were designed based on information presentation in other contexts and theories regarding the visual presentation of quantitative information. The initial field of 10 tested formats included color-based "traffic light" scales (red/yellow/green), comparisons to averages or norms, A1C trajectory depictions as well as modifications of current medical terminology (i.e., changing the name of the test). Each participant reviewed between 4 and 7 formats, depending on time. For each format reviewed, participants were shown three versions depicting differing levels of control—poor, moderate, and good. We sought both general impressions of these alternative communication formats as well as ratings of format clarity and assessments of participants' ability to rank the depicted levels of control accurately. The interviews were audio-recorded, transcribed and reviewed by two independent coders to identify themes and analyzed using nVivo software. Based on participant feedback the individual formats were revised and the field of formats narrowed towards the goal of identifying two formats to test more rigorously in a future study.

RESULTS: We completed 25 interviews. The mean age of participants was 56.8 years (range 26–82 years), 17 were women, the majority was African-American, and 9 of the 25 reported education beyond high school. While most participants mentioned the A1C without interviewer prompting and generally understood its relationship to

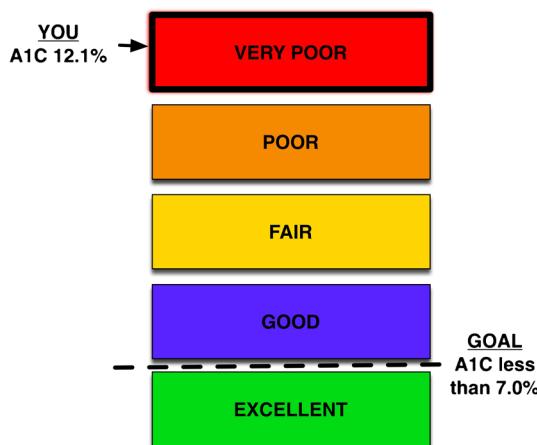

diabetes control and disease outcomes, actual understanding of the measure was poor and stated ideal A1C values were often erroneous, with some stating goal A1C values as low as 3 %. Common reasons participants cited for poor understanding of the A1C were personal denial of disease seriousness and lack of effort. In the second part of the interview, formats associated with both accurate ranking of control levels and high ratings of clarity: 1) employed the colors red, yellow and green; 2) included actual numbers on top of pictorial representation of control; 3) indicated directionality (low = better); and 4) provided clear targets/goals. While participants generally felt graphs were difficult to understand, they frequently led to accurate identification of control and, for those who stated they felt comfortable with graphs, they were preferred over more simple formats. Synthesizing all participant feedback, two final formats have

been selected for further study: both of which include the four identified qualities (images of the final formats are included below).

CONCLUSIONS: In this group of patients with diabetes, there was high value placed on being given a numbers in the evaluation of diabetes control and, in spite of poor understanding of the A1C, its relationship to disease outcomes was clear to most. Several common attributes of the designed communication formats were well received by participants and based on their feedback two final formats have been selected. Future studies will focus on evaluating their impact on increasing patient understanding of their diabetes control, improving patient satisfaction with provider communication, and altering diabetes-related behaviors and outcomes.

UTILIZATION OF SURVEY TO IDENTIFY HAND-OFF RELATED NON-ROUTINE EVENTS Jessica Kuester^{1,2}; Bambi Wessel^{2,1}; Matthew Doers¹; Tessa Damm¹; Jennifer Carnahan^{2,1}; Kinsey Nattinger¹; Kathlyn E. Fletcher^{2,1}. ¹Medical College of Wisconsin, Milwaukee, WI; ²Zablocki VA, Milwaukee, WI. (*Tracking ID #1936654*)

BACKGROUND: Resident work hour regulations have led to increased periods of time in which hospitalized patients are cared for by covering residents. Previous research has found that such cross-coverage can lead to potentially preventable adverse events. We utilized a facilitated survey to specifically identify hand-off related non-routine events (NREs), a proxy for patient safety. Hand-offs occur when patient information and responsibility for care are passed from one clinician to another.

METHODS: Utilized a 14 question yes/no survey on 44 post-call residents (PGY 1,2,3) on the inpatient medicine wards at an academic medical center to attempt to identify hand-off related non-routine events. Example questions include: "Were any of the patients sicker than you expected?" "Was there any written or verbal information provided by the prior team that was incorrect, missing, and/or misleading?" A "yes" response was a positive screen for all questions except number 7 which asked "As your shift unfolded, were your expectations about these patients realized?"

RESULTS: Approximately 80 % of residents surveyed (35/44) identified at least one NRE occurring on their shift. Forty-five percent (20/44) of the residents reported that something happened to a patient that was unexpected, unusual, notable, or surprising during the cross-cover period. Thirty-two percent of residents (14/44) found patients to be sicker than expected. Fifty-seven percent (25/44) had to perform an unanticipated or unplanned action while caring for the other teams' patients. Nearly 30 % (13/44) found that there was written or

verbal information provided by the prior team that was incorrect, missing, and/or misleading. While, 32 % (14/44) could identify that there was at least one deviation from ideal/pREFERRED care during their patient coverage. Fisher's test was utilized to calculate two-tailed p values between PGY1 and PGY2-3 responses. There were no statistically significant differences between PGY1 and PGY2-3 responses for each of the 14 questions.

CONCLUSIONS: We were able to demonstrate that the majority of residents were able to identify at least one NRE during their cross-coverage period that was associated with a poor quality hand-off. Plans for future research include evaluating if improvement in written sign-out documents decrease the number of NREs and thus increase patient safety.

UTILIZING ITERATIVE CASE PRESENTATION TO DEMONSTRATE CONCEPTS OF CLINICAL REASONING John Musgrave¹; Ryan Kraemer^{1,2}; Jason L. Morris^{1,2}; Carlos Estrada^{2,1}. ¹The University of Alabama at Birmingham, Birmingham, AL; ²Birmingham VAMC, Birmingham, AL. (*Tracking ID #1928099*)

BACKGROUND: Clinical problem solving (CPS) exercises have emerged as a means of exploring the nuances of clinical reasoning. In this format, a case is iteratively presented with interposed commentary from an expert clinician. We aim to characterize the clinical reasoning concepts of published CPS exercises as an initial step towards incorporating such exercises into clinical reasoning curricula.

METHODS: Literature review and text analysis in three steps: **First**, identified CPS exercises (table of contents review, 4 journals; Jan 2010-May 2013). **Second**, compiled a list of clinical reasoning concepts from seminal narrative reviews (seven educators voted from a list of 49 concepts; items with <5 votes were excluded). **Third**, utilized a regular expression search engine to identify specific mentions of

clinical reasoning concepts (including synonyms) in each CPS exercise via automated, batched searches. Search engine compatible text files created using a custom JavaScript function in Acrobat® X. Superfluous text (titles and references) was redacted with regular expression text editing software. Electronic search results concordant with word-by-word article reviews. The primary outcome was the presence of each clinical reasoning concept in each article. Differences between journals were examined with the Chi-square test.

RESULTS: We identified 79 CPS exercises: 41 (52 %) in the *N Engl J Med*, 22 (28 %) *J Hosp Med*, 11 (14 %) *J Gen Int Med*, and 5 (6 %) *Am J Med Sci*. Six concepts were mentioned in >10 % of the articles: *diagnosis* 79 (100 %), *context* 20 (25.3 %), *bias* 13 (16.5 %), *illness script* 11 (13.9 %), *problem representation* 10 (12.7 %), *hypothesis* 9 (11.4 %). Concepts mentioned in ≤5 % of the articles were *cognitive error*, *framing*, *dual process*, *flexibility*, *metacognition*, *system error*, *overconfidence*, and *naturalistic decision making*. Differences between journals were observed on all but five concepts (all $p \leq 0.005$, data not shown).

CONCLUSIONS: CPS exercises represent an accessible learning tool capable of detailing expert clinical reasoning while simultaneously addressing the nuances of core clinical reasoning concepts. This study helps to characterize relevant clinical reasoning concepts which have been discussed in CPS exercises.

VALIDATION OF NON-SMOKING STATUS BY SPOUSE FOLLOWING A CESSATION INTERVENTION Raul Mejia¹; Eliseo J. Perez-Stable²; Sandra Braun¹; L. Peña¹; Steve Gregorich². ¹Hospital de Clínicas, Universidad de Buenos Aires, Benos Aires, Argentina; ²University of California, San Francisco, San Francisco, CA. (*Tracking ID #1938644*)

BACKGROUND: Following cessation interventions self-report of smoking abstinence with biochemical verification is defined as the “gold standard” outcome. Because obtaining biochemical verification is challenging and costly in community studies, we compared self-reported cessation among participants completing treatment to the smoking status reported by the spouse or proxy.

METHODS: Participants in this study were smokers who had reported quitting 12 months after the cessation intervention. Participants had either attended a smoking cessation clinic based at a university hospital primary care program or they were patients seen by private practice physicians who had participated in tobacco cessation training in Buenos Aires. A subsample of spouses of these participants was then interviewed by telephone to ask about their partner’s smoking status. We compared the participants’ responses to those from the spouses.

RESULTS: At 12 months 346 of 1423 smokers had quit; 161 non-smokers were called and 140 proxies (spouses) of these participants were interviewed. They had an average age of 51 years, 69 % were women, and 49 % had >12 years of education. Mean number of cigarettes per day was 20.1 (SD=9.9) and the average number of quit attempts was 2.4 (SD=1.2). Cessation methods used were medical advice or behavioral change only (21 %), bupropion treatment (56 %), nicotine replacement therapy (20 %), and/or varenicline (3 %). At 12 months, of the 140 spouses interviewed, only 10 (7.1 %) reported that their partners continued to be smokers. The agreement between self-response and proxy report was 92.9 % Kappa=0.9286

CONCLUSIONS: These results suggest that proxy-reported data on smoking status could be used to validate self-reported results in smoking cessation trials in low-resource countries in place of biochemical verification.

VARIABILITY IN ADHERENCE TO OPIOID PRESCRIPTION GUIDELINES AMONG ADULT PRIMARY CARE PROVIDERS Allison Lange¹; Karen E. Lasser^{1,2}; Ziming Xuan³; Laila Khalid¹; Donna Beers¹; Orlaith Heymann¹; Christopher W. Shanahan¹; Julie Crosson¹; Jane M. Liebschutz¹. ¹Boston Medical Center, Boston, MA; ²Massachusetts Department of Public Health, Boston, MA; ³Boston University School of Public Health, Boston, MA. (*Tracking ID #1936182*)

BACKGROUND: In order to reduce prescription opioid misuse, clinical guidelines recommend that primary care providers (PCPs) use opioid treatment agreements and urine drug screens to monitor patients on opioid therapy for chronic non-cancer pain, with risk for medication misuse informing monitoring intensity. Little is known about variability among individual PCPs in adherence to opioid management guidelines and whether guideline non-adherence by PCP is associated with greater misuse of opioids.

METHODS: We examined 12 months (September 2011–August 2012) of electronic health record (EHR) data from adult primary care clinics at two community health centers and one urban safety net hospital. Patients age 18–89 were included if they had received >3 opioid prescriptions for chronic pain within a six-month period and

were not receiving active cancer treatment. PCPs were included if they had >4 eligible patients. Binary outcome variables were evidence of guideline adherence through (1) EHR documentation of an opioid treatment agreement (OTA) ever, and (2) Urine Drug Screen (UDS) in the past 12 months. Evidence of misuse was a binary outcome of 2 or more early opioid refills (>2 prescriptions written 7–25 days after the previous prescription for the same medication). Covariates were patient demographics, number of primary care visits (past year), number of Emergency Department visits (past year), number of patient risk factors for opioid misuse (age <45, drug use disorder, alcohol use disorder, tobacco use, and mental health disorder), morphine equivalent daily opioid medication dose (MDD) >50 mg/day, PCP type (attending, resident, nurse practitioner), and site of care. We used odds ratios to examine the correlations among patient-level binary outcomes, and Pearson correlations to examine the relationships among PCP-level aggregates of outcomes across patients within PCPs. Further, we used multi-level modeling to account for patient clustering within PCP and examine substantive variance attributable to PCP characteristics.

RESULTS: Sixty-seven PCPs prescribed opioids to 1,546 patients (mean patients per PCP: 23, median: 14, range: 4–95). No PCP met 100 % of guideline practices, and PCPs showed wide variability in adherence. PCPs had a mean of 48 % of patients with OTA (median: 50 %, range: 0–100 %). PCPs had obtained >1 UDS for a mean of 56 % of patients (median: 59 %, range: 0–100 %). Among the three outcomes, the PCP-level variance for OTA and UDS were greater compared to the variance for early refill. The variance for UDS decreased from 1.75 to 0.87 after adjustment for covariates and site ($p < 0.001$). Step-wise adjustment of the variance for UDS evaluated which portion of the adjustment led to the difference in variance. Adjustment for patient-level covariates decreased variance from 1.75 to 1.14 ($p < 0.001$); further adjustment for PCP type did not decrease the variance ($p < 0.001$). Adjustment by site decreased the variance substantially to 0.88 ($p < 0.001$), reflecting differences in UDS prevalence across the sites (24 %, 37 % vs. 67 %). At the patient level, the presence of >50 mg/day MDD was associated with increased odds of early refill (OR=2.92, 95 % CI 2.30–3.70), of UDS (OR=2.65, 95 % CI 2.06–3.41), and of an OTA (OR=1.93, 95 % CI 1.53–2.44). OTA was associated with UDS (OR=8.46 95 % CI 6.65–10.75) and early refill (OR=1.56, 95 % CI 1.27–1.93), and early refill was associated with UDS (OR=1.76, 95 % CI 1.42–2.18). PCPs with higher aggregates of MDD among their patients tend to have greater proportions of patients with early refills ($r=0.38$, $p=0.002$) and UDS ($r=0.46$, $p < 0.0001$). PCPs with greater proportions of patients with UDS tend to have greater proportions of patients with OTA ($r=0.34$, $p=0.005$) and with early refills ($r=0.27$, $p=0.03$).

CONCLUSIONS: PCPs practicing with an urban underserved population show substantial heterogeneity in adherence to opioid prescription guidelines, with only half of patients getting recommended procedures. PCP use of urine drug screens, but not use of agreements, appears to be heavily influenced by the practice environment. Although high daily doses of opioid are associated with increased monitoring, they are also associated with evidence of greater misuse. Examining the time dependent relationship between monitoring and multiple early refills could help distinguish whether monitoring practices help prevent potential opioid misuse or are a reaction to it.

VARIATION IN OBESITY AND DIABETES PREVALENCE AMONG ASIAN ETHNIC GROUPS Alison Diamant; Susan Babey; Joelle Wolstein. UCLA, Los Angeles, CA. (*Tracking ID #1933269*)

BACKGROUND: The growing epidemics of diabetes and obesity threaten to dominate health care resources and worsen quality of life. Little is known about the prevalence of diabetes and obesity among Asian groups as researchers rarely disaggregate data on Asians. To inform the development of effective interventions we studied the variation in prevalence of diabetes and obesity among nine Asian ethnic groups. Methods: We used data from four waves of the California Health Interview Survey (CHIS), a large population-based telephone survey with over-sampling of Asian households and interviews conducted in five Asian languages. Using combined samples from 2001/2003 and 2007/2009, we assessed the prevalence of diabetes and obesity by Asian groups controlling for sociodemographic characteristics.

METHODS: We used data from four waves of the California Health Interview Survey (CHIS), a large population-based telephone survey with over-sampling of Asian households and interviews conducted in five Asian languages. Using combined samples from 2001/2003 and 2007/2009, we assessed the prevalence

of diabetes and obesity by Asian groups controlling for sociodemographic characteristics.

RESULTS: In 2001/03 Japanese (8.4 %) had the highest and Koreans (2.1 %) had the lowest prevalence of obesity, while in 2007/09 Filipinos (12.2 %) and Japanese (11.7 %) had the highest rates, while Chinese (3.4 %) had the lowest prevalence. In 2001/2003 the overall prevalence of diabetes among Asians was 5.7 %, but was most prevalent among Japanese (11.3 %) and significantly less prevalent among South Asians (3.4 %), Chinese (4.1 %), Koreans (4.8 %) and Vietnamese (5.4 %). By 2007/2009 diabetes prevalence had increased to 7.1 % overall, with significant increases among Chinese, Koreans, Filipinos, and South Asians. In multivariate analyses we found significant variation by Asian ethnic group for obesity and diabetes. All single Asian groups are less likely than Whites to be obese, but Filipinos, Japanese, and South Asians are more likely than Chinese to be obese. Regarding diabetes Filipinos (OR 2.0, 95 % CI 1.3, 2.9), Koreans (OR 2.1, 95 % CI 1.4, 3.0) and South Asians (OR 3.1, 95 % CI 2.1, 4.5) are more likely than whites to have diabetes.

CONCLUSIONS: The prevalence of obesity and diabetes varies significantly by Asian ethnic group. The development and implementation of culturally appropriate interventions are needed to address these growing problems. Where possible, research on diabetes, obesity and other chronic conditions should examine variation by Asian ethnic groups and include sufficient sample sizes to enable such analyses, rather than relying on a summative measure of all Asians.

WALKING THE TALK TO IMPROVE ERROR REPORTING Chaitanya Mandapakala^{1,2}; Diane L. Levine²; John D Dingell VA Medical Center, Detroit, MI; ²Detroit Medical Center, Detroit, MI. (*Tracking ID #1938661*)

BACKGROUND: The Institute of Medicine's landmark report, "To err is human; building a safer health system" highlighted the importance of discussing medical errors in healthcare. Since then, quality and safety organizations have recommended incident reporting. Learning from adverse events or even latent errors is crucial for quality improvement and patient safety. Yet under reporting remains a continuing problem, especially among physicians. The Internal Medicine (IM) residency program at Detroit Medical Center has over 100 residents who rotate at multiple clinical sites including a Veterans Medical Center (VAMC). Residents rotate at the VAMC for 0–3 months per year. Intermittent rotation and lack of continuity makes it challenging to implement patient safety initiatives, such as improving the incident reporting among residents. In addition, residents have to learn to use a different kind of electronic reporting system at each of their clinical sites. Baseline reporting information provided by the VAMC Patient Safety officer (PSO) showed that between July 2012 and June 2013 residents reported only 2 incident reports. The objective of this quality improvement initiative was to improve error reporting at VAMC by IM residents by understanding the barriers to reporting and implementing changes using Plan-Do-Study-Act (PDSA) cycles to achieve change.

METHODS: Residents completed a pre-intervention questionnaire on the first day of their IM rotation at VAMC to see if they were aware of, and knew how to use, the Electronic Patient Incident Reporting (EPIR) system. Root cause analysis (RCA) was performed and multiple barriers to incident reporting were identified. Based on the information obtained, interventions were developed and implemented by the Chief Resident for Quality Improvement and Patient Safety (CRQS) in PDSA cycles. Information on the number of incidents reported by medicine residents was provided monthly by the PSO. Interventions implemented through PDSA cycles have been summarized in Table 1.

RESULTS: The number of incidents reported over time have also been shown in Table 1. Incidents reported were plotted over time in an XmR control chart (with upper and lower control limits at 3σ) to understand the impact made by our interventions. On review of the baseline data from July 2012 to July 2013, if things were allowed to continue as they were, there was a 99 % probability that the number of incidents reported would be 0–1 per month. Current data over 5 PDSA cycles (32 incidents from August 2013 to December 2013) suggests that if our efforts continue to show similar results, there is a 99 % probability that the number of incidents reported would be 0–19 per month.

CONCLUSIONS: RCA and PDSA cycles allowed us to identify and overcome barriers that prevented resident error reporting. Education (talking) alone was insufficient to increase error reporting. Walk rounds (walking) in conjunction with reinforcing education (talking) allowed us to increase error reporting. Discussion of potential events for reporting at the point-of-care increased error reporting. Walk rounds are effective but time intensive (1–1.5 h per day). To further develop the culture of safety the next PDSA cycles will focus on

identifying resident champions from each year of training who will encourage and help their peers identify and report incidents (peer-to-peer coaching) to allow for sustainability and transportability to other clinical sites in our training program.

Table 1: Incidents reported over time with PDSA based interventions

Time	Intervention	Incidents reported by residents
July 2012– Dec 2012	None (baseline data)	1
Jan 2013– June 2013	None (baseline data)	1
July 2013	None (RCA initiated to identify barriers)	0
Aug 2013	PDSA cycle 1: 1-hour orientation lecture (Education) to educate residents on EPIR (Talking)	1
Sep 2013	PDSA cycle 2: Education + Daily Patient Safety Walk Rounds ie., CRQS made his own rounds and asked residents 2 questions: a) Have you come across any incident (adverse events or near misses) that you think needs to be reported? b) What can I do to help you report this incident?	4
Oct 2013	PDSA cycle 3: Education + Daily Patient Safety Walk Rounds + Observing rounding teams daily to aid in identifying errors and encouraging a culture of reporting	13
Nov 2013	PDSA cycle 4: Education + Articles posted on resident website showing importance of reporting, screenshots of how to use the electronic system and process after reporting + Weekly Patient Safety Walk Rounds	8
Dec 2013	PDSA cycle 5: Same as PDSA 4	6

RCA = Root Cause Analysis; PDSA = Plan Do Study Act; CRQS = Chief Resident for Quality Improvement and Patient Safety

WARFARIN THERAPY AMONG PATIENTS NEWLY DIAGNOSED WITH CANCER: EXAMINING CONTROL AND OUTCOMES BY INDICATION FOR THERAPY Daniel B. Ambrus^{1,2}; Adam Rose^{1,2}; Joel Reisman¹. ¹Bedford VHA, Bedford, MA; ²Boston Medical Center, Boston, MA. (*Tracking ID #1938651*)

BACKGROUND: While extensive guidelines have been published regarding the management of warfarin for non-valvular atrial fibrillation (AF) in a variety of settings, the problem of a new cancer diagnosis adds significant complexity and uncertainty. Furthermore, there seems to be a significant gap in the literature regarding patients on warfarin for AF rather than for prophylaxis or treatment of venous thromboembolism (VTE) in the setting of cancer.

METHODS: We started with 122,875 veterans who had been receiving warfarin for at least 6 months from a Veterans' Health Administration Medical Center (VAMC) from October 1st, 2006 through September 30th, 2008. We identified patients with incident cancer during that time by ICD-9 codes. Patients with a history of cancer prior to the study period were excluded from the analysis. To examine adherence to warfarin by indication for anticoagulation, we compared the mean time spent in therapeutic range (TTR) between the baseline period (the six months prior to diagnosis) and up to a year following diagnosis. To examine outcomes, we first compared crude all-cause mortality, major bleeding and stroke rates in the 6 months following cancer diagnosis between patients anticoagulated for VTE and AF. To enhance validity, we then constructed propensity-matched samples of patients with VTE and AF, with matching for presence of metastasis, recent major hospitalization, highly toxic chemotherapy, socioeconomic status and access to care, as well as significant non-cancer comorbidities. Patients receiving low-molecular weight heparins were excluded. Cox models were used to obtain hazard ratios for all-cause mortality, major bleeding and stroke. A similar but separate propensity matching analysis was also performed to examine adjusted outcomes for patients who did and did not continue warfarin following cancer diagnosis, regardless of indication.

RESULTS: Among patients with any cancer ($N=1,936$), TTR decreased by an average of 6.5 % in the AF group and by 6.1 % in the VTE group between the baseline period and the first 6 months after diagnosis. There was no difference in average TTR between baseline and months 7–12 for either indication. During

the six-month follow up period after cancer diagnosis, crude rates of all-cause mortality (8.0 %, 9.0 %), major hemorrhage (5.2 %, 5.7 %), or stroke (2.6 %, 2.4 %) did not significantly differ between AF and VTE, respectively. Propensity matched analysis for a diagnosis of AF as indication showed that AF (as compared to VTE) was associated with improved survival [(HR=0.80),($p=0.01$)], a non-significant trend toward decreased hazard of stroke [(HR=0.38),($p=0.06$)], and no apparent effect on major hemorrhage [(HR=1.13),($p=0.69$)]. Propensity matched analysis for persistence with warfarin after cancer diagnosis (as compared to patients who did not persist) showed significantly improved survival regardless of indication [(HR=0.75),($p<0.001$)], with non-significant trends toward lower hazard of stroke [(HR=0.60),($p=0.07$)] and major bleeding [(HR=0.86),($p=0.29$)].

CONCLUSIONS: In patients already receiving warfarin, a new diagnosis of cancer conferred poorer anticoagulation control regardless of indication for therapy, and outcome measures 6 months after diagnosis were similar between indications, though slightly favoring AF in the adjusted analysis. Clinical guidelines, which currently address anticoagulation therapy for treatment or prevention of VTE in the setting of cancer, should also explicitly address how to treat patients anticoagulated for AF who are newly diagnosed with cancer.

WATER IS GOOD FOR HEALTH? NOT IN ALL PATIENTS Sourabh Aggarwal; Vishal Gupta. Western Michigan University School of Medicine, Kalamazoo, MI. (*Tracking ID #1940229*)

BACKGROUND: There is a lot of ambiguity on ideal daily water intake (DWI) requirements especially in patients with underlying cardiovascular symptoms. There is no literature to date that has studied impact of regulated water intake in patients with cardiac symptoms. The average DWI recommended by various societies lack any concrete scientific evidence. The present quality improvement study was designed to identify influence of intensive patient education and effective communication on DWI restriction and its impact on clinical outcomes in patients with cardiovascular symptoms and unregulated water intake.

METHODS: This was a prospective pilot study conducted at our cardiovascular clinic. All patients who presented to our clinic with symptoms of shortness of breath (SOB), chest pain, dizziness, palpitations and peripheral edema were asked for DWI. The patients whose DWI was greater than 2 L/day and were optimally medically managed were included in this study. Patients with underlying systolic heart failure, left ventricular ejection fraction $\leq 45\%$ and chronic kidney disease were excluded from the study. The patients were weighed at baseline, their fluid intake recorded. Extensive water intake education was given to patients and were advised to restrict DWI. Primary outcome to be measured was symptomatic improvement in abovementioned symptoms. Patients were followed every 3–6 months in our clinic and importance of fluid restriction re-iterated with extensive patient education at follow up visits. Symptoms were noted and weight measured at each follow up visit. SPSS was used for statistical analysis, $p<0.05$ was considered statistically significant

RESULTS: 65 patients (42 females, 23 males) were enrolled in the study with mean age of 55.16 ± 12.44 years and mean follow up of 1.92 ± 0.56 years (range 0.85 to 3.36 years). The average fluid intake decreased from 2.82 ± 1.93 L/day to 1.48 ± 0.95 L/day, with mean decrease of 1.34 ± 0.21 L/day ($p<0.001$). The mean weight decreased from 219.2 ± 7.4 lb to 203.5 ± 6.9 lb with mean weight loss of 15.8 ± 3.2 lb ($p=0.06$) At end of study, 71.43 % patients reported

improvement in shortness of breath ($p<0.001$), 38.47 % reported improvement in chest pain ($p=0.09$), 25 % patients reported improvement in dizziness ($p=0.77$), 74.36 % patients reported improvement in leg edema (<0.001), 77.28 % patients reported improvement in palpitations ($p<0.001$) and 42.86 % patients reported improvement in leg pain ($p=0.24$). The improvement in symptomatology was reciprocated in both genders individually with significant decrease in shortness of breath, peripheral edema and palpitations.

CONCLUSIONS: This is first study to date which analyzed the impact of fluid restriction in symptomatic patients with unregulated water intake. This shows that non-pharmacologic intervention of fluid restriction was associated with significant improvement in SOB, palpitations and peripheral edema in patients. Also, patient education on water restriction led to significant reduction in DWI and was associated with weight loss in these patients.

WE NEED TO TALK: PCP COMMUNICATION IN THE ERA OF A SHARED EMR Leslie Sheu; Kelly A. Fung; Michelle Mourad; Suman Ranji; Ethel Wu. University of California, San Francisco, San Francisco, CA. (*Tracking ID #1933345*)

BACKGROUND: Shared electronic medical record (EMR) systems can facilitate effective communication between inpatient and outpatient providers to ensure safe transitions from hospital to home. We surveyed primary care physicians (PCPs) in the Department of General Internal Medicine at our academic medical center 1 year after inpatient EMR implementation to assess satisfaction with discharge communication and the desired content of communication at discharge.

METHODS: We administered an anonymous 17-question electronic survey about patients discharged from the inpatient Medicine service to resident and attending PCPs ($n=124$) at our academic medical center. The survey was designed to determine: 1) overall PCP satisfaction with current communication practices from the inpatient team at patient discharge, 2) perceived adequacy of automatic discharge notifications, and 3) perception of the types of patients and hospitalizations requiring additional high-thought communication at discharge.

RESULTS: Seventy-five of 124 (60 %) providers completed the survey. Thirty-nine (52 %) PCPs were satisfied or very satisfied over communication at patient discharge. While most reported receiving automated discharge notifications (71 %), only 39 % felt that the notifications plus the discharge summaries were adequate communication for safe transitions of care. The PCPs surveyed felt that for patients with complex hospitalizations, additional email or verbal communication was needed in addition to the discharge summary (Figure 1), however, only 31 % reported receiving such communication. When asked about the content of additional communication, PCPs reported many elements to be important, most notably 1) medication changes, 2) follow-up actions for the PCP, and 3) active medical issues.

CONCLUSIONS: Shared EMR systems afford new opportunities for communication and record sharing between inpatient and outpatient providers. However, our PCPs reported the need for additional communication to ensure safe transitions of care. Our survey suggests that for complex hospitalized patients, there are opportunities for further standardization of communication around transitions of care. Next steps at our medical center include focused surveys and interviews of PCPs whose patients were recently discharged, creating templates/guidelines for PCP communication at discharge, and implementing an inpatient-wide initiative to improve discharge communication.

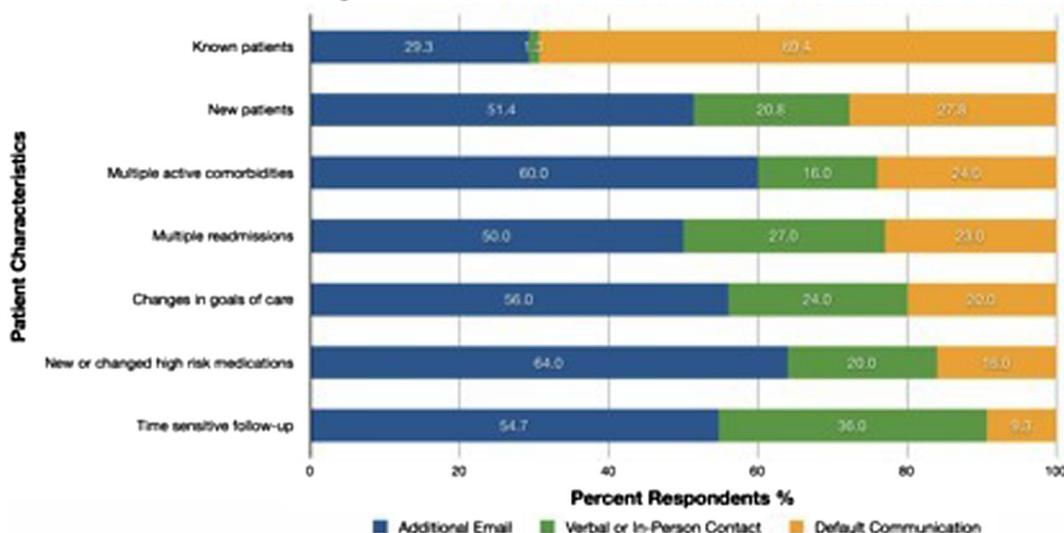

Figure 1. Patient Characteristics and Desired Mode of Communication

Figure 1. Patient Characteristics and Desired Mode of Communication. For patients with complex hospitalizations, PCPs indicated the preferred mode of communication at discharge. Default communication included discharge notification and discharge summary (orange) compared to additional forms of communication, either email (blue) or verbal contact (green).

Patient characteristics and desired mode of communication

WEATHERING THE STORM: THE IMPACT OF HURRICANE SANDY ON PRIMARY CARE PRACTICE AT THE NEW YORK VA MEDICAL CENTER
 Mark D. Schwartz^{1,3}, Ashley E. Jensen^{2,1}; Matthew Beyrouty^{2,1}; Katelyn Bennett^{1,2}; Scott Sherman^{1,3}; Joseph Leung^{1,2}; Neil Shapiro^{1,2}. ¹VA NY Harbor Healthcare System, New York, NY; ²NYU School of Medicine, New York, NY; ³NYU School of Medicine, New York, NY. (Tracking ID #1937759)

BACKGROUND: Superstorm Sandy dramatically disrupted primary care (PC) services at the Manhattan campus of the VA New York Harbor Healthcare System (NY Harbor). The hospital was evacuated and closed on October 28, 2012, and remained closed for 6 months to undergo major repairs. Previous research of the impact of natural disasters on PC utilization is limited, but Hurricane Katrina in New Orleans highlighted the value of quickly establishing flexible “medical homes” following a disaster. In 2010 the VA established its own medical home model (Patient Aligned Care Teams, PACT), which includes strategies for panel management and expanding health care beyond the in-person encounter. During 6 months of displacement, NY Harbor staff provided PC services remotely by telephone, secure messaging, and walk-in access clinics at other VA facilities throughout New York City. The storm abruptly accelerated the need for panel management and remote care strategies, creating a unique opportunity to study how PC staff and patients coped with these changes.

METHODS: In this observational study, 48 PC staff that care for approximately 16,000 veterans were surveyed 2 months following the storm (Displacement), and 6 months after returning to the hospital (Return) about the impact of the storm on their practice, stress, satisfaction, and perceived impact on patient care. Staff responded to a 7-item measure of panel management self-efficacy (11-point scale, Cronbach’s $\alpha=0.9$, maximum score of 70), and a 3-

item scale of confidence in providing remote care (11-point scale, $\alpha=0.8$, maximum score of 30). Using VA administrative data, PC service use including visits, telephone encounters, and secure messages was tracked to compare utilization patterns before the storm, during Displacement, and after Return. We also compared the proportions of each providers’ hypertensive patients with blood pressure (BP) $>140/90$, and diabetic patients with hemoglobin A1c $>9.0\%$ before and after the storm. We tested the correlation between clinicians’ panel management self-efficacy and the proportions of their patients with uncontrolled BP and A1c values.

RESULTS: Of the 36 respondents at Displacement (77 % response rate), 27 % had to evacuate their homes during the storm, 72 % lost power for >24 h, and 31 % reported damage to their property. During Displacement, 35 % felt that patients were well cared for, but upon Return this increased to 78 % ($p<0.001$). During Displacement, 77 % said that when they return to the hospital, patients will need to be seen in person less often, 67 % would provide more care by telephone, and 52 % would use more secure messaging. Upon Return, only 48 % of staff reported that they believed patients need to be seen in person less often ($p=0.04$), however 70 % said they provide more care by phone and 67 % said they use more secure messaging than before the storm. From Displacement to Return, the proportion with greater work stress (compared to before the storm) decreased from 51 to 45 % ($p=0.80$), while job satisfaction increased from 45 to 75 % ($p=0.05$). The staffs’ panel management self-efficacy increased from a mean (SD) of 34.9 (10.9) during Displacement to 44.0 (15.1) on Return (26 % increase, $p=0.002$). Staff confidence in providing remote care also trended 8.5 % higher ($p=0.18$). Provider’s with higher self-efficacy scores for panel management had fewer diabetic patients with out of range A1c readings for the 3 months immediately following the storm ($r=-0.47$, $p=0.03$) and 6 months following the storm ($r=-0.52$, $p=0.02$), but not prior to the storm; while the proportion of hypertensive patients with out of control BP was not correlated with panel management self-efficacy ($r=0.36$, $p=0.59$).

CONCLUSIONS: Following Hurricane Sandy, PC staff at the NY Harbor were forced to innovatively accelerate the deployment of panel management and remote care strategies,

through which they successfully maintained access to care for their patients. This experience has had an impact on the PACT PC model, with substantially increased self-efficacy in panel management (linked to better diabetes control), and improved confidence in providing remote care. Growth in remote care was sustained upon return to the hospital. These results argue for expanding the training of medical home teams in panel management and remote care strategies. These findings thus have implications for disaster planning as well as for advancing medical home models.

Average Monthly Primary Care (PC) Encounters and Outcomes Before and After Hurricane Sandy

	Before Storm (May–Oct. 2012)	Displacement (Nov. 2012–Apr. 2013)	Return (May–Oct. 2013)
Total # of PC of Encounters	6,356	5,251	5,643
% of encounters by phone	25.2	45.5	28.4
Total # of secure messages	350	561	577
% of hypertensive patients with BP > 140/90	23.6	28.1	28.3
% of diabetic patients with A1c >9 %	23.8	25.1	28.2

WEIGHT GAIN AFTER ART AND ASSOCIATION WITH SURVIVAL IN 4315 HIV INFECTED MEN AND WOMEN Bianca F. Yuh¹; Janet P. Tate^{1,2}; Amy C. Justice^{1,2}. ¹Yale School of Medicine, New Haven, CT; ²Veterans Affairs Connecticut Healthcare System, West Haven, CT. (*Tracking ID #1934619*)

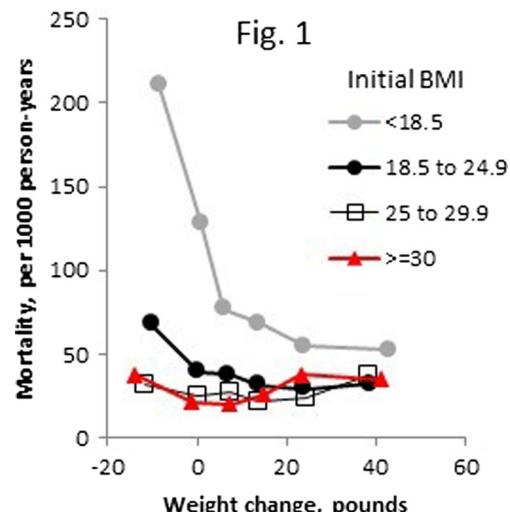

BACKGROUND: With increasing prevalence of overweight and obesity among HIV infected patients, providers need to understand implications of weight gain. Although the association between overweight/obesity with multiple co-morbid conditions and excess mortality is well-established in the general population, the relationship of weight gain and disease burden in HIV infected patients in the modern ART era remains unclear. Therefore, we evaluated weight gain in the 12 months following ART initiation and its association with subsequent mortality.

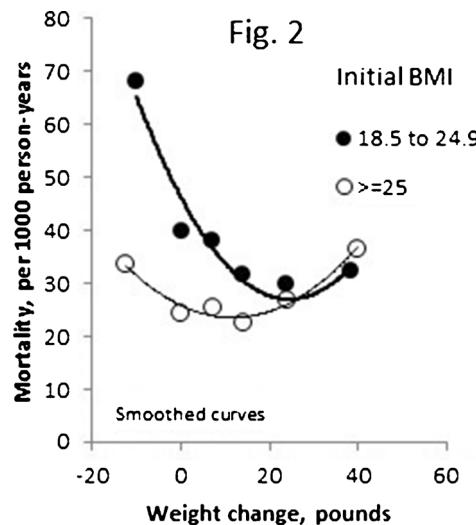

METHODS: Patients from the Veterans Aging Cohort Study who initiated ART between 2000 and 2008, with recorded weight at baseline and 1 year later were included and followed another 5 years for mortality. BMI was classified as underweight (<18.5), normal (18.5–24.9), overweight (25–29.9) and obese (≥30).

Mortality rates were determined as a function of weight gain, stratified by initial BMI. We used logistic regression to identify predictors of weight gain.

RESULTS: The sample of 4188 men and 127 women had mean age of 48; 55 % were black. Only 6 % were underweight at ART initiation, but 30 % were overweight and 12 % were obese. After 12 months of ART, mean weight gain was 8.2 lb, but 902 (21 %) patients gained ≥20 lb. Higher weight gain, up to about 20 lb, was associated with lower mortality regardless of initial BMI, but there was no survival advantage to greater gains (Fig. 1). In fact, mortality increased with weight gain >20 lb in those with normal initial BMI. In those with initial BMI ≥25, mortality rates increased with weight gain >15 lb. After adjustment for initial BMI, both CD4<100 cells/ml [OR=3.2, (95 % confidence interval 2.8–3.8)] and hemoglobin <12 g/dL [2.9 (2.5–3.5)] were strongly associated with weight gain and new obesity.

CONCLUSIONS: In general, weight gain after ART initiation was associated with lower mortality especially among initially underweight and normal weight patients. However, mortality increased with excess weight gain. Based on these findings, providers should counsel all patients to avoid weight gain >20 lb; Overweight and obese patients should limit weight gain to 15 lb. This is consistent with recommendations made to pregnant women where optimum weight gain depends on starting BMI. Patients with low CD4 and/or low hemoglobin should be especially cautious.

WEIGHT LOSS ASSOCIATED WITH CHOLINESTERASE INHIBITORS IN PATIENTS WITH DEMENTIA IN A NATIONAL HEALTHCARE SYSTEM
Meera Sheffrin; Yinghui Miao; W. John Boscardin; Michael A. Steinman. UCSF and the San Francisco VA Medical Center, San Francisco, CA. (*Tracking ID #1931500*)

BACKGROUND: Cholinesterase inhibitors are a commonly used therapy for dementia. Conflicting data from randomized trials suggest cholinesterase inhibitors may lead to weight loss, which is of concern as weight loss in older adults has been associated with increased mortality. Because the selected patient populations in clinical trials may not reflect drug effects in real-world clinical settings, we sought to determine if initiation of cholinesterase inhibitors is associated with clinically significant weight loss in patients with dementia in a national healthcare system.

METHODS: Using national data from the Veterans Affairs health system from 2007 to 2010, we identified patients aged 65 or older with dementia who were new users of cholinesterase inhibitors, and a control group of patients who were new users of other chronic medications (non users). Patients with a diagnosis of heart failure or cancer or unstable weight during a one-year baseline period were excluded. Patients were matched using a propensity score model with baseline clinical and demographic characteristics including initial weight and weight trajectory. The primary outcome

was risk of 10 lb weight loss, defined by the first recorded weight \geq 10 lb lower than the baseline weight. A secondary confirmatory outcome was mean change in weight over 12 months. In secondary analyses, we evaluated outcomes in an on-treatment analysis, matching users and non-users by treatment duration.

RESULTS: Of 6,504 patients that met study criteria, 1190 new users of cholinesterase inhibitors were matched to 2247 non-users. The propensity-matched cohorts were well balanced on baseline covariates; mean age was 78 years, 98 % were male, and mean weight at baseline was 175 \pm 35 lb. Of patients who started cholinesterase inhibitors, 58 % were prescribed donepezil, 41 % rivastigmine, and 1 % galantamine. Overall, 78 % of patients started on cholinesterase inhibitors were still taking using the drug at 12 months. Patients initiated on cholinesterase inhibitors had a higher risk of weight loss compared to non-users over 12 months (HR 1.29, 95 % CI 1.12 - 1.49). At 12 months, 31 % of patients on cholinesterase inhibitors had experienced \geq 10 lb weight loss compared 25 % of non-users (number needed to harm=18 over 1 year). The number of weight measures in the follow-up period was similar between the two groups ($p=0.99$). In secondary analyses of mean weight change, there was a mean weight loss of 1.9 lb/year in patients on cholinesterase inhibitors, compared to a mean weight loss of 1.6 lb/year in non-users ($p=0.002$). To see if there were clinically important subgroups in which cholinesterase inhibitors were associated with greater risk of weight loss, we analyzed data stratified by age, comorbid burden, and initial weight. There were no significant differences in the impact of cholinesterase inhibitor use on weight loss across age groups, levels of comorbid burden, or levels of baseline weight.

CONCLUSIONS: Patients with dementia started on cholinesterase inhibitors had a substantially higher risk of clinically significant weight loss over a 12 month period compared to matched controls, with a number needed to harm of 18 over 1 year. Clinicians should consider the risk of weight loss when deciding whether to prescribe cholinesterase inhibitors in patients with dementia, and consider these medications as possible culprits if substantial weight loss occurs.

WHAT ARE CANCER CENTERS ADVERTISING TO THE PUBLIC? A CONTENT ANALYSIS OF PRINT AND BROADCAST MEDIA Laura B. Vater¹; Julie M. Donohue³; Robert M. Arnold²; Douglas B. White⁴; Edward Chu⁵; Yael Schenker². ¹University of Pittsburgh Graduate School of Public Health, Pittsburgh, PA; ²University of Pittsburgh, Pittsburgh, PA; ³University of Pittsburgh Graduate School of Public Health, Pittsburgh, PA; ⁴University of Pittsburgh, Pittsburgh, PA; ⁵University of Pittsburgh, Pittsburgh, PA. (*Tracking ID #1924475*)

BACKGROUND: Critics have expressed concerns that advertising by cancer centers exaggerates the benefits of cancer treatment and drives inappropriate demand for clinical services. To date, there has been no empirical examination of the content of cancer center advertisements. We aimed to characterize the informational and emotional content of advertisements placed by these centers.

METHODS: We conducted a systematic content analysis of all cancer center advertisements for clinical services placed in top consumer magazine ($N=269$) and television networks ($N=44$) in 2012. Using previously defined criteria for classifying health care advertisements, our multidisciplinary team developed a codebook with four domains: (1) types of clinical services promoted; (2) description of risks, benefits, indications, alternatives, and costs of advertised services; (3) use of emotional advertising appeals; and (4) use of patient testimonials and disclaimers. Two coders independently assessed all advertisements using ATLAS.ti. Kappa values for our main findings ranged from 0.77 to 1.0, indicating excellent inter-rater reliability.

RESULTS: One-hundred and two cancer centers placed 409 advertisements for clinical services in top media markets in 2012. The majority (61/102) of these centers were for-profit; 16 % (16/102) were National Cancer Institute-designated cancer centers. Eighty-five percent (87/102) of cancer centers placed clinical advertisements on television, 27 % (28/102) placed clinical advertisements in magazines, and 13 % (13/102) advertised in both media markets. The average number of unique clinical advertisements per institution was 3 (range 1–18) for magazines and 4 (range 1–45) for television. Advertisements most commonly promoted cancer treatments (359/409), often described using vague terms (e.g. “we offer you our most aggressive treatment plan”). Benefits of advertised therapies were discussed more often than risks (27 % (109/409) vs. 2 % (7/409)) but rarely quantified (2 %; 8/409). Over half (235/409) of advertisements indicated the type of cancer targeted, 9 % (38/409) indicated the stage, and 2 % (7/409) mentioned an alternative to an advertised therapy. Costs or insurance coverage were rarely mentioned (5 %; 21/409). Eighty-five percent (347/409) of advertisements included emotional appeals, most frequently evoking hope for survival (61 %; 248/409), describing cancer treatment as a fight or battle (41 %; 167/409), and evoking fear (30 %; 123/409). Medical miracles were described in 6 % (24/409) of advertisements. Nearly half (181/409) of advertisements included patient testimonials, usually focused on survival or cure (79 %; 143/181). Testimonials rarely included disclaimers (15 %; 27/181) and never described the results a typical patient might expect.

CONCLUSIONS: Advertising by cancer centers frequently promotes cancer therapy using emotional appeals that evoke hope and fear while providing scant information about risks, benefits, or costs. Further work is needed to understand how cancer center advertisements influence patient understanding and expectations of benefit from cancer treatments.

WHAT ARE INTERNS REALLY DOING POST-CALL? AN OBSERVATIONAL STUDY OF POST-CALL INTERN ACTIVITIES Luci Leykum¹; Albert Lee²; Kathryn E. Fletcher³; Carla Pezzia²; Holly Lanhant²; Jacqueline Pugh¹. ¹STVHCS / UTHSCSA, San Antonio, TX; ²UT Health Science Center at San Antonio, San Antonio, TX; ³Medical College of Wisconsin / Milwaukee VAMC, Milwaukee, WI. (Tracking ID #1935961)

BACKGROUND: While an increasing literature describes resident work activities in the hospital, no data focus on the post-call day. On this day, residents are responsible for managing diagnostic and treatment plans for a large group of new patients, making it one of their busiest periods. Understanding post-call activities may provide insights into potential patient safety concerns, or strategies for improving care and intern efficiency.

METHODS: We observed 18 interns on 11 different inpatient medicine teams for one to two hour-long periods after attending rounds on their post-call day, for a total of 29 h. We focused on interns as the “front line” of the medicine team. Observations occurred at the 2 primary teaching hospitals of the UT Health Science Center at San Antonio. We wrote field notes to describe all interactions and activities, timing the duration of each. We then described their activities and categorized their interactions.

RESULTS: Interns were seated in the team room at their computers the majority of the time. They spent almost 50 % of their time in documentation in the electronic health record (EHR) (27.6 min, range 2.8 to 51.4 min). They spent an average of only 3 min, or 5 % percent of time, outside of the team room (range 0–22 %). Interns had on average 26.2 interactions during the hour of observation (range 8–46). The number of interactions was not directly correlated with the number of patients being cared for ($r=.3$). The average duration of each interaction was 71.3 s (range 34.2 to 260.5 s). The majority of these interactions were verbal (81.6 %, range 62.5–100 %). The remainder were electronic, typically orders to nursing or pharmacy. Most communication occurred within the interns’ teams (64.6 %). The groups outside of the team with whom they most frequently interacted were ancillary staff, including ward or diagnostic service clerks (41.6 %), physicians outside of the team (25.4 %), and nurses (19.7 %). Verbal interactions with these groups were usually by telephone instead of face-to-face. We observed

interns interacting with patients in 37.9 % of observation periods. In comparison with interactions with other groups, only 13.4 % of outside-team interactions were with patients, but these interactions were much longer, averaging 10.0 mins in duration (2.3–25 mins). Interns initiated interactions 69.1 % of time (range 54.2–89.4 %). The remainder of interactions, on average 7.9 per hour, were initiated by others, most frequently by the resident.

CONCLUSIONS: Interns spent most of their time in their team rooms, documenting in the EHR, and managing a great number of interactions. Most interactions took place within their team. Interactions outside of their teams were by typically by telephone or through the EHR, and were brief. They rarely interacted with patients, though when they did they spent more time. Others initiated interactions almost 8 times an hour, interrupting interns’ work, and raising concern for potential errors. Given that the post-call day is often considered a time of rapid clinical evolution for newly admitted patients, it is surprising that interns spent little time at the bedside. It is also notable that most of the interactions interns had outside of the team were with clerks and other ancillary staff, rather than with nursing or other specialties. Our findings suggest that interns are primarily accomplishing work tasks during the post-call period.

WHAT ARE WE TELLING OUR STUDENTS? A NATIONAL SURVEY OF CLERKSHIP DIRECTORS’ ADVICE FOR STUDENTS APPLYING FOR INTERNAL MEDICINE RESIDENCY Katherine C. Chretien^{1,2}; Laura R. Willett³; Meenakshi K. Aiyer⁴; Diane L. Levine⁵; Alwin Steinmann⁶; Michael Elnicki⁷. ¹Washington DC VAMC, Washington, DC; ²George Washington University, Washington, DC; ³Robert Wood Johnson Medical School, New Brunswick, NJ; ⁴University of Illinois College of Medicine at Peoria, Peoria, IL; ⁵Wayne State University, Detroit, MI; ⁶Exempla Saint Joseph Hospital, Denver, CO; ⁷University of Pittsburgh School of Medicine, Pittsburgh, PA. (Tracking ID #1936487)

BACKGROUND: Little is known about the advice fourth year medical students planning to apply to categorical internal medicine residencies receive from their faculty advisors regarding their fourth year schedules. The objective of this study was to determine how advisors believe students should structure their fourth year in preparation for an internal medicine residency and how this may differ based on faculty’s experience with advising.

METHODS: In June 2013, Clerkship Directors in Internal Medicine conducted its annual, online, confidential, national survey of its 124 member third-year internal medicine clerkship directors (CDs). One survey section dealt with student advising. Clerkship directors (CDs) were asked whether they advised fourth year students applying for categorical internal medicine residencies, and if so, how likely they would recommend certain courses during the fourth year. Analysis included descriptive statistics and Wilcoxon rank sum tests to examine associations between recommendations and length of time advising as well as number of students advised per year. In a free text question, CDs were asked why they might advise students to take an “away rotation.” Responses were analyzed using an inductive, iterative process involving two independent coders and periodic discussions for consensus. Discrepancies were resolved through discussion or by involving a third author. The Institutional Review Board at Case Western Reserve University determined that the protocol did not fit the definition of human subjects’ research per 45 CFR 46.102.

RESULTS: Seventy-six percent (94/123) responded. Of these, the majority advised fourth year medical students (83/94; 88 %). CDs had advised for a mean of 12.2 years (range 1–45; SD 8.58); 45.3 % advised an average of >20 students a year. CDs most encouraged students to take a medicine sub-internship (Likert scale mean 4.84, SD 0.61, with 1 = strongly discourage and 5 = strongly encourage), critical care (4.38; SD 0.79); medicine specialty clinical rotation (4.01; SD 0.80); and emergency medicine (3.75; SD 0.97). They were least likely to encourage a research rotation (2.92; SD 0.80), a non-clinical rotation (2.54; SD 0.81), and a non-medicine sub-internship (2.44; SD 0.96). An intern preparatory course was encouraged or strongly encouraged by 40.3 % of CDs, required by 11.3 % of schools and not offered at 12.5 % of schools. There was no difference in fourth year course recommendations between CDs who advised fewer versus more students, or for CDs who had advised for shorter versus longer amounts of time. For students who were interested in subspecialty fellowship training, CDs tended to encourage (Likert scale mean 3.39; SD 0.78) students to take a rotation in that subspecialty, with those CDs advising more students (>20), less likely to recommend this ($p=0.01$). CDs believed students should spend a mean of 6.6 months doing clinical rotations during their fourth year (range 1–10; SD

1.91). In response to the free-text question asking why CDs might advise medical students to take an “away” rotation, 75 respondents generated 127 evaluable comments. The comments fell into 3 major themes: broadening the student’s educational experience (32 % of responders); allowing a student to become more knowledgeable about a particular program or city (56 % of responders); or attending a program of interest with the expressed or implied possibility that it might improve the student’s chances of matching at that program (69 % of responders). Some CDs responded to the question by stating that they did not recommend away rotations.

CONCLUSIONS: Internal medicine clerkship directors who advise fourth year students applying to internal medicine residencies encourage certain courses during the fourth year and believe the majority of the fourth year should be spent doing clinical work. These recommendations can help inform students planning internal medicine careers, other faculty advisors, educational administrators, and internal medicine program directors.

WHAT BRINGS YOU IN? THE CAUSE OF HOSPITALIZATIONS AMONG YOUNG ADULTS Anna Volerman¹; Sonal Parasmampuria²; Valerie G. Press¹; David Meltzer¹. ¹University of Chicago Medicine, Chicago, IL; ²Columbia University, New York City, NY. (*Tracking ID #1934624*)

BACKGROUND: Although generally considered a healthy population, young adults age 16 to 30 years old account for more than one million hospitalizations in the United States every year. Among young adults, there is an increasing sub-population afflicted with chronic diseases that put them at high risk for hospitalization and at times repeated hospitalizations. In order to better understand the high utilizers among young adults, we undertook a secondary data analysis. Our objective was to identify the most common causes for hospitalization among young adults and to determine what diagnoses were associated with frequent hospital admission in this population. **METHODS:** We performed a cross-sectional analysis of three data sets that provide information on all-payer inpatient care as part of the Healthcare Cost and Utilization Project (HCUP). The 2010 California State Inpatient Database (SID) was used to determine the causes of hospitalization among young adults. We also examined the causes of multiple hospital admissions for the same patient in a given year using the patient identifiers within the SID. To assess the generalizability of our results to the broader young adult population in the United States, we created a national database for this target population by combining data from the 2009 Kids’ Inpatient Database (KID) for ages 16 to 20 and the 2010 Nationwide Inpatient Sample (NIS) for ages 21 to 30. Both of these databases contain de-identified data. We examined the causes of hospitalization among young adults in the United States and compared it to the SID data. Frequencies and percentages were calculated with data stratified by age, gender, race, income quartile and payer.

RESULTS: The 2010 California SID contained 373,640 young adults with a total of 574,780 hospitalizations. The mean age at the time of hospital admission was 23.44 years. The average hospital length of stay was 4.94 days. The most common reason for hospital admission was a diagnosis related to pregnancy, childbirth or postpartum care, regardless of payer. When obstetric-related diagnoses were excluded, 194,893 young adults were included in the data analysis, with an equal percentage of males and females. The majority of young adults in the SID were hospitalized once during the year (82 %); nearly one in five patients was admitted more than one time. When obstetric-related diagnoses were excluded, 30 % (n=59,012) of young adults had more than one hospital admission during the year. The most common diagnoses for young adults with multiple admissions in a year were chronic illnesses, infections and mental disorders. The most common chronic diseases resulting in multiple hospital admissions included: Hereditary Hemolytic Anemia, Diabetes Mellitus, Hypertensive Chronic Kidney Disease, Epilepsy and Recurrent Seizures and Diseases of Pancreas. Among young adults hospitalized with one of these five diseases, 67 % had multiple hospitalizations in a year (ranging from 90 % for Hereditary Hemolytic Anemias and 49 % for Epilepsy). These chronic conditions mirror the list of chronic illnesses leading to hospitalization among young adults in the United States based on the NIS and KID databases.

CONCLUSIONS: Our study demonstrates that a substantial fraction of hospitalization among young adults unrelated to childbirth is due to a set of young adults with chronic disease, mental illness and infections, who are also at

high risk for multiple hospital admissions. Thus, the successful management of chronic diseases is a key target in efforts to decrease inpatient utilization among young adults. New models of care are necessary for young adults with chronic disease to successfully engage them in their disease during a time of rapid social, emotional and physical change. Evaluating the effect of such interventions on current and future health care utilization and outcomes for young adults should be considered an important research priority.

WHAT DO PATIENTS WANT? A SERIES OF QUALITATIVE INTERVIEWS WITH READMITTED PATIENTS Theodore Long^{1,2}; Sheila Antony^{1,2}; Alexander Pine^{1,2}; Amish Desai^{1,2}; Alexandra Norcott^{1,2}; Cali Luco^{1,2}; Emily M. Meyer^{1,2}; Rebecca Brienza^{1,2}. ¹VA Connecticut Healthcare System, West Haven, CT; ²Yale University School of Medicine, New Haven, CT. (*Tracking ID #1938293*)

BACKGROUND: With an increasing emphasis on patient-centered outcomes, there is a need to understand what aspects of care are most prioritized by patients. While studies in primary care have demonstrated that patient-centered practice is associated with decreased healthcare utilization, and more recently that patient-centered care may reduce cardiovascular mortality, the adoption of such practices is inconsistent. This study sought to determine the elements of patient-centered care that are valued by Veterans who have high levels of interaction with the hospital system, as demonstrated through recent hospital readmissions.

METHODS: As part of an ongoing study, a total of n=4 semi-structured interviews were conducted with Veterans at the West Haven Veterans Affairs Medical Center (WHVA) who were on a current 30 day readmission. The interview guide was informed by pilot interviews and studies in the area of patient-centered care. Researchers conducted in-depth interviews (approximately 45 min to 1 h per encounter) with patients regarding their healthcare priorities; confidentiality was maintained per VA protocol using patient identification reference numbers stored by study investigators. ATLAS.ti was used to facilitate coding, theme generation, and quote management. Specifically, interview transcripts were topic-analyzed by an interdisciplinary team who developed codes both iteratively and inductively, capturing insights from participating Veteran patients. Tenets of Grounded Theory were used to guide analysis and organize final code structures and predominant themes.

RESULTS: Four major patient care priority themes emerged during this exploratory analysis: (1) the importance of setting the agenda for primary care visits, (2) the necessity of being listened to by clinicians, (3) the desire to feel independent and manage one’s own care at home, and (4) the ability to manage medical problems with outpatient clinicians to avoid admission. Patients stated that they valued their independence and wanted to seek out medical care on their own terms by setting the visit agenda. They were appreciative of the coordination of care in the outpatient setting and wanted further follow up, with the commonly stated goal of remaining at home and avoiding admission.

CONCLUSIONS: Veterans with increased hospital utilization value setting the agenda for their health care, especially in primary care, and prioritizing their independence by self-managing their conditions at home. These Veterans concluded that being listened to was one of the most important aspects of patient care, and consistently stated that they valued outpatient care and prioritized avoidance of hospital admission.

WHAT HAPPENS WHEN AFRICAN ANCESTRY PATIENTS LEARN THEY HAVE A GENETICALLY INCREASED RISK FOR A CHRONIC DISEASE? WHAT DO THEIR DOCTORS THINK? Carol Horowitz¹; Kadija Ferryman^{2,1}; Rennie Negron¹; Mayra Rodriguez¹; Erwin Bottinger¹; Saskia Sanderson¹; Randi Zinberg¹. ¹Mount Sinai School of Medicine, New York, NY; ²New School, New York City, NY. (*Tracking ID #1939516*)

BACKGROUND: Few genetic markers are reliably associated with chronic disease risk and thus few non-theoretical studies have examined how patients and doctors view such risk testing. A recently-discovered variant in the APOL1-gene is associated with a five-fold risk of end-stage renal disease (ESRD) among hypertensives. This variant, which originated in Africa to protect against trypanosomiasis, occurs in 15 % of persons with self-reported African Ancestry (black/African American) vs. <1 % of Whites. We conducted in-depth

interviews to explore patients' views on genetic testing and their reactions to receiving APOL1 genetic test results and risk information. We also interviewed primary care physicians to assess their attitudes about using genomic risk information to assess ESRD risk and communicating this risk as part of clinical care for their Black patients.

METHODS: Eligible patients have participated in a bio-repository, self-identify as Black or African American and have hypertension, but no diabetes or kidney disease. After informed consent, patients were tested for the APOL1 gene variation and then met with a genetic counselor who returned their results. We conducted in-depth interviews at baseline (pre-testing), and immediately and 30 days after they received genetic risk results. We also used purposive sampling to identify and interview primary care providers from a large teaching hospital and a network of health centers. All interviews were audiotaped, transcribed, and our team coded transcripts and developed themes using ATLAS.ti and grounded theory.

RESULTS: We recruited 26 Black adult patients with a mean age of 56 years, 73 % had the high risk APOL1 gene risk variation, 73 % were female, 69 % had a yearly income <\$30,000 and 27 % had < high school education. We also recruited 15 physicians with a mean age of 39 years; 60 % female, 13 % Black; 50 % in practice >5 years. At baseline, patients had low knowledge of genomics and of kidney disease and their risk for it, but most perceived an inherent benefit to knowing their genetic risk status. After return of results, patients with high-risk alleles felt the information they received was useful, empowering, made them more aware of their health risks, motivated them to better control their hypertension and general health, and planned to share the results with their providers. Patients without increased genetic risk were relieved and most stated they were more conscious of the importance of blood pressure control. Patients reported that the connection between their race and genetic risk was enlightening, made sense, could explain disparities in a way that did not blame patients, were aware other ethnic groups also had unique genetic risks, and they showed little concern about abuse of this information. Physicians felt poorly prepared to test or discuss genetic test results with patients, reported no genetics education since medical school, but were interested in learning to use it as part of patient care, if evidence-based guidelines show such tests can improve patient outcomes. They wanted time-efficient ways to be trained and to share information with patients, including electronic clinical-decision and patient support materials. Some physicians were concerned about using genetic testing for an allele that is associated with African Ancestry.

CONCLUSIONS: Hypertensive patients with African Ancestry had a generally positive reaction to receiving chronic disease genetic risk information, and doctors were interested in, but unsure of how to provide them with this information. Future research should explore whether diverse patients and their providers can use such information to improve healthcare, behaviors and outcomes.

WHEN LESS IS MORE: RESULTS OF A RANDOMIZED CONTROLLED TRIAL ON ASSISTING AND ARRANGING SOCIAL NETWORKS FOR WALKING IN SEDENTARY ADULTS Liza Rovniak¹; Jennifer Kraschnewski²; Christopher Sciamanna²; Ding Ding³; Melissa Bopp⁴; Daniel George⁵; James Sallis⁶; Melbourne F. Hovell⁷. ¹Penn State College of Medicine, Hershey, PA; ²Penn State-Hershey Medical Center, Hershey, PA; ³University of Sydney, Sydney, NSW, Australia; ⁴Pennsylvania State University, State College, PA; ⁵Pennsylvania State University, Hershey, PA; ⁶University of California, San Diego, San Diego, CA; ⁷San Diego State University, San Diego, CA. (Tracking ID #1938319)

BACKGROUND: Epidemiological research suggests that social networks are critical for adopting and sustaining regular physical activity (PA). However, little is known about how best to "engineer" online or in-person social networks to increase PA among sedentary adults. The 5A Model of Behavior Change predicts that "arranging" social networks for PA would be more effective than simply "assisting" participants to build social networks for PA. However, no study to our knowledge has tested this hypothesis.

METHODS: We randomly assigned 308 sedentary adults to three groups: (1) Arranging Networks: weekly feedback on online and in-person social network interactions for walking, and access to an online social networking site for PA, plus 12-week evidence-based walking program and weekly social networking tips for PA; (2) Assisting Networks—High Dose: 12-week evidence-based walking program and weekly social networking tips only; (3) Assisting Networks—Low Dose: weekly

social networking tips only. Ongoing process evaluations were conducted to ensure treatment fidelity. In-person assessments were conducted at baseline, post-program, and 6-month follow-up. Differences between groups were analyzed using ANCOVA, adjusted for demographics and baseline scores.

RESULTS: At baseline, participants were 61.6 % female, 83.4 % overweight/obese, and 8.1 % non-White, with a mean age of 50.3 years; 87 % and 83 %, respectively, completed the post-program and 6-month assessments. The Assisting Networks-Low Dose group demonstrated a greater increase in accelerometer-measured light/lifestyle PA from baseline to 6-months (14.1 mins/day), relative to the Assisting Networks-High Dose (~9.2 mins/day) and Arranging Networks (~3.0 mins/day) groups ($p < .05$). There were no significant between-group differences at post-program or 6-months in accelerometer-measured moderate/vigorous PA or in objectively-measured aerobic fitness, body mass index (BMI), and waist circumference. Within-group analyses indicated that all groups either maintained, or significantly improved, their accelerometer-measured moderate/vigorous PA, BMI, and waist circumference from baseline to 6-months. Qualitative analyses indicated that many of the study's middle-aged participants lacked interest in visiting online social networking sites for PA. Many participants reported that it was easier to walk alone than to schedule walks with others.

CONCLUSIONS: Unexpectedly, "assisting" sedentary adults to build social networks for PA with weekly tips yielded slightly better objectively-measured outcomes than "arranging" social networks with online networking sites and weekly follow-up. These findings suggest that more needs to be learned about the best strategies for engineering social networks for PA. Future research should explore if study findings replicate among more diverse populations, and how to further improve outcomes. The low-dose, cost-effective intervention to "assist" social networks for PA could easily be replicated and disseminated as part of automated physician-delivered PA interventions.

WHERE DO CURRENT COMPUTERIZED PHYSICIAN ORDER ENTRIES (CPOES) STAND IN AVERTING/FACILITATING MEDICATION ERRORS IN THE UNITED STATES AND CANADA? Tewodros Eguale^{1,2}; Mary Amato^{4,1}; Sarah P. Slight³; Andrew C. Seger¹; Diana L. Whitney⁵; David W. Bates^{1,2}; Gordon D. Schiff^{1,2}. ¹Brigham and Women's Hospital, Boston, MA; ²Harvard Medical School, Boston, MA; ³The University of Durham, Durham, United Kingdom; ⁴Massachusetts College of Pharmacy and Health Sciences, Boston, MA; ⁵Baylor College of Medicine, Houston, TX. (Tracking ID #1938527)

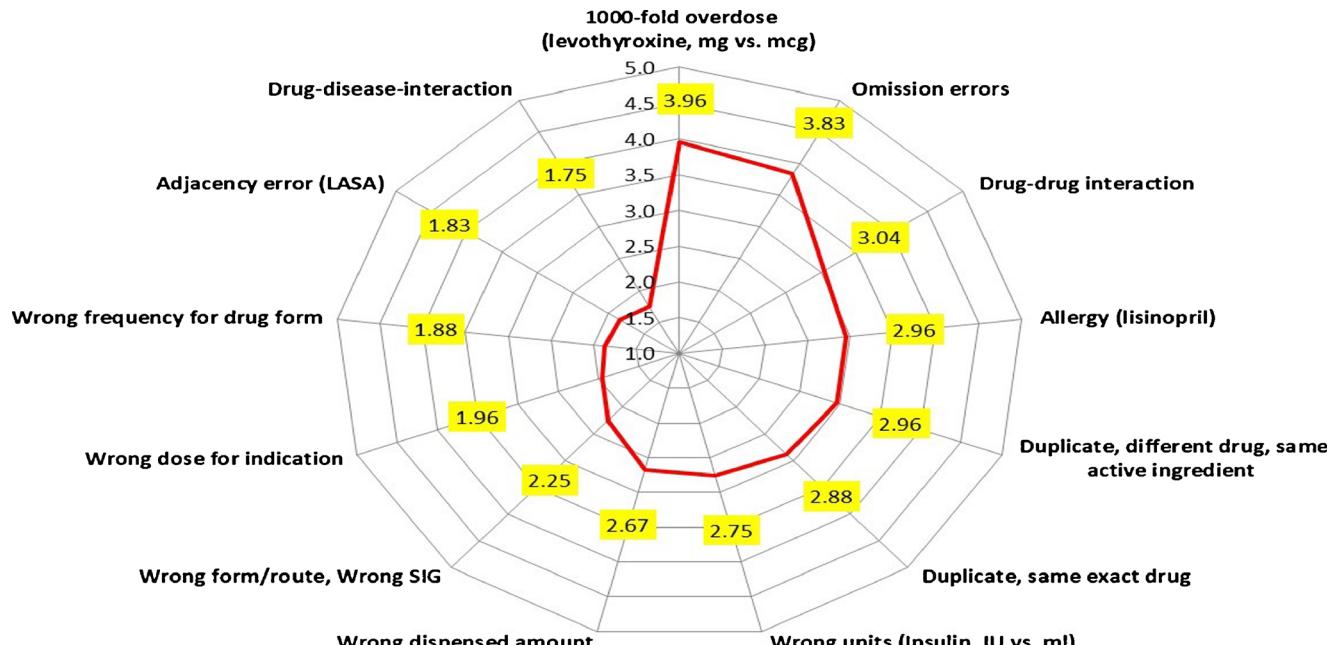

BACKGROUND: Computerized Prescriber Order Entry (CPOE) has long been considered and demonstrated to be a high-leverage tool for preventing medication errors and incentives' are being provided to accelerate its adoption. However, there is a growing awareness and increasing documentation of concerns that CPOE can also introduce or facilitate new errors. Recently, an in depth analysis of USP MEDMARX medication error reporting database resulted in the creation of 'test cases' to evaluate the vulnerability of CPOEs in facilitating or averting medication errors in inpatient and outpatient settings. The outpatient test cases include allergy, drug-drug interaction, disease-drug interaction, omission errors, too high doses, duplicate drugs, wrong units, wrong dispensed amount, adjacency errors, and wrong dose for indication. The objective of the study was to evaluate the extent to which leading CPOEs systems in US and Canada handle erroneous outpatient test case scenarios.

METHODS: Sixteen (11 US and 5 Canada) CPOE systems were selected for evaluation and typical users were recruited to enter the erroneous orders on test patients. Outcome was measured using a Likert scale ranging from 1 to 5, where 1 represent 'easy' to enter the erroneous order and scales 2-4 represent increasing degree of difficulty and 5 represents 'impossible' to enter the erroneous order. To compare the test cases, mean scores and proportions were calculated and radar plot was used to facilitate comparison of test cases.

RESULTS: Scores for US and Canada were combined since there is no statistically significant difference between the CPOEs tested in the two countries. The figure shows the mean scores for the 13 test cases. The tested CPOEs performed worst in averting drug-disease interaction error (pioglitazone was accepted for congestive heart failure patients). The CPOEs performed poorly in detection of look-alike-sound-alike errors (penicillamine vs. penicillin), wrong frequency for the drug form error (Cardizem CD 120 mg PO QID), and wrong dose for the indication error (Methotrexate 15 mg PO daily for rheumatoid arthritis). The CPOEs performed

better in averting too high doses, drug-drug interactions, and omission of strength of a drug and in allergy situations. Overall, 52.8 % of the erroneous orders passed through easily or with minor workaround and in 19.2 %, it was not possible to complete these orders. Moreover, only 29.2 % of the orders generated warnings.

CONCLUSIONS: Current CPOEs are generally vulnerable in facilitating potential medication errors. Developers and users need to be aware of this potential for error, and should build strategies to protect patients by improving the safety of CPOE systems.

Radar plot showing mean score for each test scenario across all tested CPOEs in difficulty of entering erroneous orders. The red line ideally should occupy the most outer grid (score 5), i.e. impossible to enter any erroneous orders.

WHO ARE YOU GONNA CALL? A STUDY OF HOW RESIDENTS MANAGE UNCERTAINTY WHEN CARING FOR CLINIC PATIENTS ¹Audrey L. Tanksley¹; Julie Oyler¹; Shana Ratner²; Laura Ruth Venable¹; Vineet Arora¹. ¹University of Chicago, Chicago, IL; ²University of North Carolina, Chapel Hill, NC. (Tracking ID #1938642)

BACKGROUND: One third of Internal Medicine training occurs in the ambulatory setting, yet evidence suggests we are not adequately preparing trainees for outpatient practice. With the changing healthcare system there is a growing need for assessment of outpatient education, and a substantial interest in improving the quality of this training. While the literature to date has highlighted effective strategies for attending supervision in the inpatient setting, few have evaluated the ambulatory setting. The aim of this study is to describe resident satisfaction with clinic supervision and management of uncertainty with clinic issues.

METHODS: From 2010 to 2013, Internal Medicine residents at an academic center completed an end-of-year survey on satisfaction with supervision during their continuity clinic experience and how they dealt with uncertain clinical situations. Trainees were asked to rate overall satisfaction with availability, continuity, amount of supervision during and outside of clinic for the faculty preceptor. They were also asked to select the strategies they use to manage uncertainty when faced with a clinical issue for their patients outside of clinic hours. They were asked to report on a 5-point likert scale how frequently they contacted the attending, asked a resident they knew, read about the topic, asked the on service resident, waited until next visit, asked chief resident or other. Trainees were divided by postgraduate year into two groups consisting of interns and upper level residents. T-tests were used to evaluate associations between postgraduate year and frequency of strategy for management of uncertainty.

RESULTS: From 2010 to 2013 categorical and med-peds residents were required to complete an end of year survey, response rate was 90 % ($n=343$). While 78 % of residents were satisfied with availability of their clinic preceptor outside clinic, only half (56 %) were satisfied with continuity of clinic preceptor. In addition, while 90 % were satisfied with amount of supervision during clinic, only 63 % were satisfied with amount of supervision outside clinic. When trainees were asked how they managed uncertainty for clinic issues outside of clinic, 84 % reported reading about the topic, 42 % asked a resident they know, 26 % asked the on service resident, 22 % contacted the preceptor, 14 % waited until the next visit to address the clinical issue. When comparing upper residents to interns, residents were more likely to report contacting the faculty preceptor (PGY1 mean=2.48, PGY2+ mean=2.81 $p=0.018$) while interns were more likely to ask the on-service resident (PGY1 mean=3.36, PGY2+ mean=2.45 $p=0.0001$). Residents commented, “The preceptors are all fantastic—more continuity would probably be helpful.”

CONCLUSIONS: When residents are faced with a clinic patient issue outside of clinic hours for which they are uncertain, they utilize the “hierarchy of assistance” by consulting the literature and asking colleagues before contacting the attending. Interestingly, upper level residents reported contacting the faculty preceptor for uncertainty more than interns, and interns contacting on-service residents more frequently than upper level residents. This could reflect in part a reluctance of interns to contact the attending or a greater familiarity and comfort with advanced residents for contacting the attending. Regardless, previous studies have described the implication of this step up approach in the inpatient setting and how it can lead to delay of care and patient harm. Further studies are needed to define when clinic attending supervision is warranted, and the most effective ways to improve continuity of the preceptor.

WHO IS PERFORMING INVASIVE BEDSIDE PROCEDURES AT AN ACADEMIC MEDICAL CENTER, AND WHY? Cynthia Kay¹; Jeffrey L. Jackson²; Dai Takahashi¹. ¹Medical College of Wisconsin, Milwaukee, WI; ²Clement J. Zablocki Veterans Affairs Medical Center, Milwaukee, WI. (*Tracking ID #1923968*)

BACKGROUND: The performance of most procedures are no longer required as part of medicine residency training. However, residents and internists practicing in hospitals often care for patients requiring certain procedures. Our mixed-method study's aims were to assess the procedure practice patterns at an academic medical center, explore patient characteristics that may affect service performing these procedures, and assess factors influencing residents' decision making regarding procedures.

METHODS: The yearlong study began February 2013 at the Medical College of Wisconsin. We prospectively collected data on adults admitted to resident or hospitalist services who underwent thoracentesis, paracentesis, or lumbar puncture. Data included procedural characteristics (procedure; service performing the procedure; primary team), patient characteristics (age; gender; comorbidities; BMI; anticoagulation use; INR; antibiotic use; delirium) and admission characteristics (day of week; time of admission). Two approaches were used to explore residents' decision making. We conducted resident focus groups and also invited residents to complete a survey each time their patient had a listed procedure. The Likert-scaled survey assessed six potentially important factors: time, patient comorbidities, supervision, attending's comfort, personal experience, and comfort with the procedure. The study was approved by our institution's IRB. All residents provided informed consent.

RESULTS: Over a 9-month period, 307 procedures were performed, with 213 on the resident teams and 94 on the hospitalist service. Thoracentesis was most common (44 %), followed by paracentesis (41 %), and lumbar punctures (15 %). Most procedures ($n=253$, 72 %) were referred, either to radiology ($n=179$, 58 %) or to the Hospital Procedure Service ($n=74$, 24 %). Only 54 (18 %) were done by residents. Hospitalists performed few procedures (3 %), significantly less (3 %, $p<0.0005$) than residents. There was no difference in likelihood of referral by type of procedure ($p=0.43$), day of week, time of admission or other patient characteristics. Focus groups identified six themes that contributed to the likelihood of referral: time, attending's comfort, supervision, resident's comfort, patient comorbidities, and experience. Among survey respondents ($n=81$), 52 % were interns and 48 % residents; the response rate was low (27 %). Factors cited as important in the decision to refer included lack of training (RR: 6.3, 95 % CI: 2.1–19.3), level of resident comfort (RR: 3.8, 95 % CI: 1.9–7.6), available supervision (RR: 2.4, 95 % CI: 1.2–4.9) and attending's comfort (RR: 1.9, 95 % CI: 1.1–3.4). Unimportant factors included lack of time (RR: 1.4, 95 % CI: 0.8–2.9) and patient comorbidities (RR: 0.8, 95 % CI: 0.4–1.6). On multivariable modeling, independent predictors of referral included lack of training (RR: 6.9, 95 % CI: 1.7–28.3) and resident's lack of comfort (RR: 4.3, 95 % CI: 1.4–13.6).

CONCLUSIONS: Most procedures are referred. While focus groups identified time, supervision, comfort with procedure, and comorbidities as important factors in the decision to refer, the resident survey found that time and patient-specific characteristics (such as age and comorbidities) were not important. Factors cited for referral included lack of training, supervision and comfort with the procedure (both for resident and attending). If a goal is to prepare residents to perform procedures when needed, then better training or supervision may be required. Further research is necessary to determine if and how these procedural practice patterns affect residents, patients, and health care.

WHY AREN'T MORE PRIMARY CARE RESIDENTS GOING INTO PRIMARY CARE? STUDYING PROGRAM FACTORS THROUGH QUALITATIVE INTERVIEWS WITH PRIMARY CARE RESIDENTS Theodore Long¹; Olatunde Bosu²; Krisda H. Chaiyachati¹; Bradley G. Richards¹; Nicole Krenitsky²; Leslie Curry³; John P. Moriarty¹; Stephen J. Huot¹. ¹Yale School of Medicine, New Haven, CT; ²Yale School of Medicine, New Haven, CT; ³Yale School of Public Health, New Haven, CT. (*Tracking ID #1936518*)

BACKGROUND: Nearly two-thirds of primary care internal medicine residents report that they do not plan to have a career in primary care or general internal medicine. As we face a potential shortage of up to 44,000 adult care generalists by the year 2025, it is crucial to understand why residents who demonstrate interest in primary care by virtue of entering into primary care residency programs are choosing to not enter the primary care workforce. Others have examined resident satisfaction, indebtedness, and specialty consideration among residents, but it remains largely

unknown how these factors contribute and whether other factors that have not been explored are also contributing to the decision to pursue another specialty. We seek to understand programmatic factors that may influence career choices among primary care residents using qualitative interviews.

METHODS: One interviewer completed in-depth 1 h interviews with second and third year residents in the Yale Internal Medicine Primary Care Program using an instrument developed from pilot interviews and existing literature. Two members of the research team independently coded the transcripts and then met to go over coding and resolve differences. The code structure was developed in stages based on grounded theory, using a systematic and inductive approach to generate insights from the comments of the study participants. Using the constant comparative method, the research team then identified emerging themes and refined codes. ATLAS was used for coding, audit trails, and pulling quotes.

RESULTS: To date eight interviews have been completed. Analysis revealed six themes of program-related experiences emerging from the coding. We characterized three of these themes as having potentially negative impact and three as having potentially positive impact on trainee decision to pursue a career in primary care. The themes related to potential negative impact were: mismatch between trainee expectations and actual experience with the practice of primary care; challenges with disjointed care including interruption of continuity by inpatient rotations; and inadequate communication between practice teams and subspecialists. Residents commonly entered training with the ideal of caring for the underserved, but were challenged by limited resources to meet the full range of needs of this population. Themes related to potential positive impact on trainee decision to pursue a career in primary care were: culture of like-mindedness amongst colleagues including comfort with change; positive reflections on outpatient curriculum; and appreciation of exposure to various models of primary care.

CONCLUSIONS: Our results suggest that residents enrolled in primary care programs identify experiences in training that may negatively or positively impact their decision to enter into a career in primary care. Addressing those aspects of training that potentially negatively impact this decision (continuity, adequate resources to address the spectrum of needs of an underserved population, communication with specialists) and strengthening those aspects of training that may positively impact this decision (creating a culture that supports and encourages primary care, having a robust ambulatory curriculum, and providing exposure to a range of primary care delivery models) may increase the proportion of residents enrolled in primary care training programs who pursue a career in primary care. Recognizing the limitations of a single program study, we are broadening these initial findings by undertaking interviews with trainees enrolled in two other differently structured primary care residency programs.

WILLINGNESS TO PARTICIPATE IN CANCER CLINICAL TRIALS AMONG PROSTATE CANCER PATIENTS: THE RELATIONSHIP WITH RACE/ETHNICITY AND HEALTH LITERACY Celia P. Kaplan^{1,2}; Anna Napolis^{1,2}; Steven Gregorich¹; Tung T. Nguyen^{1,2}; Jennifer Livaudais-Toman¹; Eliseo J. Perez-Stable^{1,2}; Eric J. Small^{1,2}; Mack Roach^{2,3}. ¹University of California San Francisco, San Francisco, CA; ²University of California San Francisco, San Francisco, CA; ³University of California San Francisco, San Francisco, CA. (*Tracking ID #1935608*)

BACKGROUND: Clinical trials provide the foundation for advances in cancer diagnostics and therapeutics and are the major channel for translating treatment-related discoveries in cancer care into clinical practice. To ensure that the benefits and burdens of this research are distributed fairly among all cancer patients and that research findings are generalizable, it is important that minorities participate in clinical trials. However, enrollment of African Americans and Latinos remains lower than that of non-Latino whites. Limited health literacy, more common among minorities than whites, is a key barrier to clinical trial recruitment. We sought to examine the association between race/ethnicity, health literacy and stated willingness to participate in clinical trials among prostate cancer patients.

METHODS: Potential participants consisted of men diagnosed with prostate cancer in 2008 between the ages of 18 and 75, recruited through the California Cancer Registry, living within 60 miles of a site offering access to one or more clinical trials in eight California counties: Alameda, Contra Costa, Marin, Monterey, San Francisco, Santa Clara, Santa Cruz and Los Angeles Counties. Between November 2011 and November 2012, we identified all cases of prostate cancer in African American, Latino and Asian American patients and a random sample of prostate cancer cases in white men. Participants completed a 30-minute telephone interview in English, Spanish or Chinese (Mandarin or Cantonese) to assess their attitudes, knowledge and willingness to participate in prostate cancer clinical trials. Health literacy was assessed with a 3-item previously validated scale that asked about comfort reading

hospital materials, filling out medical forms, and understanding written information (scale scores ranged from 1 to 5, dichotomized as <3.5=low literacy, ≥3.5=medium-high literacy). In multivariable analyses, logistic regression was used to estimate effects of ethnicity and health literacy on willingness to participate. We estimated odds ratios [OR] and 95 % confidence intervals [CI].

RESULTS: A total of 1,869 men were contacted and the final sample included 855 men for a response rate of 46 %. More than half (52 %) were age 65 years or older. The ethnically diverse sample included white (42 %), Latino (24 %), African American (19 %) and Asian American men (15 %). More than 50 % completed college. Nearly 70 % were born in the U.S. The majority of men (98 %) were insured and 81 % had medium to high health literacy (composite score ≥3.5). Only 17 % believed that “clinical trials are beneficial” but 75 % believed that “clinical trials are important”, while only 38 % expressed a willingness to participate in clinical trials. Bivariate and multivariable analysis results are presented in Table 1.

CONCLUSIONS: Among men with prostate cancer, African American and Latino men expressed a greater willingness to participate in prostate cancer clinical trials

	Willing to participate %	OR (95 % CI)	aOR* (95 % CI)
Race/Ethnicity			
Non-Latino white	34 %	Ref	Ref
African American	44 %	1.31 (0.89–1.92)	1.69 (1.01–2.82)°
Asian	30 %	0.85 (0.55–1.32)	0.86 (0.46–1.61)
Latino	55 %	2.21 (1.55–3.14)°	1.75 (1.01–3.05)°

than non-Latino white men. Health literacy was not associated with willingness to participate. Given lower rates of clinical trial participation in these racial/ethnic groups, our findings suggest that factors other than willingness to participate affect actual participation and need to be explored.

Table 1. Bivariate and multivariable analyses: Willingness to participate in prostate cancer clinical trials

*Analysis is also adjusted for age, marital status, education, nationality, employment, health insurance, prior research participation, knowledge of clinical trials, attitudes towards clinical trials, and Gleason score. $p<0.05$

WOMAN CLINICAL SCHOLARS: “SOMETIMES YOU NEED TO CLIMB OUT A WINDOW, AND SCALE THE FIRE LADDER, TO GET TO THE PLACE YOU WANT TO BE.” Adina Kalet¹; Jennifer Rockfeld¹; Nina Bickell²; Kathryn E. Fletcher³; Kate Schwartz¹. ¹NYU School of Medicine, New York, NY; ²Mount Sinai School of Medicine, NY, NY; ³Medical College of Wisconsin, Milwaukee, NY. (Tracking ID #1939410)

BACKGROUND: To effectively build the next generation of academic physicians, we will need to understand factors that enable fellowship-prepared women to thrive in academia. To describe and explore the complexity and challenges of creating work/life satisfaction in academic medicine we studied woman graduates of the Robert Wood Johnson Clinical Scholars Program (CSP, Class of 1976–2011).

METHODS: We surveyed every woman graduate of the CSP graduate up through 2011 ($n=360$) by both email and post. The survey instrument (12 prompts requiring open text responses) was designed to explore current work situation, personal definitions of success and accomplishments, job negotiations, career regrets or disappointments, predominant feelings about work life, and advice for others. All data was de-identified and 4 independent readers coded overlapping subsets of the data. A coding scheme fit to the data was refined through discussion and applied to the data by two analysts using Dedoose™ qualitative analysis software.

RESULTS: After 5 reminders 104/360 (29 %) of the cohort responded, mean age 45 (range 32 to 65), 6 % single, 85 % partnered, and 8 % divorced/separated, 87 % have children (average number of children 2.15, range 1 to 5). Preliminary analysis revealed the following major theme categories: Work, Balance, Mentoring, Home/Family, Managing Change, Flexibility, Negotiation, Collaboration, Definitions of Success, and Advice. Respondents endorsing being very satisfied were more likely to describe work as personally and locally meaningful, having the needed scheduling flexibility to care for family, egalitarian spousal support, mentoring and other supportive relationships at work and home and were conducting collaborative research on teams. Less common themes include: issues of self care or neglect, painful regrets, leaving academia, being childless by choice. Work hours, financial

constraints and availability of mentoring were among the issues, which differed by clinical discipline. Strategies to manage work-life balance were specific to stage of career and age of children. Younger women emphasized both setting boundaries while home and working from home. Senior women described “atypical” paths through and away from academia with career transitions resulting from discordance among work, need for schedule flexibility and institutional values including gender based discrimination, spousal career changes, and/or need for better career-fit. The majority of these women were highly satisfied and passionate about their work, even those early career women uncertain the effort will be worthwhile. Remaining flexible and open to opportunities, mentoring, building teams to do multi-disciplinary collaborative research work, valuing supportive relationships and seeking ongoing meaningful work in later life were significant themes for experienced academic women. Detailed advice about how to survive tough times was shared.

CONCLUSIONS: These CSP graduates are largely satisfied with and passionate about their work and family life and feel, proud and grateful to have pursued meaningful work despite the challenges and uncertain future. Thriving in academic medicine involved remaining flexible and managing change and chaos. Although, currently generalizability is limited we are establishing reliability of coding, conducting subgroup analysis, validating findings through member-checking, and increasing response rates.

WOMEN VETERANS’ EXPERIENCES AND PREFERENCES WITH VA PRIMARY CARE: A QUALITATIVE STUDY Alicia A. Bergman¹; Richard M. Frankel²; Alison B. Hamilton¹; Elizabeth M. Yano¹. ¹Greater Los Angeles VA Healthcare System, North Hills, CA; ²Indiana University School of Medicine, Indianapolis, IN. (Tracking ID #1939722)

BACKGROUND: The growing presence of women Veterans in Veterans Administration (VA) healthcare settings has prompted greater attention to improving women’s health (WH) primary care needs. VA policy now recommends that women patients be seen by primary care providers (PCPs) with specialized WH training/experience, who see them for both primary and gender-specific care in the context of a single visit. However, more information is needed regarding the perceptions and preferences of women Veteran patients themselves. The goal of this qualitative study was to develop a better understanding of the experiences and challenges women Veteran patients face as they navigate VA primary care.

METHODS: Semi-structured interviews were conducted with 30 women Veteran patients at the Indianapolis VA Medical Center. All participants visited a PCP in one of five primary care or community based outpatient clinics within the past year. Permission was obtained from 15 PCPs to invite their patients, and purposive sampling was used for sample diversity.

RESULTS: Qualitative thematic analysis of the interviews revealed four major themes: 1) preference for one-stop-shop approach, 2) improving access, 3) the importance of being proactive, and 4) perceived differences in care. A majority of patients expressed their preference for the comprehensive and integrated one-stop-shop approach to primary care for women Veterans; instead of making separate appointments for women’s health related care (e.g., pap smears, breast exams, contraceptive counseling) in the Women’s Clinic or with a private gynecologist, seeing one WH-PCP for everything offered several perceived benefits for patients, including convenience, familiarity and comfort, not having to repeat information, and receiving consistent approaches to treatment and therapy. Many patients also discussed their desire for better access to VA primary care services, such as quicker access to appointments (including more user-friendly phone and/or computer systems to make appointments), reduced waiting times after arriving to the clinic, and flexibility in accommodating patients’ work schedules. The third theme relates to the sentiment of many women that although there is good primary care in the VA, it is necessary to be proactive and take charge of one’s own healthcare in order to receive it. Being proactive included requesting changes in PCPs when one is dissatisfied, doing front-end research before appointments, writing out lists and presenting them to PCPs, taking the initiative to coordinate same-day appointments, and calling PCPs to give them reminders. Finally, many women Veteran patients cited perceived differences in care as compared to what they believed male veterans received, such as perceptions that male Veterans in general get preferential treatment (“I can read faces and I can read lips—‘Oh shit, another female.’” [pt 4], not feeling recognized as a woman Veteran (e.g., letters addressed to “Mr.”), and not having symptoms taken as seriously).

CONCLUSIONS: Gaining in-depth knowledge about women Veterans’ preferences with VA primary care is an essential step in successfully implementing an integrated and comprehensive care model that improves their care experiences. Important

implications for clinical practice from this study include specific strategies for how PCPs can approach and communicate with women Veteran patients.

WOMEN'S HEALTH INFORMATION IN WOMEN'S MAGAZINES: OFTEN MISINFORMING Akeira Johnson¹; Julie L. Mitchell¹; Kathryn Havens². ¹Medical College of Wisconsin, Milwaukee, WI; ²Clement Zablocki Veterans Hospital, Milwaukee, WI. (*Tracking ID #1939532*)

BACKGROUND: Patients frequently receive health information from non-medical sources. In 1995, Woodford found that health messages were present in 22 % of 11 popular magazines, but little is known about women's health content in lay periodicals, and more importantly, its quality. We sought to evaluate the quantity and accuracy of information available to women in the most popular lay periodicals that are predominantly viewed by a female audience.

METHODS: Using 2012 data from the Pew Research Foundation, we selected the top ten magazines marketed to women with the largest circulation. These magazines reach >7 million persons annually. Two authors independently: 1) reviewed these magazines for text and ads pertinent to women's health, 2) recorded the amount of information in increments of 1/4 of a magazine page, 3) placed items into 1 of 10 categories, and 4) evaluated for untruthful or misleading information defined as claims not supported by scientific evidence and/or overtly false statements. When there was disagreement in the independent reviewer assessment, a re-review resulted in an easy consensus in most cases. The third author was consulted when agreement was not easy.

RESULTS: Results: Overall, 6 % of the magazines' space was devoted to women's health (WH) content. Some of the magazines had more WH information than others, ranging from 2 to 13 %. Most of the information was presented in the form of advertisements: 58 % of all WH content. Gender-specific health topics (items such as osteoporosis, dieting and fibromyalgia) were the most discussed (19 % of all WH content). Pregnancy prevention and bladder function were the second and third most discussed WH topics at 15.0 and 14.0 % respectively. The least covered subjects were menstruation and obstetrics (6 %), followed by breast health (0 %). We found 12 of 89.5 (13 %) items contained misleading information, 50 % of these misleading items were in advertisements and 50 % in magazine text. Examples of misleading items included advertisements promoting supplementation for addressing weight gain in postmenopausal women and topical agents to prevent the development of stretch marks and an article promoting the benefits of human growth hormone on youthful appearance and improved sexual function. Each magazine had at least one misleading item.

CONCLUSIONS: Women are commonly reading magazines that contain women's health information, although the overall fraction of women's health content is small. This information is in both text and ads and 13 % of all items misinform the lay population. In their approach to female patients, healthcare providers need to be cognizant that women's health misinformation is easily available, and perhaps even accessible in their waiting rooms. Approachable demeanor and open-ended questioning should be employed in exploring patient's baseline knowledge in women's health topics, particularly with regards to weight loss and menopausal topics.

WORSENING TRENDS IN THE AMBULATORY MANAGEMENT OF HEADACHE John N. Mafi¹; Samuel T. Edwards²; Nigel Pederson³; Roger B. Davis¹; Ellen P. McCarthy^{1,4}; Bruce E. Landon^{1,5}. ¹Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, MA; ²Veterans Affairs Boston Healthcare System, Boston, MA; ³Beth Israel Deaconess Medical Center and Massachusetts General Hospital, Boston, MA; ⁴Harvard Medical School, Boston, MA; ⁵Harvard Medical School, Boston, MA. (*Tracking ID #1930868*)

BACKGROUND: Headache is a universal complaint and among the most common reasons for visiting a physician. Despite numerous headache practice guidelines published over the past decade, little is known about the extent to which U.S. physicians adhere to recommended therapies or how this has changed over time. In this context, we sought to characterize trends in the management and treatment of headache from 1999 to 2010.

METHODS: Using nationally representative data from the National Ambulatory Medical Care Survey and the National Hospital Ambulatory Medical Care Survey we examined ambulatory visits for headache. Our primary outcomes included use of advanced imaging, referrals to other physicians, and use of opiates/barbiturates (guideline discordant indicators), as well as physician counseling on headache prevention and use of preventative therapies including verapamil, topiramate, amitriptyline, or propranolol (guideline concordant indicators). Other outcomes included abortive medications such as non-steroidal anti-inflammatory drugs (NSAIDs) or acetaminophen (APAP) and triptans/ergot alkaloids. We excluded visits with "red flags," such as neurologic deficit, cancer, or trauma. We used logistic regression models for each outcome focusing on a linear trend for each two-year interval, and adjusted for age, sex, race/ethnicity, insurance, symptom duration, geographic region, urban location, and whether the healthcare professional was the primary care physician (PCP), and weighted results to reflect U.S. population estimates. Additionally, we stratified findings by migraine versus non-migraine, acute versus chronic presentations, and visits to PCPs versus non-PCPs.

RESULTS: We identified 9,110 visits for headache, which represented an estimated 139 million visits from 1999 to 2010. Nearly three-quarters of patients were female and mean age remained stable at approximately 46 years. Our Table summarizes unadjusted use over time. Use of advanced imaging (computed tomography or magnetic resonance imaging) rose from 7.6 % in 1999–2000 to 14.1 % in 2009–2010 (unadjusted $p<0.001$) and referrals to other physicians increased from 7.7 to 12.9 % ($p=0.009$). In contrast, physician counseling for headache prevention declined from 22.5 % in 1999–2000 to 17.3 % in 2009–2010 ($p=0.034$). Use of preventative medications increased from 8.3 to 15.0 % ($p=0.003$) while opiates/barbiturates remained unchanged at approximately 18 %. Adjusted trends (Figure) were similar as were results after stratifying by migraine versus non-migraine, acute versus chronic presentations, and visits to PCPs versus non-PCPs, with one important difference being that non-PCPs more frequently ordered advanced imaging ($p<0.001$).

CONCLUSIONS: Contrary to numerous headache practice guidelines, physicians are increasingly ordering advanced imaging and referring to other physicians and less frequently offering first-line headache prevention counseling to their patients. Worsening adherence to headache guidelines represents an area of particular concern for our healthcare system and stands out as an important opportunity to improve the value of U.S. healthcare.

Table. Unadjusted Use over Time (% of Visits)

Year (sample n)	1999–2000 (n=1,287)	2001–2002 (n=1,694)	2003–2004 (n=1,647)	2005–2006 (n=1,453)	2007–2008 (n=1,515)	2009–2010 (n=1,514)	P-value
Advanced Imaging (CT/MRI)	7.6	7.3	8.0	10.7	13.5	14.1	<0.001
Referrals to Other Physicians	7.7	9.8	11.7	10.7	13.5	12.9	0.009

YOGA FOR URINARY INCONTINENCE IN MIDDLE-AGED AND OLDER WOMEN: RESULTS OF A PILOT RANDOMIZED TRIAL Alison J. Huang¹; Hillary Jenny²; Margaret A. Chesney¹; Michael Schembri¹; Leslee L. Subak¹. ¹University of California San Francisco, San Francisco, CA; ²Cahn School of Medicine at Mount Sinai, New York, NY. (*Tracking ID #1926774*)

BACKGROUND: Nearly one-third of middle-aged and older women suffer from urinary incontinence. Existing treatments for incontinence are associated with side effects or other limitations that reduce their accessibility and usefulness, particularly in older women. Yoga can be used to improve awareness of and control over pelvic floor muscles; decrease anxiety, stress, and associated autonomic imbalance; and improve overall physical conditioning, all of which may help improve bladder control. We examined the feasibility, efficacy, and safety of teaching middle-aged and older women to practice yoga to improve incontinence.

METHODS: We conducted a pilot randomized trial in ambulatory women 40 years and older with at least 7 stress or urgency incontinence episodes per week. Women were randomized to a 6-week yoga therapy program designed by an expert yoga panel, consisting of twice weekly group classes and once weekly home practice sessions ("yoga therapy"; $N=10$), or to wait 6 weeks before receiving gift certificates for local yoga classes ("control"; $N=9$). All participants also received written patient-oriented pamphlets about standard behavioral management techniques for incontinence, consistent with usual first-line care. Changes in incontinence frequency were measured using validated 7-day voiding diaries.

RESULTS: Mean [\pm SD] age was $61.4[+8.2]$ years, and mean baseline incontinence frequency was $2.5[+1.3]$ episodes/day. After 6 weeks, total incontinence frequency decreased by 70 % in the yoga therapy group (1.8 ± 0.9 fewer episodes/day), versus 16 % in controls (0.3 ± 1.7 fewer episodes/day, $p=0.049$). Yoga participants also reported an 83 % decrease in stress incontinence frequency (0.7 ± 0.8 fewer episodes/day), versus an 19 % increase in controls (0.2 ± 1.1 more episodes/day). Changes in urgency incontinence frequency did not differ significantly between groups (1.0 ± 1.0 versus 0.5 ± 0.5 fewer episodes/day, $p=0.20$). All yoga group participants completed at least 90 % of group classes and 100 % of home practice hours. Two women in each group reported adverse events unrelated to treatment.

CONCLUSIONS: Findings provide preliminary evidence to support the feasibility, efficacy, and safety of a group-based yoga therapy intervention to improve urinary

incontinence in middle-aged and older women. When taught in a standardized way with attention to patient safety, yoga may offer a cost-effective, community-based management strategy for urinary incontinence.

YOUR PATIENT'S SUGAR IS TOO HIGH!: RESIDENT PHYSICIAN INTER-PROFESSIONAL PHONE COMMUNICATION SKILLS Jennifer Adams; Lisa Altshuler; Jaclyn Fox; Sienna Kurland; Kathleen Hanley; Colleen Gillespie; Adina Kalet; Sondra Zabar. NYU School of Medicine, New York, NY. (*Tracking ID #1937994*)

BACKGROUND: Inter-professional collaboration (IPC) is essential for effective and safe practice, especially in new models of team-based patient care. Understanding physicians' competence in communicating with team members over the phone is a critical first step to designing targeted curricula and workplace learning experiences. This study sought to assess internal medicine residents' baseline IPC phone competence.

METHODS: Inter-professional phone skills were assessed in a 10-minute case with a "Standardized Nurse" (SN) as part of the annual 11-station OSCE for Primary Care Residents (PGY1-3, $n=23$). This outpatient case called for the physician, speaking on the phone with the RN played by a trained actor (SN), to develop a treatment plan to address their patient's recent increase in Hemoglobin A1c and creatinine, which required the discontinuation of metformin and insulin adjustment. In addition, residents were expected to recognize two errors made by the nurse. A checklist was created to assess widely accepted IPC, general communication and case specific skills. The IPC items (9) included: clarifying roles; eliciting full information using check-back technique to clarify; using C.U.S. to state Concern, feeling Uncomfortable, and that issue was about Safety; respect (valuing team member information and assessments); and teamwork (developing a plan, delegation). "SNs" were frame-of-reference trained to complete the checklists. Item response options were: not done, partly done and well done, each with descriptive behavioral anchors. Summary scores were computed for IPC and Communication items within the IPC case and communication items for the overall OSCE as % of items rated well done (all Cronbach's alphas >0.71). Residents were also surveyed after the OSCE about how prepared they felt and to self-assess performance. Frequencies are reported for specific items and means for summary scores.

RESULTS: Only 2/23 residents introduced themselves using their full name and title and no residents confirmed the identity of patient (name, MR # and DOB). 15/23 residents did not perform check-back technique for medications and dosages. 8/23 identified that metformin should be stopped and explained to the nurse using CUS. Eight residents partially or fully recognized the nurse's mistake in suggesting a change in blood pressure medicine. Almost all residents (21) made some type of interdisciplinary plan with the nurse. The mean IPC Summary Score was 27 % well done. While the overall mean communication score for all 11 cases in the OSCE was 74 %, the mean communication score specific to the IPC case was 37 %. While most residents found the case particularly challenging and complex, 87 % (16) of residents felt prepared, 7 thought they could have done better. 4.3 % ($n=1$) received a "not recommend", 30 % ($n=7$) received "recommend with reservations", 43.5 % ($n=10$) received a "recommend" and 21.7 % ($n=5$) received a "highly recommend" rating based on their overall professionalism and ability to work as a member of an inter-professional team.

CONCLUSIONS: Residents vary in their IPC phone skills and therefore Residency IPC curriculum can be targeted and tailored to address demonstrated IPC skills deficits. Given these skills are critical to safe and effective team based patient care, attention needs to be paid to developing feasible, valid assessment techniques to monitor competence in this area.

YOUTUBE AS A SOURCE OF INFORMATION FOR ATRIAL FIBRILLATION Rakshita Chandrashekhar; Sourabh Aggarwal; Mark Loehrke. Western Michigan School of Medicine, Kalamazoo, MI. (*Tracking ID #1939085*)

BACKGROUND: Internet has become an easy source for healthcare information. In recent years, websites including Google and YouTube have become increasingly

popular for searching for all possible queries. It is necessary to monitor the information, especially scientific facts, being disseminated from these open-access sites which will assist in keeping check on and further, in developing strategies to prevent spread of false information. This study analyzed how information related to Atrial Fibrillation was portrayed in video clips available on YouTube.

METHODS: YouTube (www.youtube.com) was searched on December 1, 2013 using the search terms keyword "Atrial Fibrillation". First 50 videos displayed were analyzed for the purpose of this study with the theory that a layman does not usually go beyond initial videos during random search. Videos were viewed and classified as useful, misleading and news update by 2 different viewers. Data analyses were conducted for duration of videos, number of viewers and appropriateness of videos by reliability score, content score and global quality score. Statistical analysis done by SPSS.

RESULTS: A total of 50 videos were included in analysis. Mean duration of videos was 642 s (Median 254 s), mean viewership was 22893 views (Median 2992 views, range 12–394554 views) and mean length for video posted on YouTube was 717 days (Median 591 days, range 104–2428 days). Forty three videos (86 %) were classified as useful, 5 as patient views (10 %) and 2 as misleading (4 %). Most of the videos, 26 (52 %) were uploaded by university channels, followed by independent users 17(34 %) and for-profit-companies 4(8 %). Most of the videos 22 (44 %) were focused on patient education in laymen language, followed by medical and scientific education 14 videos (28 %) and personal experience 11 videos (22 %). Two videos (4 %) were focused on drug advertisement and 1 video (2 %) discussed alternate non-approved forms of treatment. On a scale of 1–5, the mean reliability score was 3.26 ± 1.04 (Median 4), mean content score was 3.08 ± 1.06 (Median 3) and mean global quality score was 3.12 ± 1.09 (Median 3.5)

CONCLUSIONS: The results demonstrate that there is a wide variety of information on YouTube regarding Atrial Fibrillation. Though most of the videos are useful, with appropriate content form, there are elements of misleading and inappropriate information available on free internet websites. Viewers can be misled to false information which can have grave implications. As a result, public health professionals should be more vigilant in recognizing videos containing misleading information on health related issues and physicians should counsel and educate patients against inappropriate use of online videos for medical purposes. More studies are however needed for information on YouTube for other more common diseases.

CLINICAL VIGNETTES "I AM ALWAYS IN THE HOT SHOWER." CANNABINOID HYPEREMESIS SYNDROME - A CASE REPORT

Tanu S. Pandey; Tanuja Salim. John H Stroger Hospital of Cook County, Chicago, IL. (*Tracking ID #1939636*)

LEARNING OBJECTIVE 1: Marijuana is the most commonly used illicit drug in the United States. The 2010 National Survey on Drug use and Health recorded 17.4 million past month users of Marijuana. However, relatively few cases of cannabinoid hyperemesis syndrome (CHS) are diagnosed correctly and there exists a distinct lack of knowledge of this syndrome. We present a classic case of CHS in a young man with extensive use of marijuana in an effort to understand it better, especially in current times of legalization of its use across United States.

CASE: A 33 year old man with poorly controlled diabetes mellitus due to non-adherence to treatment and 18 years of marijuana use was admitted with intractable vomiting for 2 days. This was preceded by a week of nausea, abdominal discomfort and early morning vomiting. His symptoms were relieved by taking hot showers and he admitted to taking 10–20 showers in a day. His first such episode was in 2005. Since then he had multiple episodes of the same symptoms and frequent ER admissions. Vomiting was consistently relieved by taking hot showers. Severe episodes in this patient were associated with increase in the amount of marijuana used. On physical examination he had dry oral mucosa with sinus tachycardia. Abdominal exam was unremarkable. Investigational labs was consistent with diabetic ketoacidosis and he was treated successfully with return of blood glucose to normal and improvement in acidosis. However, he continued to be symptomatic with recurrent vomiting and persistent nausea and abdominal discomfort. He was witnessed by the medical team to be in the shower >10 times daily. The patient first presented to this hospital in 2011 followed by repeated admissions for the same problem. Initially, these episodes were attributed to diabetic ketoacidosis and later cyclic vomiting syndrome. Taking into account his chronic marijuana use and relief with hot showers, he was finally diagnosed with cannabinoid hyperemesis syndrome and treated conservatively, with recommended abstinence from marijuana use.

DISCUSSION: This case illustrates the classical symptoms of cannabinoid hyperemesis syndrome which include early morning emesis, a pre-emetic phase consisting of nausea and abdominal discomfort as well as symptomatic relief with hot showers. It also depicts the delay associated with the diagnosis of this syndrome and the possibility of under-diagnosis in the general population. Given the high prevalence of cannabinoid use and its legalization in several states, it is important to raise awareness amongst physicians on the side effects of cannabinoids.

"HEAVY" BREATHING: A CASE OF CEMENT PULMONARY EMBOLISM

Justin Skrzynski¹; Saad Sahi²; Arati K. Kelekar¹. ¹William Beaumont Hospital, Royal Oak, MI; ²Oakland University School of Medicine, Rochester, MI. (*Tracking ID #1936202*)

LEARNING OBJECTIVE 1: Recognize and diagnose a potentially clinically significant sequela of vertebroplasty.

CASE: Our patient is a 53 year old man presenting with dyspnea and cough. He had a complicated medical course since receiving kyphoplasty 6 months prior to admission, and was intermittently hospitalized for recurrent pneumonia and COPD exacerbation. Due to high suspicion of pulmonary embolism at presentation, contrast CT of the chest was obtained which revealed multiple nonocclusive densities in the right pulmonary artery system as well as opacities in the right middle and lower lobe. Patient later corroborated a history of bone cement embolism following his procedure. He was admitted to the intensive care unit and treated for multifactorial respiratory failure with antibiotics, diuretics, steroids and nebulizers. Despite aggressive treatment, on the ninth day of his admission he developed sudden bradycardia and expired. Autopsy was performed with final pathology results pending.

DISCUSSION: Kyphoplasty and vertebroplasty are common procedures in the treatment of vertebral compression fracture in which bone cement is injected percutaneously into a vertebral body to restore height and integrity. While the incidence of local leakage of cement into adjacent spaces can be high (up to 80–90 %), intravasation is less common (24 %) and embolization of cement less common still (4.6–6.8 %). The vast majority of cement emboli are asymptomatic and long term or serious sequelae, including death, are rarely reported. In our patient, the exact role of his cement emboli thus far remains uncertain. While our patient demonstrated no peripheral eosinophilia, he did have persistent bronchospasm which was resistant to steroids and nebulizers; we hypothesize that the long term presence of foreign material in the lungs may have caused a chronic hypersensitivity reaction. Though he had right sided opacities on imaging, he was afebrile and the differential for this finding could include pulmonary hemorrhage. Unfortunately, the patient expired before bronchoscopy could be performed. At this time, autopsy has been performed and initial pathology did demonstrate cement material in the right pulmonary artery system. The vast majority of reported cement emboli were asymptomatic, but our patient's clinical course clearly deteriorated significantly following his kyphoplasty. Currently no consensus exists in the treatment of this condition, with attempted therapies ranging from antibiotics to anticoagulation to mechanical extraction. The exact effect of bone cement on vascular or lung tissue remains to be determined and to our knowledge no pathologic examination of cement pulmonary embolus exists in the literature. Identifying this effect as well as the true incidence of cement embolization may help in reducing morbidity and mortality for kyphoplasty and vertebroplasty in the future.

"KISSING DISEASE" OF THE LIVER

Anuhyaa Gampa; Maya Srikanth; Jordan Dale; Anupama Ananth. Rush University Medical Center, Chicago, IL. (*Tracking ID #1897930*)

LEARNING OBJECTIVE 1: Diagnose acute infectious mononucleosis secondary to EBV despite a negative heterophile antibody test, or Monospot, early in the disease course.

LEARNING OBJECTIVE 2: Recognize that clinical presentations of infectious mononucleosis may vary with age as EBV hepatitis is more likely in older adults.

CASE: A 46 year-old healthy man presented with 2 weeks of right upper quadrant pain and 1 week of a sore throat associated with fevers, malaise, jaundice, weight loss and night sweats. He visited another clinic at the onset of symptoms and was found to have an elevated AST (163), ALT (315), ALP (585), and total bilirubin (4.4). RUQ ultrasound showed a fatty liver and a mildly dilated common bile duct (0.6 cm). His labs were also notable for negative EBV IgG (EBV IgM not tested), HIV, and acute

hepatitis serologies. His CMV IgG was positive, however IgM was negative. A rapid strep test was also negative. Additionally, he had a mild leukocytosis with a lymphocytic predominance. On presentation to our institution 2 weeks later, he also acknowledged odynophagia and his exam was remarkable for jaundice, with mild RUQ tenderness, anterior cervical lymphadenopathy, and tonsillar exudates. Liver enzymes remained elevated: AST (163), ALT (315), ALP (585), total bilirubin (5.2), conjugated bilirubin (3.5), mild leukocytosis (11.7), with lymphocytosis and atypical lymphocytes noted on the differential. Another extensive workup was done and an initial Monospot test was negative. CT abdomen/pelvis was done due to the concern for lymphoma and revealed a nonenhancing 1.2 cm hypodensity in the medial right hepatic lobe and a left periaortic soft tissue mass. Liver and periaortic soft tissue mass biopsies were performed. Further EBV testing returned positive days later: EBV DNA (16,828 copies) and positive IgM antibodies. His periaortic mass biopsy was found to be metastatic seminoma while his liver biopsy was negative for malignancy and pathologic examination supported EBV hepatitis. His symptoms were self-limited and spontaneously resolved over the next few weeks. He was discharged with the diagnosis of EBV hepatitis and an incidental finding of metastatic seminoma for which he underwent an orchectomy and chemotherapy as an outpatient after his liver function studies normalized.

DISCUSSION: Although the constellation of clinical symptoms suggestive of infectious mononucleosis was present in our patient, the diagnosis was delayed by an initially negative monospot (heterophile antibody) test without the support of known EBV IgM serologies. However, EBV IgM can be negative for days despite acute infection, so it is unclear if EBV IgM testing at the time of his initial presentation at the outside clinic would have provided diagnostic benefit in this case. The longer the duration of symptoms, the greater reliability of titers for IgM antibodies directed at the viral capsid of EBV. Atypical lymphocytosis in the setting of consistent clinical symptoms can support a diagnosis of infectious mononucleosis, despite negative serologic testing. Our case underlines the importance of understanding that the sensitivity of the Monospot test is only 85 % while specificity approaches 100 %. Further viral serologies, including EBV IgM and IgG titers, should be used to confirm the diagnosis if the monospot test is negative yet clinical suspicion remains high. Thus, the Monospot test is inessential to the final clinical diagnosis of EBV infection. Symptomatic EBV hepatitis is rare and self-limited. Transaminitis associated with lymphadenopathy, fever and pharyngitis should raise concern for EBV hepatitis. Mild transaminitis is common in infectious mononucleosis without acute EBV hepatitis. However, hepatitis from EBV can present prior to classic mononucleosis symptoms. In case studies, only 5 % of patients with infectious mononucleosis initially presented with jaundice, right sided abdominal pain and transaminitis, supporting that this presentation is uncommon, but still possible. Patients with mononucleosis need not present classically prior to developing hepatitis. Case studies show only 12 % of EBV hepatitis patients (all in their 20s) had classic mononucleosis symptoms, while 75 % who presented solely with transaminitis were older than 40. EBV hepatitis is self-limited but should be considered in evidence of transaminitis and cholestasis, especially in older adults, regardless of initial titers and symptoms.

A "TWO-HIT" HYPOTHESIS: PNEUMOCYSTIS PNEUMONIA AND DIGEORGE SYNDROME Weiyi Tan, UCLA, Los Angeles, CA. (*Tracking ID #1939645*)

LEARNING OBJECTIVE 1: Recognize that Pneumocystis Pneumonia in non-HIV patients is a disease that carries high morbidity and mortality.

LEARNING OBJECTIVE 2: Consider the use of prophylaxis against Pneumocystis jirovecii in patients with multiple sources of immunosuppression.

CASE: A 20 year-old male with DiGeorge syndrome (DGS) and history of an orthotopic heart transplant in 2010 presented with fever and shortness of breath for 1 day. The patient had a history of recurrent pneumonias. He was on minimal immunosuppression with tacrolimus and mycophenolate mofetil. He had a known IgG2 subclass deficiency, but did not have a diagnosis of complete DGS (severe immunodeficiency). Physical exam showed normal vitals and oxygen saturation of 98 % on room air. Lung sounds were diminished, particularly on the left side, with left-sided egophony. The rest of the exam was normal. Chest x-ray showed a nodular opacity in the left lower lobe. A subsequent non-contrast chest CT showed left perihilar upper lobe and lower lobe confluent airspace infiltrates and consolidation with air bronchograms suggestive for pneumonia. He was initially started on vancomycin, meropenem, levofloxacin, and ganciclovir. Rapid RSV and influenza tests were negative. He then underwent bronchoscopy with bronchoal-

veolar lavage (BAL) for further diagnostic testing. The BAL studies were positive for *Pneumocystis jirovecii* via direct fluorescent-antibody testing. His respiratory viral panel via nasal washing was positive for rhinovirus/enterovirus. His regimen was then narrowed to IV trimethoprim-sulfamethoxazole after the BAL studies resulted. Further immunologic studies showed low IgG2 levels and a low absolute CD4 count of 234, and thus intravenous immunoglobulin was administered. He slowly decompensated over the next 7 days, even on therapy. He developed hyponatremia from SIADH and IV trimethoprim-sulfamethoxazole administration. He also developed hypercarbic respiratory failure and was intubated on hospital day seven. He suffered from an ileus as well, and his antibiotic regimen was switched to IV pentamidine. After 2 days of ventilatory support, he was successfully extubated. His serum sodium improved as well and he was discharged home on oral trimethoprim-sulfamethoxazole.

DISCUSSION: This case highlights an atypical presentation of PCP pneumonia, and demonstrates the fact that patients with non-HIV PCP pneumonia have higher rates of morbidity and mortality than those who have HIV, which stresses the importance of a detailed history and a high index of suspicion for this disease. Furthermore, given his immunosuppressed state from his heart transplant and DiGeorge syndrome, the use of prophylactic antibiotics for PCP could be considered in future cases similar to this patient with a "double hit" to the immune system.

A (RING) ENHANCED APPROACH TO HIV AND CENTRAL NERVOUS SYSTEM LESIONS Alexandra Wells; John Moscona, Tulane University Health Sciences Center, New Orleans, LA. (*Tracking ID #1925933*)

LEARNING OBJECTIVE 1: Understand approach to ring enhancing lesions

LEARNING OBJECTIVE 2: Recognize ADEM as a cause for CNS disease in HIV patients

CASE: A 44 year old man with history of HIV presented with 3 weeks of progressive right upper and lower extremity weakness. Symptoms initially began with paresthesias of the fingers and progressed to weakness of right upper extremity and proximal right lower extremity. He endorsed an upper respiratory infection several weeks prior, but denied fevers, neck stiffness, or recent vaccinations. Vitals were temperature 98 F, heart rate 83, and blood pressure 130/80 mmHg. Patient was oriented to person, place, and location. Pupils were equal and reactive, with a midline, and supple neck. Strength was 3/5 throughout the right upper extremity, and 4/5 throughout the right lower extremity. There was decreased sensation to light touch and vibration of both the right upper and lower extremity. Reflexes were 3+ throughout, and Hoffman sign was positive on right hand. Plantar reflexes were down-going bilaterally. CD4 count was 426. Cerebral spinal fluid contained 10 WBC with 92 % lymphocytes, and 1 RBC. All serology was negative including VDRL, cryptococcus, JC virus, and toxoplasma. All cultures and gram stains were also negative including AFB and fungal. An MRI revealed three ring-enhancing lesions in the right frontal and parietal lobes along with the left centrum semiovale. MRI also displayed enhancement within the cervical spinal cord.

DISCUSSION: HIV is encountered commonly in internal medicine. Although rates of CNS disease have decreased with antiretroviral therapy, neurologic complications occur in over 40 % of HIV positive patients. The man described above was found to have multiple, ring-enhancing lesions on MRI despite numeric immunocompetence. With enhancing lesions, it is useful to divide the differential diagnosis into 3 categories, which include infection, neoplasm, and demyelination. Further stratifying infection risk based on CD4 will help direct serum and CSF workup. Additional imaging, and even biopsy, may be required for oncologic and demyelinating diagnoses. Imaging and CSF findings in the above case were consistent with a demyelinating process and lead to the diagnosis of acute demyelinating encephalomyelitis (ADEM). ADEM is an inflammatory demyelinating disorder of the CNS usually preceded by an infectious disease or vaccination. ADEM is estimated to occur in 1 per 125,000 people in the US with higher prevalence in children. However, ADEM has been associated with HIV infection. The hypothesis is that the HIV virus causes neuronal damage leading to an inflammatory response with consequent demyelination. Acutely, these lesions will enhance on MRI with contrast as seen in the man described above. His CSF studies revealed a lymphocytosis that was also consistent with ADEM. After ruling out major infectious causes, he was initiated on corticosteroids and was able to return to near baseline level of functioning. Given the potential for recovery with prompt treatment, it is important for the internist to incorporate

ADEM into his or her differential when evaluating HIV positive patients with neurologic symptoms.

A CASE OF ACUTE HEPATITIS B-INDUCED POLYARTERITIS NODOSA IN A PATIENT PRESENTING WITH FEVER OF UNKNOWN ORIGIN AT BELLEVUE HOSPITAL Arnab K. Ghosh; Karin Warltier. NYU, New York, NY. (*Tracking ID #1920727*)

LEARNING OBJECTIVE 1: 1. Recognize the clinical reasoning involved in assessing a patient with fever of unknown origin.

LEARNING OBJECTIVE 2: 2. Recognize the association between polyarteritis nodosa and acute hepatitis B in a patient presenting.

CASE: A 50 year old Malian man presented with a 1 month history of fevers, fatigue and anorexia. He was in his usual state of good health until 1 month prior to his presentation when he underwent evaluations at other hospitals and was diagnosed with upper respiratory tract infections. He was prescribed antibiotics and ibuprofen but his symptoms persisted. The patient immigrated to the US in 2005, worked as a freelance photographer and had recently travelled to Texas, Rhode Island and Long Island. He was previously in a monogamous relationship with a woman but denies any current sexual activity. He has smoked 3 cigarettes daily for the past 20 years, but denies other toxic habits. Physical examination was remarkable for a diaphoretic male in no acute distress with a temperature of 101.6°F, heart rate of 118, blood pressure of 124/73 and oxygen saturation of 97 % on room air. A 1 cm non tender lymph node was palpated in the anterior chain of his left neck. The remainder of his physical examination was unremarkable. Laboratory tests revealed a white cell count of 15,900/L (79.7 % neutrophils, 10.1 % monocytes), hemoglobin of 11 g/dL, platelet count of 401,000/L, c-reactive protein of 217U/mL, lactate dehydrogenase 3236 U/mL, AST 86U/L, ALT 97U/L, ALP 185U/L. HIV test was negative. Chest x-ray showed bilateral perihilar radio-opacities. The patient underwent a contrast CT of the chest, neck, abdomen and pelvis, showing edema and inflammatory soft tissue changes involving bilateral carotid and retropharyngeal spaces and severe narrowing (70 %) of the right internal carotid artery, consistent with vasculitis. This was confirmed on CT angiography of the neck. Further workup showed evidence of hepatitis B (core antigen positive, core antibody IgM nonreactive, surface antigen positive, surface antibody nonreactive, viral load 3660 IU/mL, genotype E). The patient was started on tenofovir 300 mg and prednisone 60 mg daily. A temporal artery biopsy was performed, showing no evidence of vasculitis. He responded well to both steroids and tenofovir.

DISCUSSION: Our patient's course presented as a case of fever of unknown origin. His radiological imaging was concerning for vasculitis affecting both large and medium sized vessels. Differential diagnoses include giant cell arteritis, Takayasu's arteritis, polyarteritis nodosa and Kawasaki's disease. Given this patient's epidemiology, and the finding of hepatitis B, our presumptive diagnosis was acute hepatitis B complicated by polyarteritis nodosa. Ideally a biopsy result is required for confirmation, which in this patient was negative. A well-known extra-hepatic manifestation of the hepatitis B virus is polyarteritis nodosa (PAN) [1,2]. Described as 'secondary' PAN, its etiology is not well understood, but thought to be from immune complexes causing systemic inflammation. It may affect upwards of 30 % of patients with active hepatitis B [3]. Occurring within 6 months of contracting the infection [4], hepatitis B related PAN presents with non-specific symptoms such as fever, arthralgias, muscle disease and fatigue. It may present with skin symptoms (tender erythematous nodules, purpura or ulcers), renal insufficiency, mononeuritis multiplex (70 %) gastrointestinal symptoms, and coronary artery disease [1,3].

A CASE OF ACUTE MINDFULNESS TREATMENT FOR ANXIETY FACILITATED BY ON SITE PSYCHOLOGIST IN AVA PRIMARY CARE CLINIC David Bittleman^{1,2}; Joshua Ruberg^{1,2}. 1VA San Diego, San Diego, CA; 2University of California at San Diego, San Diego, CA. (*Tracking ID #1921623*)

LEARNING OBJECTIVE 1: Recognize when an acute mindfulness exercise may help a patient in distress.

CASE: A 27 year old male veteran presented to a primary care internal medicine clinic for an initial evaluation. The patient was suffering from an undifferentiated

psychotic disorder, possibly bipolar disorder, post-traumatic stress disorder (PTSD), and was known to self-medicate with marijuana. His medications included Buspirone 10 mg three times daily, Citalopram 20 mg daily, folic acid 1 mg daily, Risperidone 1 mg in the morning , 4 mg in the evening, Thiamine 100 mg daily and Trazodone 50 mg at bedtime as needed for insomnia. From the moment the patient entered the exam room, he appeared upset and withdrawn. The veteran was frustrated with both the military and Veteran's Administration system. In particular, he felt betrayed and was worried that his disability rating would be reduced and that his disability payments would be discontinued. He sat rocking back and forth saying that he was hearing voices whispering that he should kill himself. At that point, the internist contacted the on staff psychologist and he came immediately to assess the veteran. The internist was considering sending the patient directly to the emergency department for assessment and possible psychiatric admission. The psychologist found the patient future oriented with a desire to get better and to spend time with his daughter. Yet, he was described as despondent, looking at the floor and shaking. At that point the psychologist invited the veteran as well as the primary care internist to participate in a mindfulness breathing exercise. The patient reported that following the exercise he felt less anxious, but was still worried and hearing voices. He appeared more at ease and made a bit of eye contact. He was further assessed and felt not to be an imminent risk to himself and he agreed to call the crisis line or present to the emergency department if his symptoms worsened. Plans were made to connect him with ongoing therapy and continued medication treatment. The internist felt less anxious as well following the breathing exercise and was relieved that the veteran did not need to go immediately from the office to the emergency department.

DISCUSSION: The Department of Veterans Affairs (VA) has pioneered the development of a particular kind of patient-centered medical home, the Patient Aligned Care Team (PACT). The PACT allows for seamless cooperation between primary care providers and mental health professionals (1). This case illustrates this model in action. Assessing which patients are at risk for suicide is difficult (2). The mention of suicidal ideation may cause the provider to recommend emergency room evaluation for possible psychiatric admission to the hospital. Close proximity of an onsite psychologist allowed for timely evaluation and intervention. A repeat emergency room visit was avoided. In addition, the brief mindfulness exercise helped calm the veteran as well as the internist. 1. Kearney LK, Post EP, Zeiss A, Goldstein MG, Dundon M. The role of mental and behavioral health in the application of the patient-centered medical home in the Department of Veterans Affairs. *Transl Behav Med*. 2011 December; 1(4): 624–628. [PMCID: PMC3717670] 2. Haney EM, O'Neil ME, Carson S, Low A, Peterson K, Denner LM, Oleksiewicz C, and Kansagara D. Suicide Risk Factors and Risk Assessment Tools: A Systematic Review. A CASE OF ADULT LEAD POISONING Tao Liu^{1,2}; Anne Hyson¹; Susan T. Langerman¹. 1VA Connecticut Healthcare System, West Haven, CT; 2Yale-New Haven Hospital, New Haven, CT. (*Tracking ID #1938010*)

LEARNING OBJECTIVE 1: Recognize adult lead poisoning

LEARNING OBJECTIVE 2: Manage adult lead poisoning in a primary care setting

CASE: A 49 year-old Veteran who works as a painter presented to the primary care clinic for a new patient visit. The patient, who had been working for 3 months to restore a historical home, became concerned about lead exposure, and requested lead level testing. Past medical history was unremarkable. Review of systems was positive for two-month history of bilateral shoulder and lower back pain. Vital signs were normal. Physical exam was significant for decreased range of motion of the shoulders. Basic labs and lead levels were ordered. Lead level was 156 mcg/dL. Both the patient and Connecticut Poison Control Center were promptly contacted. The patient was asked to return immediately for evaluation, and was referred to hematology, neurology and Yale Occupational and Environmental Medicine Program. Repeat lead level, which was obtained 6 days after the first level, was 95 mcg/dL. Chelation therapy was deemed not needed, given that the lead level fell rapidly and the patient subsequently changed his occupation. We recommended that the patient obtain a monthly lead level and CBC to ensure that the lead level decreases by 50 % each month.

DISCUSSION: This case illustrates the presentation and management of adult work-related lead poisoning. Occupations associated with lead poisoning include those in smelting and refining industries, brass/bronze foundries, rubber products, plastic industries, battery manufacturing, soldering, painting and construction [1]. Adverse effects of lead include anemia, suppressed immunity, neuropathy, renal failure, hypertension and gout [2]. In the history, it is important to ask about previous

occupations, exposures to fumes, dust and toxic substances, protective equipment, and eating and drinking habits in the work areas. On exam, signs of lead poisoning can include pallor, lead line on the gingiva and neurological abnormality. In addition to lead level, one can also obtain zinc protoporphyrin level which reflects lead absorption over the preceding 3 to 4 months and is a better indicator of body lead burden [3]. Primary care physicians should consider referring adult patients with lead level above 20 mcg/dL to occupational medicine specialists, and consider chelation therapy for patients with lead level above 50 mcg/dL, especially for patients with significant symptoms [4]. The decision for chelation therapy should be made in consultation with specialists. For the patient in the current case, chelation therapy was not recommended, because he did not exhibit significant symptoms and his lead level fell quickly. References 1. A CASE OF DAPSONE-INDUCED HYPERSENSITIVITY PNEUMONITIS IN A PATIENT BEING TREATED FOR LEPROSY AT BELLEVUE HOSPITAL
Arnab K. Ghosh; Rachel M. Bond; Richard E. Greene. NYU, New York, NY.
(Tracking ID #1920702)

LEARNING OBJECTIVE 1: 1. Recognize the adverse effects of dapsone, including hypoxic respiratory failure secondary to hypersensitivity pneumonitis. **CASE:** The patient is a 40 year old Chinese female previously well who is admitted with a 1 week history of malaise, anorexia, shortness of breath and a dry cough. She was diagnosed with leprosy by biopsy 2 months prior to presentation, and was started on dapsone, thalidomide and minocycline. She migrated from China to the United States in 2004. Physical examination revealed a slender female using accessory muscles of respiration, unable to speak in complete sentences, with a temperature of 103.10 F, heart rate 103, blood pressure 119/73 and respiratory rate 34, saturating at 85 % on room air. Examination also showed dry inspiratory crepitations throughout both lung fields, a papular rash on the knees and thighs with an erythematous plaque on her left elbow consistent with previously diagnosed Hansen's Disease. Labs were significant for white cell count of 700/uL with no neutrophils, hemoglobin of 11.3 g/dL and platelets 165,000/uL. Lactate dehydrogenase 1300. Liver function tests were within normal limits. Arterial blood gas on room air showed pH 7.43/CO2 32.7/O2 49.4/Lactate 1.2/SaO2 85.2 %. Chest X-ray showed bilateral interstitial infiltrates. CT Chest showed bilateral hilar and mediastinal lymphadenopathy with diffuse bilateral septal thickening and small bilateral pleural effusions. The patient was started on broad spectrum antibiotics including trimethoprim-sulfamethazole and high dose steroids for presumed Pneumocystis jiroveci. All anti-leprosy medication was stopped and a bronchoscopy was performed. Blood cultures were negative, and atypical pneumonia screen was negative. Her clinical picture improved after 3 days, whereupon her Pneumocystis stain returned negative. Bactrim was stopped, the steroid dose was decreased. She completed the course of broad spectrum antibiotics. Repeat imaging of her lungs revealed improvement.

DISCUSSION: Our patient's presentation, with worsening shortness of breath, a rash, combined with negative pneumonia workup and radiological pattern was consistent with a drug-induced pneumonitis. The patient further reported these symptoms beginning after starting dapsone. Dapsone is used for its antibiotic and anti-inflammatory properties, and as the first line therapy in the treatment of leprosy [1], a disease caused by *Mycobacterium leprae*, which infects both skin and nervous tissue. Dapsone has been implicated in a number of adverse drug reactions, involving different organ systems. Rarely, it has been associated with a drug reaction with eosinophilia and systemic symptoms (DRESS syndrome) [2]. DRESS syndrome typically involves a long latency period (upwards of 8 weeks) after exposure to the offending agent (80 % of cases are due to medications), with high fevers, morbilliform rash and associated lymphadenopathy. Often there are hepatic manifestations (60-80 % have abnormal LFTs) and renal dysfunction (10-30 % suffer interstitial nephritis). More rarely does interstitial pneumonitis occur, although case reports exist in the literature [3,4]. Treatment involves rapid recognition of

the illness and stopping the medication. In patients with pulmonary symptoms, high dose steroids are recommended. In our patient, after stopping the offending agent, and treating her with steroids, the patient improved, as evidenced by improving radiology.

A CASE OF DISSEMINATED RETROPERITONEAL PLASMACYOTOMA WITH RENAL INVOLVEMENT Naba R. Mainali; Leena Jalota; Ranjan Pathak; Shashank Jain. Reading Health System, West Reading, PA. (Tracking ID #1934062)

LEARNING OBJECTIVE 1: To describe the importance of biopsy and immunohistochemistry to confirm the diagnosis of Extra-Medullary Plasmacytoma (EMP).

LEARNING OBJECTIVE 2: To describe the treatment options available for disseminated retroperitoneal plasmacytoma.

CASE: Introduction: Extramedullary plasmacytoma (EMP) is a neoplastic proliferation of plasma cells in non-osseous sites without the involvement of bone marrow and usually occurs in the head and neck region. Herein we report a rare case of disseminated EMP that presented as a diagnostic challenge especially because of its atypical presentation and location. Case Report: A 65-year-old woman with history of retroperitoneal EMP with complete remission after radiotherapy presented with progressively worsening abdominal pain, generalized weakness and weight loss for 1 month. On examination, distension and fullness in left flank region was noted without palpable mass or organomegaly. Her laboratory results were normal except for hemoglobin 10.4 g/dl. Urinalysis revealed no Bence-Jones protein. CT abdomen and chest showed 10×16 cm left paraspinal soft tissue mass at the level of left renal hilum with hydronephrosis and 6.1×4.6 cm left pulmonary hilar mass respectively. Bone marrow biopsy revealed normocellularity with trilineage hematopoiesis and less than 10 % plasma cells, thus ruling out multiple myeloma. Fine needle aspiration cytology of the mass was positive for plasmacytoma. Her serum IgA level was elevated at 1150 g/L with normal IgG and IgM levels. Immunohistochemistry was positive for CD138 and CD38 but negative for CD45, CD19 and CD20. She did not respond well to chemotherapy with dexamethasone and lenalidomide. Radiotherapy was offered because of the large size and presence of lung metastases. She was therefore placed on comfort measures.

DISCUSSION: Retroperitoneal EMP involving kidney is an extremely rare condition and difficult to diagnose because of its unusual location and absence of symptoms until advanced stage. Definitive diagnosis of EMP requires histopathological examination and immunohistochemistry work up. EPM is highly radiosensitive; it is usually treated with combined radiotherapy and surgery or chemotherapy depending on the stage.

A CASE OF DUODENAL DIEULAFOY'S Randy Chung^{1,2}; Jeffrey T. Bates^{1,2}; ¹Baylor College of Medicine, Houston, TX; ²Michael E. DeBakey VA Medical Center, Houston, TX. (Tracking ID #1939031)

LEARNING OBJECTIVE 1: Recognize that an extragastric Dieulafoy's lesion, though rare, is an important and likely underreported cause of upper gastrointestinal bleeding

LEARNING OBJECTIVE 2: Manage a bleeding duodenal Dieulafoy's lesion with therapeutic endoscopy

CASE: The patient is a 69-year-old Caucasian male with a history of coronary artery disease and mitral valve replacement, compliant on warfarin therapy, who was admitted for melena and new-onset anemia. He was in his usual state of health until 4 days prior to admission, when he began having three episodes a day of maroon-colored stools and lightheadedness. He denied hemoptysis, hematemesis, or other overt bleeding. He did not have fever, chills, nausea, vomiting, abdominal pain, or diarrhea. In addition to warfarin, the patient also takes aspirin 81 mg daily but denied any other NSAID use. There were no significant findings on physical examination apart from positive orthostatics and mild pallor. Initial laboratory studies revealed a hemoglobin of 7.7 g/dL (compared to 13.8 g/dL 4 months prior), a prothrombin ratio (INR) of 2.28, a normal activated partial thromboplastin time (aPTT), a normal platelet level, and normal liver function tests. The patient was started on a pantoprazole drip. He received a blood transfusion with an appropriate rise in his hemoglobin level. Esophagogastroduodenoscopy and push enteroscopy were performed, which found a bleeding Dieulafoy's lesion in the second portion of the duodenum. Hemostasis was achieved with the placement of two endoclips. The

patient had no further episodes of melena following the procedure and his hemoglobin level remained stable. He was transitioned to oral pantoprazole and restarted on warfarin.

DISCUSSION: A Dieulafoy's lesion (DL) is an uncommon and likely underrecognized cause of upper gastrointestinal bleeding in which hemorrhage occurs from a tortuous submucosal arterial lesion. The lesion is most often found in the proximal stomach within 5 cm of the gastroesophageal junction. Duodenal DLs are rare, accounting for about 15 % of all DLs, but have been identified more frequently in recent years because of increased awareness of the condition. The diagnosis is inherently difficult because of the small size and obscure location of the lesion, and it is most often made during episodes of active bleeding. As with our patient, people who bleed from DLs are typically men with multiple comorbidities, including cardiovascular disease, hypertension, and diabetes mellitus. Therapeutic endoscopy is the modality of choice for the treatment of DLs. The use of vascular clips has been reported to be an effective and safe method of hemostasis in DLs, especially in thin walled organs like the duodenum. Our patient's duodenal DL bleed was effectively controlled with hemoclipping. In conclusion, clinicians should consider a Dieulafoy's lesion in any patient presenting with an upper gastrointestinal bleed, and recognize that early endoscopy during a bleeding episode is essential for accurate diagnosis and proper treatment.

A CASE OF EXTENSIVE TAKAYASU ARTERITIS IN A YOUNG AFRICAN AMERICAN FEMALE Mohammed W. Imam; Hiba Hadid; Mona Hassan. Henry Ford Health System, Detroit, MI. (*Tracking ID #1939229*)

LEARNING OBJECTIVE 1: The main objective is to highlight the importance of performing a thorough physical examination as an easy and inexpensive means of diagnosing takayasu's arteritis. This case report also highlights the epidemiological features, diagnostic criteria, and main treatment modalities of this rare disease.

LEARNING OBJECTIVE 2: This case report also highlights the epidemiological features, diagnostic criteria, and main treatment modalities of this rare disease.

CASE: We report a case of Takayasu arteritis in a 38-year old African American female who presented with discrepancies in radial pulses and inability to get a blood pressure reading in the left arm. CT angiography of head, chest, abdomen and pelvis showed multiple areas of significant narrowing in multiple major vessels, including vertebral arteries, left subclavian artery, basilar artery, and bilateral internal iliac arteries.

DISCUSSION: Takayasu arteritis, also known as idiopathic medial aortopathy or pulseless disease, is a rare chronic condition characterized by granulomatous vasculitis of unknown etiology. Women are affected in the majority of cases with the greatest prevalence in Asians. In the United States, its incidence is 1–3 new cases per year per million population. Takayasu's arteritis predominantly affects the aorta and its major branches, with the pulmonary vessels and abdominal aorta affected in over 50 % of cases. The pathogenesis of Takayasu's is poorly understood, but cell-mediated autoimmune mechanisms are thought to play a major role.

A CASE OF FEVER AND ABDOMINAL PAIN IN A YOUNGER GENTLEMAN Jocelyn A. Carter A. Carter. Massachusetts General Hospital, Boston, MA. (*Tracking ID #1940068*)

LEARNING OBJECTIVE 1: To recognize the clinical manifestations and pathophysiology of Ehlers-Danlos syndrome Type IV in the setting of an acute vascular presentation

LEARNING OBJECTIVE 2: To review evidence-based management for Ehlers-Danlos syndrome Type IV

CASE: A 31 year old gentleman without significant previous medical history presented with severe abdominal pain that started suddenly in his right and left upper abdomen. On arrival to the emergency room, the gentleman was noted to have several episodes of bilious emesis and multiple episodes of brown, watery diarrhea. A mild leukocytosis with left shift was observed along with a fever of 101.5 F and stable hemodynamics. Concerns were raised for diverticulitis or colitis and a CT abdomen/pelvis was performed demonstrating a left common and external iliac dissection (with evidence of prior extravasation without active leak) as well as bilateral renal infarcts, a small L common iliac aneurysm (1.7 cm) and a question of bilateral renal artery aneurysms. A vascular surgery consultation was placed and a CT head/neck/chest was performed without additional concerning findings. Due to concerns for the presence

of possible renal artery aneurysms, anti-coagulation was initiated with intravenous heparin. Renal artery duplex was unhelpful and a renal angiogram was planned but delayed by emergent cases. On hospital day (HD) 2, additional low grade fevers were also noted. Blood cultures drawn on admission remained negative. On HD 3, after additional questioning, the patient remembered further medical history including prior bilateral inguinal herniorrhaphies in a setting of playing sports as an adolescent and multiple bilateral spontaneous shoulder dislocations. A focused exam revealed very pale skin, periorbital hyperpigmentation, talipes equinovarus and exaggerated joint laxity. Concerns for connective tissue disease were raised. Rheumatology was consulted on HD 3 and recommended a genetics consultation to rule out connective tissue disease. Renal angiogram performance was then scheduled for early afternoon the following day (HD 4). On HD 4, the genetics fellow saw the patient just prior to the patient's transfer to the operating room for renal angiogram performance. After a discussion with the genetics attending, the genetics fellow contacted the primary team with a likely diagnosis of Ehlers-Danlos syndrome Type IV and a request for expedited cancellation of the renal angiogram, a procedure that could result in massive dissection/obliteration of arterial vasculature in an Ehlers-Danlos syndrome Type IV patient. The procedure was cancelled just moments prior to the start of the procedure. Collagen vascular disease markers were sent for testing as a part of the genetics work-up. All rheumatologic and hypercoagulability testing returned negative. An angiotensin-converting enzyme inhibitor was initiated as standard therapy. Genetics testing later returned positive for Ehlers-Danlos syndrome Type IV.

DISCUSSION: Ehlers-Danlos syndrome Type IV is a rare inherited connective tissue disorder (one of six types of Ehlers-Danlos syndromes) caused by a mutation in type III procollagen (Col3A1). It may be seen in 1/25,000 people. The diagnosis is made by identifying clinical criteria and testing positive for the type II procollagen genetic mutation. The clinical features include a characteristic narrow facies with periorbital hyperpigmentation, pale skin with visible subcutaneous vessels, easy bruising and history of arterial/digestive tract rupture. Obstetric complications may also be seen in women. Arterial complications including aneurysm rupture and dissection as well as gastrointestinal rupture can be fatal and occur in 80 % of these patients prior to reaching age 40. While there is no active reversal of this condition, medical management with optimal blood pressure control via an angiotensin-converting enzyme inhibitor with anti-TGF properties, anticoagulation (indicated in the setting of aneurysm formation) and avoidance of contact sports/strenuous activity is generally recommended. Although surgery may be performed in a setting of trauma, invasive procedures should typically be avoided. Taking a careful history and understanding the underlying clinical pathophysiology of Ehlers-Danlos syndrome Type IV as well as standard management and therapy are integral to delivering evidence-based care and avoiding catastrophic events in this population.

A CASE OF ISCHEMIC DIGITS AND PAINFUL MUSCLES Sagar Y. Patel; Matt Blackwell; Leslie Pack. Carolinas Medical Center, Charlotte, NC. (*Tracking ID #1901937*)

LEARNING OBJECTIVE 1: Discuss the diagnosis, prognosis, and treatment of calcific uremic arteriolopathy

LEARNING OBJECTIVE 2: Differentiate calcific uremic arteriolopathy from other rheumatologic disorders

CASE: A 60-year-old man on dialysis with atrial fibrillation on warfarin presented with bilateral digital necrosis and progressive lower extremity myalgias. Two weeks prior to presentation, he noticed a small lesion on his left 2nd finger that was treated with Keflex. He gradually developed numbness and ulcerative lesions on multiple digits bilaterally which progressed to dry gangrene. He also had a nine-month history of progressively worsening myalgias and weakness for which he was empirically treated with prednisone. The prednisone alleviated his pain but his weakness persisted. Multiple attempts to taper his prednisone were unsuccessful due to increasing pain. On exam, he had palpable pulses throughout, but his digits were cool with multiple necrotic, gangrenous lesions bilaterally. He had considerable muscle wasting and tenderness of his lower extremities. Strength was 4+/5 in all upper and lower extremity muscles groups. A MRI of his legs revealed diffuse muscle edema. His labs revealed an albumin of 2.2 g/dL, calcium of 8.2 mg/dL, phosphate of 7.9 mg/dL and parathyroid hormone level of 196 pg/mL. Rheumatologic labs (including ANA, anti-PR3, anti-MPO, CPK, Aldolase, Cryoglobulins, C3 and C4) were negative. Coagulopathy work-up (including Antiphospholipid Antibody, SPEP, Factor II,

V, VIII, X) was also negative. A transesophageal echocardiogram revealed moderate diastolic dysfunction but no definitive embolic source. Hand x-ray showed severe calcific vasculopathy. EMG revealed diffuse myopathic changes without fibrillation. A muscle biopsy showed moderate type II muscle fiber atrophy. Arteriograms demonstrated widely patent but severely calcified bilateral subclavian, axillary, and brachial arteries as well as severely stenotic bilateral radial and ulnar arteries. Bilateral balloon angioplasty provided pain relief and some recovery of sensory function. Inflammatory myopathy was felt to be unlikely, and steroid taper was initiated, resulting in excruciating pain. Intravenous sodium thiosulfate was started, but unfortunately our patient developed progressive digital ulcerations bilaterally with associated dry gangrene (images included), mottling of both thighs, and early signs of toe ulcerations. His condition worsened with the development of ischemic bowel and ileus. At that point, the patient and his family pursued comfort care, and he passed away shortly thereafter.

DISCUSSION: This case was felt to be an unusual example of calcific uremic arteriolopathy (i.e. calciphylaxis) - a rare complication most commonly seen in dialysis patients that is associated with significant morbidity and mortality. It is often characterized by extra-osseous calcification of the small vessels leading to ischemia with subcutaneous necrosis in areas of greatest adiposity. Less commonly, patients will present with digital ischemia, livedo reticularis, and ischemic myopathy. Labs may or may not reveal elevated parathyroid hormone levels and increasing calcium-phosphate product. Diagnosis is typically based on clinical judgment and findings of the characteristic necrotic eschars, ulcerations, indurated nodules, and dry gangrene. Biopsy of lesions can be done but, as in our case, is sometimes avoided due to concerns of poor wound healing and infection. If biopsy is performed, histologic analysis may reveal small vessel mural calcification, endovascular fibrosis, extravascular calcification, and thrombotic vaso-occlusion. Potential risk factors include female sex, obesity, hypercoagulable state and hypoalbuminemia as well as medications such as warfarin, calcium-based binders, vitamin D analogues and systemic corticosteroids. Given our patient's clinical presentation, exam findings, risk factors, key laboratory results and radiologic findings, calcific uremic arteriolopathy was felt to best explain his progressively diffuse necrosis and severe myalgias. His muscle wasting was attributed to long-term steroids. This atypical presentation of calcific uremic arteriolopathy has significant overlap with presentations of inflammatory myopathies, vasculitides and coagulopathies. Our case highlights the importance of considering this diagnosis in high risk patients. The poor prognosis of this disorder makes early recognition critical because the sooner treatment is initiated the better the chance of recovery. Treatment is a multifaceted approach with focus on correcting underlying electrolyte abnormalities, discontinuation of contributing medications, adequate dialysis, aggressive wound care and proper pain management. Parathyroid hormone levels can be reduced with cinacalcet or, in refractory cases, via parathyroidectomy. Some studies have shown improvement of skin lesions with hyperbaric oxygen chambers as well as intravenous sodium thiosulfate, an antioxidant and cation chelator.

A CASE OF ISOTRETINOIN-INDUCED ACUTE RHABDOMYOLYSIS Sara Flores; Habtamu A. Asrat; Manish Jain. Presence St. Francis Hospital, Evanston, IL. (Tracking ID #1934868)

LEARNING OBJECTIVE 1: Distinguish between benign elevation of creatine phosphokinase (CPK) and acute rhabdomyolysis.

LEARNING OBJECTIVE 2: Recognize some of the possible side effects for the systemic retinoid, isotretinoin (Accutane).

CASE: An eighteen-year-old female with no medical history presented with three days of calf cramping, generalized weakness, and cola-colored urine. There was no recent trauma or change in exercise activity. She denied smoking cigarettes, drinking alcohol, using street drugs and engaging in sexual activity. Family history was negative for rheumatologic, metabolic and myopathic disease. Oral Accutane was her only medication and was started 3 weeks prior to presentation. Vitals were normal. She was well nourished and had bilateral calf tenderness. There were no rashes. CMP and CBC were normal, but total serum CPK was 8,554 and rose to 17,116 over 12 h. Serum myoglobin was high. C-reactive protein, ESR, TSH, free T4, free T3, ANA, ASO, anti Jo-1, RF, myeloperoxidase Ab, thyroid peroxidase Ab, ANCA proteinase 3, HIV, hepatitis B and C and urine toxicology were negative. Serum creatinine was 0.67. AST and ALT were 215 and 59 respectively. Urine dipstick was positive for blood,

but no red blood cells were visible on microscopic analysis. No imaging was done. Electrocardiogram showed normal sinus rhythm, normal axis and no ST- or T-wave changes. The diagnosis was acute rhabdomyolysis. Normal saline at 125 cm³/h was administered and CPK decreased over next 24 h to 12,078. Serum Cr remained approximately 0.57. Patient's symptoms resolved within 48 h, and patient was discharged in stable condition.

DISCUSSION: Muscle pain, generalized weakness, myoglobinuria and elevated serum CPK characterize acute rhabdomyolysis. However, diagnosis requires only acute neuromuscular symptoms or asymptomatic dark urine, plus acute elevation in serum CPK five times the upper level of normal in the absence of brain or cardiac injury. Many causes exist, including muscle trauma, drugs, infections, strenuous exercise, seizures and metabolic myopathies. Although the instigation may vary, the events preceding cellular destruction are the same. Increase in intracellular calcium activates proteases, which degrade proteins within the myocyte. Reduction of ADP to ATP by the electron transport chain may also be impaired. ATP deficiency leads to malfunction of cellular membrane channels and pumps. Cellular death ensues, and calcium, potassium, phosphate and myoglobin are released. Urine dipstick cannot differentiate hemoglobin from myoglobin. Visualization of red blood cells during microscopic analysis confirms hematuria, whereas their scarcity confirms myoglobinuria. Myoglobin is rapidly excreted through the renal tubules and causes tea-colored urine at levels ranging from 100 to 300 mg/dL. As concentration increases, accumulation and blockage within renal tubules may occur, leading to acute tubular necrosis. Copious hydration is necessary to prevent acute kidney injury. Elevation of serum aminotransferases are common but do not correspond to hepatic injury. Accutane is a systemic retinoid acid that inhibits sebum production, which prevents clogging of pores and inhibits colonization by Propionibacterium acnes. Since retinoid receptors are ubiquitous throughout the body, Accutane has several potential complications, including xerosis, nausea, anorexia, transaminitis, suicidal ideation, hypertriglyceridemia and hypercholesterolemia. Craniofacial, central nervous system and thymic birth defects may occur if a woman becomes pregnant while taking oral isotretinoin. These devastating birth defects prompted the FDA to establish I-Pledge, a national registry for regulating all those having access to isotretinoin within the United States. Every patient is regulated to ensure use of two forms of birth control in female patients and monthly blood testing, including lipid panel and liver function testing. Elevation of serum creatine kinase was first reported in the 80's and 90's as a benign side effect. In the largest reported series consisting of 442 patients, elevated CPK was reported in 37.3 % of patients, but only 1.58 % had CPK levels >5000 U/L, along with symptoms. Only four cases report muscle pain or weakness, five-fold increase in serum CPK levels and myoglobinuria occurring simultaneously, 6–8 with one having a fatal outcome. Most cases are associated with vigorous exercise during treatment and describe resolution of symptoms and normalization of CPK values within days to weeks after Accutane is discontinued. Our case is the fifth reporting acute rhabdomyolysis with use of Accutane. Our patient had exercised prior to developing symptoms, but her workout was no more strenuous than usual, and there was no evidence in history or laboratory investigation of metabolic, immunologic or rheumatologic disease. Prompt recognition of the symptoms and signs of acute rhabdomyolysis was important for prevention kidney injury in a patient at otherwise low risk.

A CASE OF MYCOBACTERIUM MUCOGENICUM BACTEREMIA-DECIDING TREATMENT AND DURATION OF THERAPY Gagan Preet; Deepak Garg. WMU, Kalamazoo, MI. (Tracking ID #1937148)

LEARNING OBJECTIVE 1: To learn the management of Mycobacterium bacteremia.

CASE: 42 year old female presented with fever along with chills and rigors, malaise and nausea over past 7 days. Patient was recently diagnosed with breast cancer and had undergone bilateral mastectomies and subsequent subcutaneous implantable port (mediport) placement for the administration of chemotherapy. Her last chemotherapy was 2 weeks prior to admission. Social history was non-contributory. On physical examination patient was found to be hypotensive (BP 100/50), tachycardiac (HR 118/min), and febrile (Temp 102 F). Otherwise rest of the examination was unremarkable. Initial labs showed WBC 17000 cells/mm³, Hb 11.2 mg/dL, Plt 371. Differential showed absolute neutrophilia. Comprehensive Metabolic Panel, UA and CXR were

unremarkable. After 4 days 1 out of 2 sets of blood cultures from the mediport came back positive for acid fast bacilli (AFB). Peripheral blood cultures were negative. Subsequently patient was started on Amikacin and Clarithromycin empirically. Mediport was removed and mediport cultures also grew AFB. Both Mycobacterium isolates were finally identified as *Mycobacterium mucogenicum*. Based on the sensitivities, Amikacin was changed to oral TMP/SMX after 7 days. All subsequent blood cultures were negative for any growth. Patient improved and was discharged to complete therapy with Clarithromycin and TMP/SMX for 1 month.

DISCUSSION: Rapid growing mycobacteria (RGM) are ubiquitous organisms and in recent years have emerged as an important cause of Central line associated blood stream infections (CLABSI). RGM can also present as wide spectrum of clinical syndromes including respiratory tract, skin infections, osteomyelitis, disseminated infections. Since there are no clear guidelines on how to manage such infections, it can be challenging for the physicians to treat them. Experts report using two active agents empirically and consideration should be given to include Amikacin in initial regimen, as most of RGM are sensitive to Amikacin. But often identification and susceptibility takes more than seven days and use of Aminoglycosides may cause renal toxicity, limiting the use of Aminoglycosides as primary empiric therapy. As from our literature review most of rapid growing mycobacteria are sensitive to Macrolides and TMP/SMX, whether these agents can be used as primary oral empiric regimen needs more evidence. Other management issues including search for disseminated disease, central venous catheter removal, timing of placement of new catheter, duration of therapy and optimal definitive regimen needs more understanding.

A CASE OF PECTUS EXCAVATUM AND NEW ONSET ATRIAL FIBRILLATION Isabel Preeshagul; Gargi Bajpayee; Preety Chawla; Shamit Patel. Beth Israel Medical Center- Mount Sinai Division, New York, NY. (*Tracking ID #1940140*)

LEARNING OBJECTIVE 1: To recognize the association between new onset Atrial Fibrillation and Pectus excavatum

LEARNING OBJECTIVE 2: Review the value of cardiac imaging in patients with severe Pectus Excavatum

CASE: A 24 year old African American woman with a history of tricuspid regurgitation, and ligament laxity presented to the emergency department, ED, complaining of sudden onset of palpitations and dizziness for 1 day. Her EKG upon arrival demonstrated atrial fibrillation, AF, with rapid ventricular response at a rate of 158. She was cardioverted and started on a heparin drip for 48 h. Post cardioversion EKG revealed normal sinus rhythm at a rate of 74, right atrial enlargement and ventricular hypertrophy. Her cardiac exam was significant for pectus excavatum, palpable loud P2, and grade four pansystolic murmur at the left lower sternal border. Her musculoskeletal exam revealed long thin extremities and joint hypermobility. The remainder of her exam was normal including laboratory testing. Further evaluation with a transthoracic echo demonstrated redundant tricuspid valve leaflets, moderate tricuspid regurgitation and extrinsic compression of the right ventricle with an ejection fraction of 35 %. She then underwent a cardiac MRI to evaluate for arrhythmogenic right ventricular dysplasia that confirmed severe pectus excavatum with a pectus severity index (PSI) of four. The PSI is measured by dividing the transverse diameter of the chest by the anterior-posterior diameter on MRI. She was evaluated by cardiothoracic surgery and in 1 month will undergo the Nuss procedure-a minimally invasive surgery involving the temporary insertion of a metal bar beneath the chest wall, forcing the sternum outward.

DISCUSSION: Our case highlights the significance of recognizing the correlation of pectus excavatum in patients with new onset AF. Further investigating the underlying etiology of this cardiac arrhythmia with echo and cardiac MRI can aid in diagnosis, expediting a patient's time to corrective surgery and ultimately preserve cardiac and lung function. Our case is relevant as pectus excavatum is present in one out of every 400 births, often associated with connective tissue disorders such as Marfan and Ehlers-Danlos Syndrome and cardiac arrhythmias. The anterior positioning of the right ventricle permits compression from the depressed sternum, which increases right ventricular pressure, dilates the right atrium and potentiates conduction abnormalities. There appears to be a relationship between lone AF and pectus excavatum as demonstrated in a retrospective analysis of 545 patients with pectus excavatum. This study compared the PSI of 220 patients with lone AF to 225 patients without lone AF. The data revealed that the mean PSI was higher in those with lone AF ($P < .001$). This indicates that the severity of a patients' pectus excavatum may influence their

propensity to develop AF. Recognizing this correlation and the importance of cardiac imaging to evaluate the underlying cause of the arrhythmia is crucial, as it may alter a patient's future quality of life.

A CASE OF PERSISTENT ANTERIOR MEDIASTINAL MASS IN A PATIENT WITH GRAVES' DISEASE Rie Ueno¹; Misako Nagasaki¹; Koji Sasaki². ¹Beth Israel Medical Center, New York, New York, NY; ²The University of Texas MD Anderson Cancer Center, Houston, TX. (*Tracking ID #1934438*)

LEARNING OBJECTIVE 1: Identify the association of anterior mediastinal mass with Graves' Disease

LEARNING OBJECTIVE 2: Recognize the variable clinical course of anterior mediastinal mass and understand the importance of close radiological follow up

CASE: A 23-year-old Chinese woman with a 5-year history of Graves' disease (GD) was admitted for a newly diagnosed ovarian tumor. During workup for the tumor, computed tomography (CT) of the chest incidentally showed a large homogeneous anterior mediastinal opacity, $8.6 \times 3.1 \times 7.4$ cm. Physical examination revealed a diffusely enlarged thyroid gland. Thyroid stimulating immunoglobulins were elevated at 468 %, TSH < 0.03 mU/mL, elevated free T4 3.1 ng/dL. Mediastinal biopsy showed immature T cells, negative for primary malignancy or metastases. She was started on treatment with methimazole for hyperthyroidism, underwent salpingo-oophorectomy and was discharged with adjuvant chemotherapy for stage Ic ovarian papillary cystadenocarcinoma. Her free T4 returned to normal within 2 months after optimization of methimazole treatment. Chest CT showed that the mediastinal mass had decreased to $2.4 \times 1.2 \times 2.3$ cm at that time. However, despite maintenance of her euthyroid status, repeat CT 6 months after treatment revealed that the homogeneous mediastinal mass had increased to $5.2 \times 3.1 \times 7.2$ cm. The patient was referred to cardiothoracic surgery for consideration of thymectomy secondary to failure of regression of the mass with medical management of her hyperthyroidism.

DISCUSSION: Thymic hyperplasia in patients with Graves' Disease (GD) was first reported by Halsted in 1914. Although Michie and Gunn have reported that up to 38 % of patients with thyrotoxicosis have histologic changes in the thymus gland, these findings are usually minimal. Radiologically detectable thymic enlargement as an anterior mediastinal mass has been infrequently reported. Several cases describe that these anterior mediastinal mass often represent benign thymic hyperplasia and regress within a few months after treatment of hyperthyroidism. However, unnecessary surgical interventions have been performed in half of these cases due to a small, yet true concern for neoplasms such as thymoma. A recent review recommends surgical intervention if the size of the mass does not decrease in spite of the patient being euthyroid for several months. In our case, the size of the anterior mediastinal mass significantly increased in a 6-month follow-up despite maintenance of the euthyroid status and thus she was referred to surgery. The literature on the management of patients with GD presenting with a mediastinal mass is limited and the true risk of mediastinal neoplasms remains unknown. Our case suggests the importance of further accumulation of long-term follow up data on patients who present with mediastinal mass with GD to better understand the clinical course and the optimal timing of surgical intervention.

A CASE OF PULMONARY BENIGN METASTATIC LEIOMYOMA (BML) PRESENTING AS MULTIPLE PULMONARY NODULES (MPN) Marcia Ciccone¹; Agustin A. Garcia². ¹University of Southern California, Keck School of Medicine, Los Angeles, CA; ²University of Southern California, Keck School of Medicine, Los Angeles, CA. (*Tracking ID #1928903*)

LEARNING OBJECTIVE 1: Consider BML in a female with MPN

LEARNING OBJECTIVE 2: Recognize clinical features of BML

CASE: A 34 year-old female presented with MPN noted incidentally on chest X-ray performed for a positive PPD. She denied pulmonary symptoms or signs of systemic disease. Past medical history was significant for a seven-year history of menorrhagia and uterine leiomyomata. Family history included a maternal grandmother with uterine cancer. She is a non-smoker and a nurse. Physical exam was unremarkable. Computerized tomography (CT) of the chest showed multiple bilateral non-calcified lung nodules measuring between 3 and 19 mm. Positron emission tomography showed increased metabolic activity in the largest nodule, a uterine mass, a large extra-uterine mass, and enlarged hypermetabolic para-aortic and common-iliac nodes.

She underwent a total hysterectomy without oophorectomy. Surgical findings included multiple leiomyoma involving the uterus, parametria, peritoneum, and left para-aortic region. Pathology showed no evidence of necrosis, atypia, or increased mitotic activity. Lesions were described as best fitting BML. Repeat CT scan 5 months later showed increase size of the nodules. CT-guided core lung biopsy demonstrated a metastasizing smooth muscle tumor; diagnosis of BML was confirmed by direct comparison of lung biopsy and uterine pathology. Treatment with leuprolide 22.5 mg IM every 3 months was started. Subsequent CT scans showed decreased size of the largest nodule and resolution of the remaining masses.

DISCUSSION: Our patient presented with MPN. Work-up of these should include a thorough history and physical examination. It is essential to distinguish between benign and malignant nodules. Multiple nodules larger than 1 cm are likely due to metastatic disease from a distant primary tumor. The most common malignancies to manifest as MPN include tumors of testes, ovaries, kidneys, and breast as well as melanomas and sarcomas. Benign causes of MPN include infections, non-infectious inflammatory conditions, arteriovenous malformations, and pneumoconiosis. Our patient lacked findings to suggest these entities. A biopsy was done establishing the diagnosis of BML. BML is a rare condition of well-differentiated, extra-uterine smooth muscle tumors. The etiology is unknown. Over 150 cases have been documented, most in women with prior surgery for uterine leiomyomata. As in our case, the patient may be asymptomatic and diagnosis is incidental; however, it may also present with dyspnea and respiratory distress and has been known to cause pneumothorax and pleural effusion. The most common site of metastases is the lungs; other sites are lymph nodes, deep soft tissues, the omentum and mesentery, bones, nervous system, and the heart. In contrast to leiomyosarcoma, BML has an indolent course and is differentiated histologically by having fewer than 5 mitoses per high power field in the absence of necrosis and cytologic atypia. The mainstay of treatment is primary tumor resection and medical and/or surgical oophorectomy. Other pharmacologic interventions include aromatase inhibitors, raloxifene, tamoxifen, and progestins. Or, BML may be expectantly managed with serial imaging. This case illustrates the importance of considering gynecological conditions in women with MPN. Specifically, BML should be considered in women with history of uterine fibroids. Physicians should be aware that there is no standard treatment and management must be individualized.

A CASE OF TOXIC SHOCK SYNDROME ASSOCIATED WITH THE USE OF THE NUVARING Jack C. Naggar; Nicole Adler. NYU, New York, NY. (*Tracking ID #1897155*)

LEARNING OBJECTIVE 1: Recognize the clinical features and risk factors of toxic shock syndrome

CASE: A 21-year-old woman with a history of bulimia presented with 1 day of fever to 104.0, diffuse rash, myalgias and abdominal pain. The patient was sexually active with men, and used condoms regularly. She used the NuvaRing for contraception. Her last menstrual period was approximately 3 weeks prior to presentation, and the vaginal ring was inserted two and a half weeks prior to presentation. She reported following instructions for appropriate use of the vaginal ring. Her last sexual encounter was 1 day prior to presentation. On physical examination she was febrile to 104.8, tachycardic and hypotensive. Her exam was notable for diffuse erythroderma. She had conjunctival injection and dry cracked lips. Abdominal exam revealed mild tenderness in the upper quadrants. Vaginal exam demonstrated edematous labia bilaterally, and a thin non-malodorous yellow discharge. The NuvaRing was removed. Laboratory data was notable for a leukocytosis, bandemia and thrombocytopenia. Chemistries obtained showed lactic acidosis, and normal renal and liver function. A pregnancy test was negative. Urinalysis was positive for Leukocyte Esterase, and there were 235 WBC/high powered field. Urine culture grew pan-sensitive Staphylococcus Aureus. The same organism was isolated from vaginal cultures as well. Blood cultures were without growth. The patient was admitted to the intensive care unit with a diagnosis of toxic shock syndrome secondary to NuvaRing. She had intermittent episodes of hypotension that were responsive to fluid resuscitation. She was treated with vancomycin, clindamycin, and aztreonam. The patient improved clinically and was discharged on hospital day four to complete a course of cefadroxil.

DISCUSSION: The Centers for Disease Control and Prevention defines toxic shock syndrome as an illness with six clinical findings. If all six are present the diagnosis is confirmed. A probable diagnosis requires five of the six clinical features. They include: fever, erythroderma, desquamation, hypotension, negative body fluid cultures

(other than staph aureus, including viral serologies), and multisystem involvement. Toxic shock syndrome is described as menstrual and non-menstrual related. The non-menstrual cases occur most often post-operatively, or as a result of sinusitis, mastitis or cutaneous staphylococcal infections. Toxic shock syndrome is listed under the possible adverse effects of the NuvaRing. There are however, no case reports documenting such an association. This patient suffered from a probable case of toxic shock syndrome. While impossible to prove a causal relationship between vaginal contraceptive rings and toxic shock syndrome, this patient had no other risk factors for non-menstrual toxic shock syndrome. To our knowledge this is the first report of toxic shock syndrome associated with appropriate NuvaRing use.

A CASE REPORT OF ALTERED MENTAL STATUS FROM A PARATHYROID CARCINOMA Nanase Honda; Christine Kwan. Teine Keijinkai Medical Center, Sapporo, Japan. (*Tracking ID #1935458*)

LEARNING OBJECTIVE 1: Recognize the possibility of parathyroid carcinomas (CA), not just adenomas, in patients with primary hyperparathyroidism

LEARNING OBJECTIVE 2: Treat with en-block resection with preoperative suspicion of parathyroid CA

CASE: An 80-year-old Asian woman presents with unwitnessed loss of consciousness. Her son finds her lying on the floor after an unknown period. She denies other neurological symptoms in addition to all other review of systems. Her past medical history includes hypertension for which she takes amlodipine; she has no allergies. She smokes 1 pack/day × 50 years but does not drink alcohol nor use recreational drugs. Her family history is unremarkable. On examination, the patient is alert/oriented to person and time (baseline). Her temperature is 36 °C, blood pressure 160/75, pulse 65, respiratory rate 18, and O₂ saturation 97 % room air. Head/neck exam reveals a non-tender, hard, mobile, 2 cm mass in the right thyroid lobe; no lymphadenopathy. The rest of the examination is unremarkable. Laboratory testing, including complete blood counts and chemistry, is significant for serum calcium (Ca)=16.3 mg/dL, albumin=3.1 g/dL, corrected Ca=17.2 mg/dL, and intact parathyroid hormone (PTH)=432 pg/mL. Neck ultrasound shows a 3 cm heterogeneous mass in the right lower thyroid lobe, and sestamibi scan demonstrates focal retention of tracer over the right lower pole of the thyroid. During this time, the patient has been receiving normal saline, calcitonin, and bisphosphonate with improvement of her mental status, and she is scheduled for a parathyroidectomy for suspicion of parathyroid adenoma. In the operating room, however, a large, stone-hard mass adherent to the inferior pole of the patient's right hemithyroid is discovered; it is surrounded by a dense, fibrous, and grayish-white capsule suggestive of parathyroid malignancy. En-block resection, including the ipsilateral thyroid lobe and paratracheal lymphatic tissue, is done. Pathology results confirm the diagnosis of parathyroid CA with local invasion of contiguous soft tissue and muscle. Postoperatively, the patient's Ca decreases to 8 mg/dL, and her Ca and PTH levels are followed up as an outpatient. No further surgical treatment is currently planned because recurrent or metastatic disease has not been identified.

DISCUSSION: Parathyroid adenomas represent a common endocrine problem whereas parathyroid CA very rarely occur as they are one of the rarest human cancers. They cause hyperparathyroidism in ~0.2–5 % of cases although many case series report this entity to account for <1 % of patients with primary hyperparathyroidism. Parathyroid CA are hyperfunctional unlike other endocrine tumors that become less hormonally active when malignant. Its clinical features are caused primarily by the effects of the tumor's excessive PTH secretion rather than by tumor cells' infiltration of vital organs. Preoperative suspicion and intraoperative recognition of parathyroid CA is critical to achieve a favorable outcome. Nonsurgical therapies such as radiation and chemotherapy have yielded poor results in the treatment of parathyroid CA. In this case, the patient's clinical features consistent with parathyroid CA include a hard, palpable neck mass, hypercalcemia >14 mg/dL, high PTH >2× normal, and severe hypercalcemia symptoms. Given preoperative suspicion of parathyroid CA, en-bloc resection with avoidance of capsular violation or tumor spillage should be performed.

A CASE REPORT OF B-CELL FOLLICULAR LYMPHOMA IN AN ASYMPTOMATIC WOMAN WITH VIRCHOW'S NODE Takako Akimoto; Christine Kwan. Teine Keijinkai Medical Center, Sapporo, Japan. (*Tracking ID #1933912*)

LEARNING OBJECTIVE 1: Recognize that asymptomatic, while uncommon, lymphadenopathy can be caused by lymphoma

LEARNING OBJECTIVE 2: Recognize that Virchow's node occurs not only from abdominal/thoracic malignancies

CASE: A 68 year-old Asian woman presents with 2 weeks' history of gradual swelling in her left supraclavicular fossa that is not painful/erythematous/itchy. She denies fever, chills, weight/appetite change, night sweats, and fatigue, in addition to all other review of systems. Her past medical history includes gastric cancer status post (s/p) resection (6 years ago), hypertension, mitral valve stenosis s/p replacement, and sick sinus syndrome s/p pacemaker. She takes carvedilol, candesartan, torsemide, verapamil, and warfarin; she has no allergies. She does not use tobacco, alcohol, or recreational drugs. Her family history is significant for lung cancer in her brother. Physical examination shows blood pressure 136/86, pulse 65, respiratory rate 18, O₂ saturation 98 % room air, and temperature 36.4C. Head/neck exam reveals pale conjunctiva and 3 hard, nontender, 1×1 cm, fixed supraclavicular lymph nodes; no axillary or inguinal lymphadenopathy. The rest of the exam shows no irregularities. Laboratory testing, including complete blood counts and chemistry, is significant for hemoglobin (Hgb)=11.4 g/dL, lactate dehydrogenase (LDH) elevation (331U/L), and PT INR (2.64). Neck ultrasound shows 3–16 mm, lobular, heterogeneous lymph nodes, and biopsy reveals malignant B-cell follicular lymphoma (FL) with left supraclavicular fossa involvement. Chest/abdominal computed tomography shows lymphadenopathy in the left supraclavicular, mediastinal, abdominal paraaortic, and mesenteric lymph nodes (<3 cm); positron emission tomography reveals hot spots in the above corresponding areas. Bone marrow biopsy and immunohistochemistry shows (+) CD10/20/23 and BCL2. The patient is then started on rituximab.

DISCUSSION: Unexplained lymphadenopathy in the general population occurs in only 0.6 % annually. In a study with 2556 patients presenting to their family physician with unexplained lymphadenopathy, only 3 % requires a biopsy while 1 % has a malignancy; the prevalence of malignancies in lymph node biopsies is 40–60 %. Abdominal/thoracic malignancies can metastasize to the supraclavicular lymph nodes, Virchow's sentinel node, as seen in the above patient. In this patient, however, while she has a history of gastric adenocarcinoma, her lymphadenopathy is actually from malignant lymphoma, not an abdominal/thoracic malignancy. While no specific study about the prevalence of Virchow's node has been conducted, one study has shown that malignancies originating in the pelvis/abdomen are more likely to metastasize to the left supraclavicular lymph node and that the primary site/types of malignancies involved in the left supraclavicular lymph node are different from the right. Only ~10 % of those patients with positive nodes have a diagnosis of leukemia, non-Hodgkin's, or Hodgkin's disease. Patients with FL generally present with asymptomatic lymphadenopathy for years, and <20 % of patients present with B symptoms. The above patient likewise denies any B symptoms. Her FL International Prognostic Index=4 points (>60 years, Hgb<12 g/dL, elevated LDH, and Ann Arbor stagIVA) indicating poor survival. Regardless, this case illustrates that Virchow's node can asymptotically occur in settings besides abdominal/thoracic malignancies. 1) Fijten GH, Blijham GH. A CASE REPORT OF COLONOSCOPY'S CAUSING CARDIAC ARREST
Masayuki Ohta; Christine Kwan. Teine Keijinkai Hospital, Sapporo, Japan. (Tracking ID #1929230)

LEARNING OBJECTIVE 1: Recognize that colonoscopies may cause takotsubo cardiomyopathy with resultant ventricular fibrillation

CASE: An 84-year-old Asian woman presents with 5 days' history of gradual-onset, worsening dyspnea that improves with sitting up and worsens with lying down and exercise. She also reports nausea, decreased appetite, diaphoresis, fatigue, wheezing, orthopnea, and bilateral lower extremity edema; no fever, chills, other upper/lower respiratory, or cardiac symptoms. All other review of systems shows no abnormalities. Of note, she has undergone a routine screening colonoscopy 5 days ago. She has a history of thyroid papillary carcinoma with lobectomy, gastritis, dyslipidemia, and constipation and takes levothyroxine, famotidine, ecabet, pravastatin, and senna; she has no known allergies. Her social and family history demonstrates no risk factors.

On physical examination, her temperature=36.4 °C, pulse=52, blood pressure=144/72, respiratory rate=18, and O₂ saturation=97 % room air. She sits comfortably; alert/oriented ×3. Her head/neck and heart exams show no abnormalities, but jugular venous pressure=12cmH2O. Her breath sounds are decreased throughout but no wheezing or crackles. She has bilateral lower extremity pitting edema up to mid-shins. On labs, her blood counts, electrolytes, and thyroid function are all within normal limits except for blood urea nitrogen=19.8 mg/dL, creatinine=1.03 mg/dL (baseline 0.7 mg/dL), creatine kinase (CK)=255 U/L, CK-MB=11.7 ng/ml, and BNP=2115 pg/ml. Chest x-ray shows bilateral dull cardiopulmonary angles with cardiothoracic ratio=65 %. Electrocardiogram (ECG) reveals 2:1 atrioventricular block (AVB) and T wave inversions in V1-V6. Transthoracic echocardiogram shows an akinetic wall in the apex and mid-left ventricle (LV); ejection fraction=51 %. Given the patient's diastolic congestive heart failure, carperitide (alpha-human atrial natriuretic peptide) is given. Meanwhile, her T wave inversions increase in size while still maintaining 2:1 AVB. Eventually, she worsens to ventricular fibrillation but is successfully resuscitated with external pacemaker placement. Angiography shows right coronary artery with 75 % stenosis. LVgram shows depressed contractile function in the mid/apical segments of the LV and hyperkinetic basal wall consistent with takotsubo cardiomyopathy. With furosemide, she slowly recovers and is discharged after 1 month with permanent pacemaker placement.

DISCUSSION: Although the risk of serious complications following colonoscopy is low, ~2.8/1000 exams, they include bleeding, perforation, infection, and cardiopulmonary events. Only 3 acute cardiac failures have been reported in ~3 million colonoscopies in Japan. Takotsubo, or stress-induced, cardiomyopathy is known to be associated with emotional (30 %) or physical (41 %) stress, which includes anesthesia, surgery, gastrointestinal endoscopy, infection, and strokes. Colonoscopies comprise <1 % of all causes. Takotsubo cardiomyopathy generally has a good prognosis, but fatal arrhythmias may occur. T-wave inversions are a common ECG change (38 %) with particularly distinctive giant ones that can lead to prolonged QT. High-degree AVB occurs only rarely (1 %), but in the above case, it may have predisposed the patient to develop torsades de pointes. Although the mortality rate related to colonoscopies is only <1 %, physicians should be aware of the possibility of fatal arrhythmias.

A CASE REPORT OF NECROTIC FINGER FROM PYODERMA GANGRENOsum Yugo Soga; Christine Kwan. Teine Keijinkai Hospital, Sapporo, Japan. (Tracking ID #1948669)

LEARNING OBJECTIVE 1: Recognize that pyoderma gangrenosum (PG) can also occur in the fingers

CASE: A 36 years old Asian man presents with 3 weeks' abrupt onset, right middle finger skin necrosis along with swelling/redness for which he is initially diagnosed with purulent sore and prescribed cefazolin and incision and drainage ×2 with minimal improvement. The rest of his review of systems shows no abnormalities. His past medical history includes right leg and gluteal necrotizing soft tissue infection 3 years ago and massive gastrointestinal (GI) bleed from nonsteroidal anti-inflammatory drug use last year. He has no allergies and takes no medications. He quit tobacco and alcohol 9 months ago; prior 30 pack-years and 750 mL shochu/day ×20 years. He is an unemployed bartender and sexually active with 1 female partner but no condom use. His family history includes diabetes, alcoholism, and liver disease in his father and alcoholism in his brothers. On exam, vital signs show temperature 36.6, heart rate 90, blood pressure 105/74, O₂ saturation 99 % room air, and respirations 14. Generally, he is in no acute distress; alert/oriented ×3. His right middle finger has ulceration with necrosis from the metacarpal to distal interphalangeal joint. The rest of his exam shows no irregularities. Significant lab results reveal white blood cell 14,000/µL, platelets 63×10³/µL, partial thromboplastin time 34 s, and fibrinogen 645 g/dL; blood cultures are negative. X-ray of the right finger shows no irregularities. Given suspicion of severe necrotizing soft tissue infection and osteomyelitis, cefepime and vancomycin are given. On further chart review before elective right metacarpal bone amputation, however, last year's colonoscopy is found to show possible inflammatory bowel disease (IBD). Repeat colonoscopy reveals swelling and redness of the entire large bowel and cobble-stone appearance in the sigmoid colon; biopsy shows neutrophilic infiltration and crypt abscesses at the lamina propria consistent with IBD (probably ulcerative colitis (UC)). Given this diagnosis, his finger necrosis is most likely PG. Mesalamine is initiated, and epidermization is performed after 3 weeks with improvement of his finger.

DISCUSSION: PG is a rare (3–10/million/year), chronic, often destructive inflammatory skin disease in which a painful nodule/pustule breaks down to form a progressively enlarging ulcer with a raised, tender, undermined border. Lesions present either in the absence of any apparent underlying disorder (40–50 %) or in association with a systemic disease, such as IBD. PG occurs in 2–12 % of IBD

patients (UC > Crohn's) and can precede colitis or occur at any stage of the disease, even after colectomy. In most patients, symptoms of UC precede PG, and exacerbations of the bowel disease frequently correlate with worsening of the skin lesions. It, however, may not be closely related to the activity of colitis and may persist for long periods while bowel disease is quiescent. PG mostly occurs in the lower limbs (47 %) and trunk (16 %), less commonly in the hand (13 %). Few other case reports demonstrate its occurrence in the upper extremities, so it usually gets misdiagnosed as repetitive infections or skin carcinomas. To avoid misdiagnosis, therefore, one should consider PG in cases of recurrent skin necrosis. REFERENCES Callen JP. Pyoderma gangrenosum. Lancet 1998; 351: 581–585. Holmlund DEW, Wahlby L. A CASE REPORT OF POLYARTERITIS NODOSA-ASSOCIATED ACUTE AORTIC DISSECTION Tomonao Hashimoto; Christine Kwan. Teine Keijinkai Medical Center, Sapporo, Japan. (*Tracking ID #1929118*)

LEARNING OBJECTIVE 1: Recognize that polyarteritis nodosa (PAN) can affect large vessels, such as the aorta, leading to dissections

CASE: A 54 year-old Asian woman presents with sudden onset, stabbing, continuous, non-radiating substernal chest/thoracic back pain \times 30 min that awakens her from sleep. She also complains of diffuse, continuous abdominal pain and constipation \times 4 days. She denies all other review of symptoms. The patient's medical history includes uterine myoma, hypertension (HTN), and rheumatoid arthritis but no medications; she has undergone Caesarian section. She has no drug allergies and has quit smoking 5 years ago; prior 29 pack-years. She drinks 1 can of beer/night. Her family history is not significant. Physical examination shows blood pressure (BP) 135/76 right and 137/87 left, pulse 55, respiratory rate 28, O₂ saturation 97 % room air, and temperature 36.4C. She is lying in bed in pain but alert/oriented \times 3. The rest of the exam demonstrates no abnormalities. Laboratory testing, including complete blood counts, chemistry, cardiac/liver enzymes, and hepatitis panel, is all within normal limits. Electrocardiogram shows normal sinus rhythm, Q wave in III, and T wave inversions in V1 and V2. Chest X-ray shows no irregularities. Plain computed tomography (CT) reveals stool in the ileum and ascending/sigmoid colon. Meanwhile, her symptoms spontaneously improve, and she is discharged with a diagnosis of constipation and given a laxative. Nine days later, however, she presents with severe abdominal pain and syncope. Enhanced CT then shows Stanford type B aortic dissection with multiple aneurysms in the hepatic/gastric arteries. Abdominal angiography reveals left hepatic artery rupture for which transarterial embolization is performed. Further questioning reveals unintentional 6 kg weight loss in 8 months and diastolic BP $>$ 100 mmHg \times 2 years. She is thus diagnosed with PAN and started on prednisolone; follow-up angiography 2 weeks later confirms improvement of aneurysms. Her aortic dissection is medically managed with candesartan and bisoprolol.

DISCUSSION: Acute aortic dissections (AAD) usually present with abrupt onset, sharp, and “tearing” chest/back pain, like the above patient, and risk factors include HTN, atherosclerosis, preexisting aortic aneurysm, vasculitis, and collagen diseases. Diagnosis can be made by chest CT with contrast, but the above patient, however, only receives non-contrast CT on initial evaluation. Treatment of Stanford type A dissections includes surgery while type B includes medical management, like the above patient. PAN, a vasculitis involving small-/mid-sized arteries, typically presents with systemic symptoms, such as fever, weight loss, and hypertension. The American College of Rheumatology's classification criteria can be used to help in diagnosis although the most definitive technique is biopsy; an alternative includes the presence of microaneurysms on angiography. In the above patient, while she does have a history of untreated HTN and rheumatoid arthritis, her newly-found aneurysms from PAN have most likely caused her AAD. Only 1 other case report shows AAD caused by PAN; autopsy reveals necrotizing vasculitis in the vasa vasorum of the aorta, which the authors conclude to have caused AAD. Other studies have also shown a possible alternative mechanism of AAD involving the vasa vasorum. Given this possible link, PAN can, therefore, involve large vessels, like the aorta.

A CASE SERIES OF AN EMERGING INFECTION IN THE UNITED STATES: INVASIVE KLEBSIELLA PNEUMONIAE Linnea S. Amesur^{1,2}; Daniel I. Kim^{1,2}; Jon Persichino^{1,2}; Made Sutjital^{1,2}; Armen Eskandari^{1,2}; Vida Jahangiri^{1,2}. ¹University of California, Riverside, Riverside, CA; ²Riverside County Regional Medical Center, Moreno Valley, CA. (*Tracking ID #1935091*)

LEARNING OBJECTIVE 1: Recognize the emergence of invasive Klebsiella pneumoniae in non-Asian populations in the United States

LEARNING OBJECTIVE 2: Diagnose and treat invasive Klebsiella pneumoniae in a timely fashion for better patient outcomes

CASE: We present a case series of 10 patients with invasive community acquired Klebsiella pneumoniae infections at a county hospital from 2010 to 2013. The data for this study was collected retrospectively. Charts were reviewed for the patients' hospitalizations. Data collected included age, gender, race, recent travel, country of origin, type of infection, and evidence of dissemination. We gathered information about medical conditions and co-morbidities that may be risk factors for invasive infection, including diabetes mellitus, cancer, steroid use, recent chemotherapy, recent radiation therapy, lung disease, liver disease, alcohol use, kidney disease, and central line or catheter use. In our results, the age range of patients was between 24 and 75 years of age, with a median age of 51. Most of the patients were male (7). The ethnicities of the patients were five Latino, two Caucasian, two Asian, and one African-American. Four were born in the United States (2 Caucasian, 1 Latino, 1 African-American). Four were born in Mexico (all were Latino), and the remainder two patients were born in Asia (Laotian and Cambodian). One had travel history within the past 10 years to South East Asia, and another patient had travel history within the past 2 years to Mexico. The types of infections most commonly seen were liver abscesses (5), followed by soft tissue infections (3), pelvic abscess (1), and pyelonephritis (1). Of the soft tissue infections, one patient had Fournier gangrene, one had neck abscess, and one had necrotizing fasciitis. Seven of the patients showed evidence of disseminated disease including bacteremia (4), urinary tract infection (4), and lung involvement (2). Most patients were septic on presentation and seven patients had elevated liver enzymes. The most common risk factors associated with invasive K. pneumoniae infections were diabetes (40 %), followed by renal failure (30 %) and history of cancer (20 %). All 10 of our patients survived after treatment with appropriate antibiotics.

DISCUSSION: Klebsiella pneumoniae, a member of the Enterobacteriaceae family, is a common human bacterial pathogen that can cause urinary tract infections, pneumonias, bacteremia, and intra-abdominal infections. It is recognized as a highly pathogenic organism that causes disease in the community and nosocomial settings. Invasive K. pneumoniae was first described in the early 1980's in Taiwan as the cause of pyogenic liver abscess. Since then, its emergence is most notable in Asian countries causing not only liver abscess but also pneumonia, urinary tract infection, brain abscess, endophthalmitis, pyogenic meningitis, empyema, septic pulmonary emboli, and osteomyelitis. Over the last decade, there is an increasing rise of this syndrome in the United States, emphasizing the importance of early recognition, diagnosis, and treatment. Most of these invasive infections are caused by the hypermucoviscous serotypes K1 and K2 and genotypes magA and rmpA. Hypermucoviscosity increases the virulence of K. pneumoniae, making it resistant to phagocytosis. The phenotype is identified in the laboratory using the “string test.” Patients with liver abscesses typically present with fever, chills, and abdominal pain. However, patients with invasive K. pneumoniae may present with leukocytosis, thrombocytopenia, abnormal liver function tests, and increased glucose in the blood. Diabetes mellitus appears to be the most prevalent risk factor at 29 %. Hospital mortality rate has been reported between 9 and 11 %. Antibiotics are given based on culture and sensitivity results, although ceftriaxone has proven effective in most liver abscesses. While invasive K. pneumoniae infections are common and well reported in Asia, they are rare in the United States. There are few case reports published and only one small case series described in California which reports infections affecting mostly patients of Asian descent. Previous cases in the United States occurred in primarily patients of Asian descent while our case series displayed a higher occurrence in Latino patients, which may indicate a different predisposition than previously reported for invasive infections in the United States. The emergence of K. pneumoniae in the United States, and most significantly in the Latino population, emphasizes the importance of recognizing invasive K. pneumoniae as the cause of liver abscesses, soft tissues infections, and other invasive diseases in non-Asian populations.

A CATASTROPHIC SCENARIO OF A HEART DEFECT Samian Sulaiman; Salih Samo; Muhammed Sherid; Husein Husein; Shahriar Dadkhah; Ahmet A. Oktay; Nadia El Hangouche; Muhammad Shahreyar; Ana Inashvili; Addis Asfaw; Preethi Subramanian. St. Francis Hospital. Evanston, IL. (*Tracking ID #1939294*)

LEARNING OBJECTIVE 1: Patent Foramen Ovale (PFO) occurs in 25 to 30 % of the general population. It should be considered a normal anatomic variant and not a pathological finding in the absence of possible paradoxical embolism or other specific clinical conditions. Testing for PFO is indicated in patients with paradoxical thrombo-

embolic events or cryptogenic stroke (defined as stroke of undetermined pathogenesis). PFO is more common in patients with cryptogenic stroke than in the general population (approximately 50 % to 60 % vs. 20 % to 25 %)

CASE: 40 year-old male who presented with left leg pain that started half an hour prior to presentation. The pain was dull, 10/10 in severity and was associated with tingling. In the Emergency department, absent pulses were noticed in the left dorsalis pedis and posterior tibial arteries. The left foot was colder and paler as compared to the right side. The Rest of physical exam was normal. His past medical history was insignificant. He was a non-smoker and was drinking alcohol only occasionally. Urine toxicology was positive for cocaine and amphetamine. The rest of labs were normal. Left lower extremity CT angiography showed complete occlusion of the femoral artery starting at above the knee segment of the popliteal artery and extending into the anterior and posterior tibial and peroneal arteries. Heparin infusion was started. Patient underwent left trans-femoral embolectomy under general anesthesia and he was intubated. Next day, he developed tachycardia and acute hypoxic respiratory failure. CT chest with contrast showed bilateral large pulmonary emboli. Given his venous and arterial emboli, suspicion of paradoxical embolism was raised. Trans-esophageal echocardiography with agitated saline was performed and showed Patent Foramen Ovale with right to left shunt. Despite the full dose of anticoagulation, patient developed left thalamic embolic stroke 4 days after admission. An Inferior Vena Cava filter was placed. Patient was finally extubated and he was referred to another facility for percutaneous closure of the defect.

DISCUSSION: Anatomic closure of the PFO occurs later in infancy in the majority of the population, but autopsy and detailed contrast echocardiographic studies demonstrate that anatomic closure is incomplete in approximately 1 of every 4 adults. Transesophageal echocardiography with agitated saline contrast enables shunt identification in PFO. An incidentally detected PFO generally requires no follow-up or treatment. If a PFO is deemed likely to be causally related to an embolic event, as is the case in this patient, therapeutic options for secondary stroke or other embolic event are controversial. These therapeutic options include medical therapy with antiplatelet agents or anticoagulation, and surgical or percutaneous closure of the defect.

A CEREBROVASCULAR ACCIDENT: ORAL CONTRACEPTIVE PILLS AND PATENT FORAMEN OVALE David Linz¹; Harish Jasti². ¹University of Pittsburgh Medical Center, Pittsburgh, PA; ²University of Pittsburgh, Pittsburgh, PA. (*Tracking ID #1929275*)

LEARNING OBJECTIVE 1: To counsel women about the risk of thrombotic stroke with estrogen containing oral contraceptive pills (OCP).

LEARNING OBJECTIVE 2: To appraise the evidence for device closure of patent foramen ovale (PFO) to prevent recurrent neurological events.

CASE: A 34 year-old woman presented to the ER 1 h after experiencing difficulty speaking. The patient was talking on the telephone when, all of a sudden, she felt as if she could not get her thoughts out. She could laugh, and could speak one or two words at a time, but could not communicate in full sentences. Her husband witnessed her difficulty speaking and asked her to write out her thoughts, but she could not. She had no facial asymmetry, muscle weakness, or altered sensation. She had no significant past medical history. Her medications included a combination oral contraceptive pill containing 20 µg of ethinyl estradiol. She had no family history of cardiovascular disease, hypercoagulable disorders, or malignancies. Examination was notable for an NIH stroke scale of 2, for moderate to severe expressive aphasia. The rest of her neurological exam was normal. Laboratory analysis was remarkable for a hemoglobin A1c of 5.4 and a fasting LDL of 103. A comprehensive hypercoagulable screen was negative. EKG and 48-hour telemetry showed normal sinus rhythm without any irregular activity. MRI of the brain showed a left frontal infarct and MRA showed a corresponding thrombosis of a small mid sylvian arcade vessel. Transthoracic echocardiogram showed normal heart function, without any valvular abnormalities or mural thrombi; however, a PFO was detected by intravenous contrast injection. Bilateral lower extremity ultrasound and CT venography of the pelvis did not detect any venous thrombosis.

DISCUSSION: Stroke is among the leading causes of morbidity and mortality, and nearly 25 % of the 795,000 strokes that occur each year in the US are recurrent attacks. Diagnosis of the stroke etiology is critical for directing efforts for the prevention of recurrent stroke. This patient had no clear identifiable source, such as a cardioembolism, large artery atherosclerosis, or small artery disease. Furthermore, she had no family history of hypercoagulable disorders and blood analysis did not detect any hypercoagulable states. However, her estrogen containing OCP increased the risk of arterial or venous thromboemboli, which can paradoxically cross her PFO. In a 15-year Danish historical cohort study, women were 1.3 to 2.3 times more likely to have an arterial thrombosis if they were taking a combination oral contraceptive pill with

30 to 40 µg ethinyl estradiol, and 0.9 to 1.7 times more likely if they were taking a pill with 20 µg, compared to non-users. The difference amongst progestin type was minimal and progestin-only products, including the levonorgestrel-releasing IUD and subcutaneous implants, did not significantly increase the risk of thrombotic stroke. The authors estimated that among 10,000 women who use OCPs containing 20 µg for 1 year, 2 will have arterial thromboses and 6.8 will have venous thromboses. Secondary prevention of stroke is especially important in patients with PFO because the estimated rate of recurrence is 25 % within a 4-year period. To date, there have been three randomized controlled trials evaluating the effectiveness of percutaneous closure of PFO, and none of these trials has shown a statistical benefit in preventing recurrent neurological events as compared to medical therapy with antiplatelets or anticoagulants. These studies were limited by low enrollment, lower-than-expected event rates, relatively short follow-up, and modest statistical power. A recent meta-analysis does suggest that device closure may have a beneficial effect with an overall reduction in the hazard for a recurrent neurological event of 33–39 %. The safety of the devices was comparable to medical therapy with a low incidence of serious adverse events, the most common being atrial fibrillation. In conclusion, this patient should be counseled that taking an estrogen containing OCP increases her risk of thrombotic stroke, and that the benefit of percutaneous closure of her PFO compared to medical therapy to prevent recurrent neurological events is uncertain.

A COMPLEX CASE OF ATYPICAL PHEOCHROMOCYOMA Jessica Thibault¹; Kelly Menachof²; David Saxon¹; Ingrid Lobo^{1,2}. ¹University of Colorado Hospital, Aurora, CO; ²University of Colorado, Denver School of Medicine, Aurora, CO. (*Tracking ID #1933750*)

LEARNING OBJECTIVE 1: Recognize both typical and atypical presentations of pheochromocytoma.

LEARNING OBJECTIVE 2: Diagnose and treat pheochromocytoma.

CASE: A 48 year-old previously healthy Caucasian male presented to an outside hospital complaining of several months of gradually progressive dyspnea on exertion. Chest CT revealed bilateral sub massive pulmonary emboli (PE) and an incidental large, incompletely visualized right suprarenal mass. A dedicated abdominal CT showed a 10 cm right adrenal mass. He was discharged on anticoagulation and a CT guided needle biopsy was done 3 weeks later. The day after his biopsy, he was admitted to the same hospital with altered mental status and shortness of breath. He was found to have an ischemic right sided thromboembolic CVA, new acute systolic heart failure with an ejection fraction of 25 %, and bilateral pleural effusions. He was also noted to have episodic hypertension, tachycardia, and fevers with nausea and vomiting. He denied any chest pain, orthopnea, PND, diaphoresis, headaches, palpitations, or fevers prior to admission. Patient also denied a family history of cardiac disease or neuroendocrine tumors. He was started on appropriate medical therapy for heart failure, PE, and CVA and transferred to us for further evaluation and treatment. On presentation he was thin but well appearing, with a blood pressure of 93/60 and otherwise normal vitals. He was oriented with no focal findings. He had JVD of 10 cm, an S4, decreased breath sounds in the bases and fine crackles in the mid lung fields bilaterally. His exam was otherwise normal. A nuclear stress test showed global hypokinesis and a prior infarct in the left circumflex distribution. Repeat CT scans confirmed the adrenal mass without evidence of malignant spread. Laboratory studies were remarkable for urine metanephrenes and normetanephrenes of 9870 (0–300) and 3174 (0–400), plasma metanephrenes and normetanephrenes of 14.9 (0–0.49) and 9.95 (0–0.89), normal 24 h urine cortisol levels, and elevated TSH (6.4) and low free T4 (0.7). The final pathology from his biopsy was consistent with a pheochromocytoma. During the patient's hospitalization, he was hypotensive to the 80s/40s without episodic hypertension. We diuresed him aggressively and continued treatment for his heart failure, PE, and CVA. Given the complexity of this case, Endocrinology, Surgery, Neurology, Cardiology, Oncology, and Anesthesiology were consulted to prepare for surgical resection. Alpha and beta blockade was started with prazosin 1 mg TID and metoprolol 6.25 mg BID. The patient's systolic blood pressures were consistently in the low 80s and further titration was not possible. He underwent right adrenalectomy 2 weeks later. The surgery and postoperative course were complicated by hypotension requiring 3 vasoactive medications. By post-op day 3, he was weaned from these medications. He was discharged on post-op day 7 with stable blood pressures. Pathology confirmed pheochromocytoma confined to the fibrous capsule and no morphologic evidence of malignancy. To date, the patient's cardiac function has not improved with an ejection fraction of 12 %. The patient's urine metanephrenes, while decreased from prior, remain elevated, concerning for residual pheochromocytoma vs paraganglioma. He is scheduled for an MIBG scan to evaluate this further.

DISCUSSION: The World Health Organization defines pheochromocytoma as a tumor arising from chromaffin cells in the adrenal medulla. Pheochromocytomas are

rare tumors that often cause symptoms due to secretion of catecholamines including norepinephrine, epinephrine, and dopamine. The classic triad of symptoms described in the literature include episodic diaphoresis, headache, and tachycardia. Patients are often found to have episodic or sustained hypertension. However, up to 10–15 % of patients may present with normal blood pressure and up to 50 % may be asymptomatic. Other presenting signs and symptoms may include cardiomyopathy, hyperglycemia, orthostatic hypotension, anxiety, and weight loss. The diagnosis is suspected by elevated urine and/or serum metanephrines greater than 2 times the normal limit in combination with either MRI or CT showing an adrenal or extra-adrenal mass suspicious of pheochromocytoma. It is ultimately confirmed by tissue diagnosis, usually at the time of resection as biopsy is risky and can precipitate adrenergic storm. Approximately 10 % of pheochromocytomas are malignant at the time of diagnosis. Treatment involves high risk surgical resection with pre-operative therapy, typically with a combination of alpha and beta blockade, to prevent hypertensive crisis. Risk is increased in patients with cardiomyopathy, as our case illustrated. Given the low incidence of pheochromocytomas and the myriad of possible presenting symptoms, some of which are very atypical, clinicians must maintain a high level of suspicion for this disease.

A CRUNCHING COLD Lisa Lee; David Dayan-Rosenman; Geeta Laud. Montefiore Medical Center, Bronx, NY. (*Tracking ID #1937565*)

LEARNING OBJECTIVE 1: Recognize the clinical presentation of spontaneous pneumomediastinum associated with alveolar rupture.

LEARNING OBJECTIVE 2: Understand the management of asthma-induced spontaneous pneumomediastinum.

CASE: A 25 year-old woman with history of well controlled mild-persistent asthma presents with a chief complaint of a day of cough, rhinorrhea and difficulty breathing consistent with asthma exacerbation followed by the sudden onset of sharp retrosternal pleuritic chest pain associated with increased shortness of breath. The pain is devoid of radiation and worsens with bending down. Vital signs on presentation were significant for heart rate of 103, respiratory rate of 22, saturation of 88 % on ambient air and Peak Flow of 160 L/min (from a baseline of at least 340 L/min). Physical exam revealed a thin, young woman in pain breathing rapidly but without help of accessory muscles, able to speak in full sentences in a normal voice; Heart sounds were distant and regular, without rubs, murmurs, or gallops. Crepitus was heard over the precordium with each heartbeat. There was no jugular venous distention and the trachea was not deviated. There were minimal diffuse end-expiratory wheezes. An electrocardiogram showed sinus tachycardia. Serum chemistries were significant for a leukocyte count of 7.5 k/uL and normal cardiac enzymes. Chest X-ray showed right upper lateral pneumothorax and pneumomediastinum. Subsequent chest CT showed pneumomediastinum extending into the neck and hila associated with a small right pneumothorax along the fissures. A diagnosis of pneumomediastinum secondary to alveolar rupture in context of asthma exacerbation was made and the patient was admitted for observation. The patient improved clinically and did not require surgical intervention. She was discharged home 2 days later after repeat imaging showed resolution of the pneumomediastinum.

DISCUSSION: Spontaneous pneumomediastinum (SPM) should be considered in patients with lung disease presenting with chest pain and dyspnea. SPM occurs when high alveolar pressures cause alveolar rupture and dissection of air into adjoining structures, spreading through the perivascular and peribronchial space into the mediastinum. The most common presenting symptoms are chest pain and dyspnea. The most sensitive sign of SPM is crepitus heard over the neck or precordial area. The most specific sign is a crunching sound that is synchronous with the heartbeat—termed Hamman's sign and resulting from the heart beating against mediastinal emphysema. Spontaneous PMD reported incidence falls between 1 in 800 and 1 in 42,000 hospital admissions and affects predominantly young, thin males. A history of asthma is reported in up to half the cases, chronic interstitial lung disease is also common in older patients. The radiographic findings are distinct and X-ray is the first-line modality for evaluation. SPM can be identified in the frontal view by lucency surrounding mediastinal structures including outlining of the superior aspect of the diaphragm and elevation of the heart. In lateral view, lucency can surround the ascending aorta, the aortic arch, the retrosternal, precardiac, periaortic, and peritracheal areas. CT scan is more sensitive than X-ray though it is unclear whether it is helpful as most of the additional cases identified may be too small to be clinically significant. SPM is usually benign condition that is managed conservatively with analgesia, supplemental oxygen and avoidance of maneuvers that increase intrathoracic pressure such as coughing or straining. It usually resolves spontaneously within 2 weeks and recurs in less than 5 % of cases. Surgical treatment SPM with mediastinotomy is reserved for the extremely rare cases when SPM leads to

cardiopulmonary decompensation. Important related conditions to rule out are tension pneumothorax and esophageal rupture.

A CURIOUS CASE OF NEFARIOUS NODULES: ANTIGEN AND CULTURE NEGATIVE PULMONARY HISTOPLASMOSIS Michael G. Nanna; Varidhi Nauriyal. Yale-New Haven Hospital, New Haven, CT. (*Tracking ID #1936389*)

LEARNING OBJECTIVE 1: To review the presentation of histoplasmosis.

LEARNING OBJECTIVE 2: To review the appropriate workup & briefly, the treatment for histoplasmosis.

CASE: A 41 year old otherwise healthy immunocompetent gentleman presented with a two week history of dyspnea, non-productive cough, fevers, chills and pleuritic chest pain. He recently moved to Connecticut eight months prior to presentation and had chickens while living in Puerto Rico. Admission physical examination was notable for bilateral crackles and tenderness over the right costochondral area. Chest radiograph on admission revealed multiple pulmonary nodules along with hilar adenopathy concerning for an infectious, inflammatory or neoplastic process. A chest computed tomography (CT) scan demonstrated scattered dense bilateral pulmonary nodules, some with central cavitation. The patient clinically decompensated with fever to 102.2° Fahrenheit, leukocytosis to 14,600, tachycardia and tachypnea. Broad spectrum antibiotics were initiated and a repeat CT scan revealed a large loculated right sided empyema, for which a chest tube was placed. The patient went for bronchoscopy, right decortication and right upper lobe wedge resection. A complete infectious, inflammatory and neoplastic workup including blood, pleural fluid, tissue and bronchoalveolar cultures, did not reveal the diagnosis. Histoplasma urine antigen was negative. Lung tissue pathology demonstrated necrotizing granulomas. The patient was extubated on post-operative day two and discharged with presumptive diagnosis of bacterial pneumonia complicated by empyema and lung abscess. A fungal stain from the wedge resection following discharge demonstrated yeast forms consistent with Histoplasma capsulatum located within a granuloma. We initiated the patient on itraconazole therapy and referred him for infectious disease follow up.

DISCUSSION: The differential diagnosis of lung nodules and fever can be separated into malignant, inflammatory and infectious categories. Histoplasmosis is an important potential diagnosis in this group of patients and represents the most common endemic mycosis in the United States. The prevalence of histoplasmosis is highest in the states along the Ohio and Mississippi River valleys, as well as Puerto Rico, Central and South America. Histoplasmosis is most frequently classified as primary pulmonary or disseminated in nature. Pulmonary histoplasmosis can present acutely or chronically with cough, dyspnea and constitutional symptoms, with clinical severity ranging from asymptomatic to critically ill. Disseminated histoplasmosis usually occurs in patients who are immunosuppressed, pediatric or elderly and may present with fatigue, weight loss and fever, as well as an assortment of more specific symptoms depending on the potential organ system involved. The appropriate workup should include blood cultures, chest radiograph, computed tomography, urine antigen, serum antigen, antibody assays, cytology and histopathology. Notably, negative antigen testing does not rule out significant disease burden, particularly in immunocompetent individuals as seen with this clinical vignette. Urine antigen testing is 99 % specific, 92 % sensitive in patients with disseminated histoplasmosis and 75–80 % sensitive in patients with acute pulmonary histoplasmosis, while lung histopathology only provides 50 % sensitivity. The appropriate treatment regimen depends on the host and disease severity, with amphotericin B and itraconazole the anti-fungal agents of choice.

A CURIOUS CASE OF SMALL CELL CARCINOMA Anishka D'Souza; Stanley K. Dea2; Deepthi Karunasiri3. 1Olive View- UCLA Medical Center, Sylmar, CA; 2Olive View- UCLA Medical Center, Sylmar, CA; 3Olive View-UCLA Medical Center, Sylmar, CA. (*Tracking ID #1937065*)

LEARNING OBJECTIVE 1: Recognize the importance of performing a complete physical exam when evaluating a patient.

LEARNING OBJECTIVE 2: Recognize that the differential diagnosis of a young male with painful rectal bleeding extends beyond hemorrhoidal disease.

CASE: A 24-year-old Caucasian male with no significant past medical history presented to the emergency department with a 1 year history of intermittent rectal bleeding and 1 month of worsening anorectal pain. The patient had been evaluated by an outside clinic several weeks prior to admission, where he had been told that his symptoms were secondary to hemorrhoids. No rectal exam was performed there. On presentation, he denied fevers, chills, weight loss, or abdominal pain. He also denied any history of sexually transmitted infections or family history of colorectal cancer. Physical examination was significant for a firm mass on digital rectal exam, as well as

a firm, non-mobile, 2 cm right inguinal lymph node. Labs were significant for iron deficiency anemia, with a normal-range CEA and negative HIV. CT scan of the abdomen and pelvis showed circumferential wall thickening of the rectum extending to the anus with bilateral inguinal and perirectal lymphadenopathy. Flexible sigmoidoscopy revealed a circumferential ulcerated mass in the distal rectum. Biopsy of the mass revealed a poorly-differentiated neuroendocrine carcinoma. Based on pathology, disease was felt to be most consistent with small cell carcinoma. A fine needle aspiration of the right inguinal node was positive for metastatic disease. CT of the chest and MRI of the brain showed no distant metastases. PET showed intense FDG uptake in the rectal mass and regional lymph nodes with no abnormal tracer uptake in the chest or abdomen. The patient was started on cisplatin and etoposide for Stage IIIB disease with referral for possible radiation after completing six cycles.

DISCUSSION: Small cell carcinoma is a neuroendocrine malignancy most commonly associated with cancer of a pulmonary origin. Extrapulmonary small cell carcinoma is a rare occurrence, accounting for about 2.5 % of all small cell carcinomas. While gastrointestinal origin accounts for 23 to 33 % of extrapulmonary cases, primary anal involvement is extremely rare with only a handful of cases documented in the literature. Chemotherapy is the mainstay of treatment. Given the paucity of clinical literature on this disease, drug regimens traditionally have been based on those for pulmonary small cell carcinoma, namely, platinum-based drugs with etoposide. Unfortunately, the disease tends to follow an aggressive course with a generally poor prognosis despite treatment. This case illustrates the importance of performing a careful rectal exam when symptoms dictate. The differential diagnosis of a young male with painful rectal bleeding extends beyond hemorrhoidal disease and a careful physical examination may have led to an earlier diagnosis in this patient.

A CURIOUS CAUSE OF A NON-HEALING ULCER Anna Maria Affan; Praveena N. Iruku; Keyvan Ravakhah. St Vincent Charity Medical Center, Cleveland, OH. (*Tracking ID #1936840*)

LEARNING OBJECTIVE 1: Diagnosis and management of a non tuberculous mycobacterial skin infection.

CASE: This is a 35 year old male presented with a chief complaint of severe back pain. His recent hospitalization was for a laminectomy for L4 spondylosis with herniated nucleus pulposus. The patient was discharged a few days after the procedure and he did well, including going on a cruise with his wife. In addition to the pain, he reported intermittent serous discharge at the site for approximately 2 weeks. Review of systems was unremarkable. Preceding his visit to our institution, the patient visited another hospital with the same complaints and was prescribed ciprofloxacin for 7 days. Initially there was some improvement in the wound but it soon regressed. His past medical history was significant for hypertension controlled on lisinopril. He had a laminectomy in 1997 after a stress fracture. His family history was noncontributory and his social history was positive for smoking a pack per day with alcohol use occasionally. On examination he appeared comfortable. Vital signs were stable. Back examination revealed a tender, non-erythematous wound. The upper portion of the wound had superficial dehiscence and was soft suggesting some fluid in the sub epidermal area. The lower aspect of the wound had a slight area of dehiscence with superficial scab formation and minimal tenderness. The mid portion of the wound appeared largely intact and was firm suggesting healing. There was no purulent drainage. Examination was otherwise unremarkable. Laboratory results were remarkable only for a creatinine of 1.3. MRI of the lumbar spine was done but did not reveal neither subcutaneous fluid collection nor bony infection. The wound was debrided and tissue sample sent for culture. It was positive for *Mycobacterium fortuitum* (*M. fortuitum*). The patient was placed on several antibiotics pending sensitivity which took several weeks to arrive. The organism was found to have sensitivity of, but not limited to Ciprofloxacin and linezolid. These antibiotics were used orally for 6 weeks. The patient returned 2 months after initial presentation with another wound dehiscence while on the aforementioned therapy. Again imaging of the back was done which showed no deep infection. The wound although superficial was debrided, and cultures sent. *M. fortuitum* persisted. Trimethoprim-sulfamethoxazole was added to current regimen in light of initial sensitivities. The patient responded well after 4 months of therapy with no current untoward event.

DISCUSSION: *M. fortuitum* is a nontuberculous mycobacterium (NTM). It is described as a rapidly growing mycobacterium and is ubiquitous in soil and water. Surgical-site infections due to *M. fortuitum* infection have been documented where the patient may develop a nonhealing but nonspreadng wound or skin ulcer. Commonly the source is contamination of the wound, directly or indirectly, with colonized water. Recall that our patient went on a cruise subsequent to his surgery. The prevalence of NTM in both pulmonary and extrapulmonary pathology is increasing. A recent study in 2013 reported *M. fortuitum* complex as the most common cause of skin and soft tissue infection due to rapidly growing mycobacteria in a patient selection in Korea. NTM are resistant to conventional antituberculous drugs. Susceptibility typically is seen to amikacin, linezolid and moxifloxacin which

was noted in our patient. However, susceptibility testing does not guarantee clinical success as was seen in this case. No specific treatment guidelines exist, however a multidrug regimen combined with surgical debridement is often used for therapy. Prolonged antibiotic therapy is generally required with increased preference for two antimicrobials. The duration of therapy to prevent relapse remains unclear.

A CURIOUS MANIFESTATION OF AMOXICILLIN-INDUCED DRESS SYNDROME Musa A. Sharkawi; Noormuhammad Abbasakoor; Sarju Ganatra. Lahey Hospital & Medical Center, Burlington, MA. (*Tracking ID #1923654*)

LEARNING OBJECTIVE 1: Recognize the diverse clinical features of DRESS syndrome

LEARNING OBJECTIVE 2: Manage a patient with life-threatening DRESS syndrome

CASE: A 19-year-old Caucasian male presented to the emergency department with high-grade fevers, a morbilliform rash, adenopathy, hepatitis, thrombocytopenia and eosinophilia 14 days after being started on amoxicillin for symptoms of sinusitis. His symptoms quickly deteriorated during the first 24 h of hospitalization to involve respiratory compromise requiring intubation and meeting criteria for acute respiratory distress syndrome. Diffuse bilateral pulmonary infiltrates were seen on chest X-ray [Figure 1] which was clear on admission. A chest CT scan was remarkable for diffuse pulmonary edema with prominent air bronchograms [Figure 2]. A bronchoscopy and bronchoalveolar lavage revealed a bloody aspirate and pulmonary eosinophilia indicating diffuse alveolar hemorrhage. Extensive workup for autoimmune disorders, bacterial, viral, fungal and parasitic infections was unrevealing. A punch biopsy of the skin was compatible with a hypersensitivity reaction as it showed superficial perivascular dermatitis with eosinophils. DRESS syndrome was diagnosed with rapid regression of symptoms after treatment with high dose methylprednisolone was initiated. The patient made a full recovery and was discharged home on day 13 of hospitalization with a very slow steroid taper.

DISCUSSION: Drug rash with eosinophilia and systemic symptoms (DRESS) is an idiosyncratic and potentially life-threatening syndrome. It is a type of delayed hypersensitivity reaction which usually presents 2–8 weeks after the initiation on the offending agent. The main culprits are allopurinol, aromatic anticonvulsants and sulfonamides, even though 50 Drugs can induce DRESS [1]. It has been described as “the great clinical mimicker” as it masquerades as acute severe sepsis. It presents with fever, cutaneous drug eruption, hematological abnormalities, and systemic manifestations including adenopathy and a wide array of internal organ involvement. There has only been a handful of cases of DRESS syndrome as a consequence of amoxicillin. In our case, the most life-threatening manifestation was diffuse alveolar hemorrhage and eosinophilic pneumonitis causing acute respiratory distress syndrome. Pulmonary involvement is present in only 5 % of cases of DRESS [1]. Use of the Naranjo adverse drug reaction probability scale indicated a “probable” relationship (score of 5) between the patient’s development of DRESS syndrome and treatment with amoxicillin. The Scoring System for Classifying DRESS Cases developed by Kardaun et al. was used and a “definite” score gave us the diagnosis [2]. DRESS can be associated with human herpes virus 4, 6, and 7 infections; thus, serology of these viruses should be checked. The main treatments of DRESS are withdrawal of culprit drug and a very slow corticosteroid taper. Diagnosing DRESS is challenging due to the diversity of cutaneous manifestations and organs involved and as such, there should be a high clinical suspicion for this disease if the introduction of a new drug is followed by a rash, eosinophilia and a sepsis-like syndrome. A DEADLY SORE THROAT Joshua T. Hanson. 1University of Texas Health Sciences Center, San Antonio, San Antonio, TX; 2South Texas Veterans Health Care System, San Antonio, TX. (*Tracking ID #1939321*)

LEARNING OBJECTIVE 1: Recognize the need for an expanded differential diagnosis in acute pharyngitis.

LEARNING OBJECTIVE 2: Recognize the features of Lemierre’s syndrome.

CASE: A 26-year-old man presented to the emergency department with complaints of sore throat, mild fevers, and odynophagia. Symptoms had begun 1 week prior to presentation, but worsened significantly with the presence of trismus in the preceding 3 days. Given tonsillar asymmetry on examination, a bedside needle aspiration of the peritonsillar space was attempted without return of purulent material. Subsequently, the patient began to experience rigors and became febrile to 38.3 °C with a pulse of

138 beats per minute. A complete blood count demonstrated a white-cell count of 27,500 per microliter and a platelet count of 62,000 per microliter. The sodium was 125 millimoles per liter. The patient was admitted for systemic inflammatory response syndrome with a concern for sepsis. Broad-spectrum antibiotics and resuscitative fluids were initiated. The next morning the patient's clinical condition had stabilized, biochemical assessment, including white blood cell count, had begun to normalize, and both sets of blood cultures drawn the previous day grew gram negative rods and gram positive cocci. Broad-spectrum antibiotics were continued while speciation of the organisms revealed *Fusobacterium necrophorum* and β-hemolytic, group C streptococci. In response to the presence of *F. necrophorum* bacteraemia, the patient underwent ultrasonography of the neck, which revealed no thrombus, and computed tomography of the chest with contrast, which revealed multiple scattered soft tissue and ground glass nodular opacities throughout the lung parenchyma. These findings were consistent with septic emboli. Antibiotic therapy was changed to continuous penicillin infusion. The patient was discharged with outpatient intravenous antibiotic therapy for 2 weeks followed by a four-week course of oral therapy with amoxicillin. The patient presented to follow-up with no lasting effects.

DISCUSSION: For the internist, sore throat is a very common presenting complaint. Acute pharyngitis accounted for 12.5 million office visits in 2006 and the infectious causes of pharyngitis are varied. Taken all together, viruses account for roughly 50 % percent of cases. Rhinovirus, coronavirus, influenza, parainfluenza, and adenovirus are all common culprits. Less common viral causes of acute pharyngitis include cytomegalovirus, EBV, HSV-1, HSV-2 and HIV. *Streptococcus pyogenes* accounts for 5 to 15 % of all cases of acute pharyngitis and is the typical cause of acute bacterial pharyngitis and Groups C and G streptococci cause a minority of streptococcal cases. Other bacteria, including *N. gonorrhoeae*, *C. pneumoniae*, *C. diphtheriae*, and *F. necrophorum* can cause acute bacterial pharyngitis. *F. necrophorum* is an anaerobic, Gram-negative pleomorphic rod-shaped bacterium and the putative cause of Lemierre's syndrome, first described in 1900 by Courmont and Cade. However, Lemierre described postanginal sepsis (tonsillitis followed by thrombophlebitis and complications, including metastatic disease and septic emboli) with such precision that subsequent authors have used his name. Despite longstanding recognition, there remains no formal case definition for the syndrome. There is variation in published case series as to the source of the infection, as well as whether internal jugular vein thrombosis is a requirement. Some authors omit this requirement, permitting pulmonary emboli as a sign. In a literature review, Riordan suggests a formal case definition with three components, namely: 1. History of anginal illness or compatible clinical findings, 2. Evidence of either metastatic lung lesions or metastatic lesions in other sites, and, 3. Either evidence of internal jugular vein thrombophlebitis or isolation of *F. necrophorum* or *Fusobacterium* sp. from blood cultures or a normally sterile site. Lemierre's syndrome is rare; studies estimate a yearly incidence rate of 0.8 to 1.5 cases per one million people. A review of case series indicates 89 % of patients were aged 10 to 35 years. There are no true time trends available, however case reports and case series of the syndrome were numerous in the early half of the 20th century, declined during the 1950s through 1970s, and increased during the 1980s. Some authors suggest the decline was due to widespread use of antibiotics and the current increase due to changes in antibiotic prescribing patterns. In the modern era, one study estimates under 5 % case fatality in appropriately diagnosed cases. Co-infection with streptococcal species is common. This case highlights the need for clinicians to remain vigilant for all of causes of acute pharyngitis. It is of particular importance among adolescents and young adults presenting with acute pharyngitis lasting longer than is usual with features of systemic disease. While Lemierre's syndrome is rare, the incidence may be rising, is life threatening, and is Treatable.

A DIAGNOSIS MISSED UNTIL A MEDICAL STUDENT GOT INVOLVED

Adam Kost; Alda Maria Gonzaga. University of Pittsburgh Medical Center, Pittsburgh, PA. (Tracking ID #1934160)

LEARNING OBJECTIVE 1: Recognize the features and generate a differential diagnosis for platypnea-orthodeoxia syndrome.

LEARNING OBJECTIVE 2: Consider a right-to-left shunt or shunt physiology as etiology of hypoxia in instances where there is hypoxia that is difficult to correct with supplemental oxygen.

CASE: An 85-year-old female with a history of dementia, paroxysmal atrial fibrillation and orthostatic hypotension presented to the emergency department (ED) after a syncopal episode associated with hypoxia. During a brief walk, she developed shortness of breath and lightheadedness. She sat down and felt better after a brief rest; however, her symptoms recurred with walking. After sitting again, she had a 5-minute episode of unresponsiveness without any abnormal movements, incontinence, cyanosis or diaphoresis. She had regained consciousness by the time paramedics arrived but her oxyhemoglobin saturation by pulse oximetry was only 69 %. On

arrival to the ED, she required 15 liters (L) of supplemental oxygen via a non-rebreather mask. An arterial blood gas obtained while she was saturating 88 % on 15 L of oxygen revealed: pH 7.42, pCO₂ 39, pO₂ 56, HCO₃ 25 with a base excess of 1. Shortly thereafter however, she was weaned to room air and maintained normal saturation levels. Other labs including blood counts, a complete metabolic profile, d-dimer, troponin and BNP were all within normal limits. While hospitalized, she was mostly asymptomatic with oxygen saturations nearing 100 % while breathing ambient air. An EKG revealed normal sinus rhythm with normal intervals and axes. A chest x-ray was unremarkable, as was a spiral CT scan of the chest to evaluate for pulmonary embolism. An MRI of the brain showed evidence of chronic small vessel ischemic disease but no acute intracranial disease. She was briefly transferred to the ICU after a desaturation event where she again required supplemental oxygen nearing 100 % FiO₂ (fraction of inspired oxygen) but did not require intubation or positive-pressure ventilation. She had an electroencephalogram (EEG) that did not reveal any epileptiform discharges. A transthoracic echocardiogram (TTE) was within normal limits. She returned to the general hospital wards. While walking with a medical student to assess her functional status, she again desaturated, which corrected quickly when she returned to a supine position. This raised suspicion for platypnea-orthodeoxia syndrome. A second TTE with bubble study revealed a right-to-left (R>L) shunt suggestive of a patent foramen ovale (PFO) or atrial septal defect (ASD) that was later verified to be a PFO by cardiac MRI. She underwent closure of her PFO and had resolution of her symptoms.

DISCUSSION: The platypnea-orthodeoxia syndrome is characterized by dyspnea (platypnea) and desaturation (orthodeoxia) in the upright position. It requires an anatomic and functional component. The anatomic component is a R>L shunt that may be intra-cardiac (e.g. PFO, ASD) or intra-pulmonary (e.g. arterio-venous malformation or AVM). The functional component allows for intermittent shunting preferentially in the upright position. In the case of ASD/PFO, there are alterations of the atria and/or septum such that R>L blood flow across the shunt, which is minimal in the recumbent position, becomes augmented due to positional alterations (i.e. standing) favoring R>L blood flow. The differential diagnosis of platypnea-orthodeoxia syndrome includes cardiac causes (PFO, ASD, pericardial effusion, constrictive pericarditis), pulmonary causes (emphysema, pulmonary AVM) and GI causes (hepatic cirrhosis, hepatopulmonary syndrome). The treatment is aimed at correcting the source of shunting. One concerning aspect of this case was the extensive work-up that was pursued prior to arrival at a diagnosis that could have been deduced from history and examination. The presence of a R>L shunt was suggested by hypoxemia that was difficult to correct even with supplemental oxygen approaching 100 % FiO₂. While both V/Q mismatch and shunt physiology will cause hypoxemia, the hypoxemia in V/Q mismatch will generally correct more easily with supplemental oxygen. In shunt physiology, which may be due to true R>L shunts (e.g. PFO/ASD, pulmonary AVMs) or pulmonary airspace disease with perfusion of unventilated lung (e.g. pneumonia, pulmonary edema), the hypoxemia may require higher percentages of supplemental oxygen or fail to correct even with 100 % FiO₂. In this case, the patient had saturation levels of only 88 % during a desaturation episode despite being on 15 L of oxygen. The other features of her presentation, particularly the moment-to-moment changes in symptoms and oxygen requirement, made other causes of shunt physiology, like true airspace filling disease, unlikely. Since a shunt was not considered earlier, her initial standard TTE was a missed opportunity; PFOs and ASDs are often not structurally apparent on a standard TTE unless a bubble study is also done to demonstrate the presence of a shunt.

A DRAMATIC PRESENTATION OF EOSINOPHILIC ESOPHAGITIS Saad M. Emhmed Ali. Presence Saint Francis Hospital, Chicago, IL. (Tracking ID #1940150)

LEARNING OBJECTIVE 1: Importance of maintenance of high degree of suspicion for eosinophilic esophagitis as a cause of dysphagia.

LEARNING OBJECTIVE 2: importance of detailed analysis of patient dietary habits in identifying eosinophilic esophagitis associated food allergy.

CASE: A 26-year-old man presented to the emergency department with complaints of dysphagia, nausea and substernal discomfort for 3 h. His symptoms began while he was eating a boneless piece of chicken and he had had the feeling of "food is stuck in my chest." The patient had a history of food impaction in his esophagus 2 years ago and food particles were removed endoscopically. Otherwise, he did not have a significant past medical or surgical history and he was not on any medications. He had no known allergies and his family history was unremarkable. On physical examination he appeared anxious and was in mild distress. His vital signs were within normal limits except elevated blood pressure (184/107 mmHg). Physical examination was unremarkable otherwise. The initial laboratory tests included CBC with differentials, basic metabolic panel and liver function tests and all of the parameters were within normal limits. The patient was admitted to general medicine floor for

further diagnostic workup. Shortly after admission, he vomited and disimpacted food particles and his symptoms resolved. Esophagogastroduodenoscopy was performed and showed some linear furrows and multiple mucosal nodularities on the upper and mid esophagus without reflux esophagitis. No foreign body was observed. The stomach and duodenum appeared normal. Biopsy specimens from the upper and mid esophagus showed intense eosinophilic infiltration in the esophageal mucosa while biopsy specimens from the stomach and duodenum were normal. Diagnosis of eosinophilic esophagitis (EoE) was made based on the history and endoscopic and histological findings. On further questioning he reported previous episodes of dysphagia with eating chicken. The patient was started on proton pump inhibitors and he was told to strictly avoid chicken or chicken containing food. On discharge, he was referred to an allergist for food allergy testing.

DISCUSSION: In conclusion, EoE is clinicopathologic disorder diagnosed by taking into consideration both clinical and pathologic information without either of these parameters interpreted in isolation. EoE is defined by the following criteria: symptoms related to esophageal dysfunction (i.e., dysphagia, food impaction or regurgitation), eosinophil-predominant inflammation on esophageal biopsy (characteristically consisting of a peak value of >15 eosinophil per high-power field), mucosal eosinophilia isolated to the esophagus and persistence of these findings after a PPI trial and exclusion of secondary causes of esophageal eosinophilia. A response to treatment (dietary elimination; topical corticosteroids) supports, but is not required for, diagnosis. When approaching a patient with dysphagia, it is essential to keep EoE in the differential diagnosis. Detailed history plays an important role in timely diagnosis and appropriate management.

A FAMILY AFFAIR: CHOOSING CONTRACEPTION FOR WOMEN AT RISK OF THE PROTHROMBIN MUTATION Heidi J. Schmidt, University of California, San Francisco, San Francisco, CA. (*Tracking ID #1928453*)

LEARNING OBJECTIVE 1: Make informed decisions about whether to screen asymptomatic women with a family history of the prothrombin mutation

LEARNING OBJECTIVE 2: Risk stratify contraception choices for asymptomatic carriers of the prothrombin G20210A mutation

CASE: A 25 year-old woman with no past medical history presents to her primary care doctor for a well woman exam. Her sister was recently diagnosed with the prothrombin G20210G >A mutation as a result of a peri-partum DVT. Her only medication is a combined oral contraception pill. She is a non-smoker and has no personal history of thrombosis. Given concern for increased thrombophilia in this young woman taking combined oral contraception, she underwent and screened positive for the prothrombin mutation. Contraception was changed to the levonorgestrel-releasing intrauterine system to reduce the risk of thrombotic events.

DISCUSSION: The prothrombin mutation has an estimated prevalence of 1–3 % (heterozygotes) in the United States and is most common in Caucasians [1]. This guanine to adenosine mutation in the noncoding region of the pro-thrombin gene is inherited in an autosomal dominant fashion and leads to increased levels of prothrombin, which is then converted to the pro-coagulant thrombin. The prevalence of venous thromboembolism (VTE) in asymptomatic individuals who are heterozygous for the prothrombin mutation AND have a first-degree relative with VTE is 5–7 % [2]. However, the risk of VTE increases 16–59 fold in prothrombin heterozygotes who use oral contraceptives [3]. Given this increased risk, it has been suggested that women with a first degree relative with a prothrombin mutation should be screened in order to inform birth control choices. However, it may also be reasonable to advise alternative forms of birth control WITHOUT testing for thrombophilias given that their risk may be elevated even if testing for thrombophilias is negative [4]. The costs of screening and patient-specific characteristics need to be weighed individually until more data is available. Unopposed oral progestin contraception does NOT increase the risk of VTE in young women [1]. Similarly, the levonorgestrel-releasing intrauterine device does NOT increase the risk of VTE, leading to the consensus that it is also a safe contraceptive option in women with inherited thrombophilias including the prothrombin mutation [5, 6]. Women who have a first-degree relative with the prothrombin mutation should use unopposed progestin contraception (or a barrier device) regardless of whether they themselves have been screened for the pro-thrombin mutation. A GONOCOCAL CONUNDRUM: THE ETHICS AND LIMITS OF PARTNER NOTIFICATION IN CONNECTICUT Sheila M. Quinn; Julie R. Rosenbaum. Yale School of Medicine, New Haven, CT. (*Tracking ID #1933356*)

LEARNING OBJECTIVE 1: Understand and describe the process of reporting sexually transmitted infection (STI) diagnoses to the state Department of Health (DOH).

LEARNING OBJECTIVE 2: Weigh the ethical considerations regarding disclosure when diagnosing a patient with a (STI)

CASE: A 29-year-old male presented with dysuria and penile discharge and was subsequently diagnosed with gonococcal urethritis. Having acquired the STI from an isolated extra-marital encounter, he did not want to tell his wife. We explained the risk to his wife's health, and encouraged him to disclose the information to her. However, given his continued refusal, we urged him to ensure she received medical care promptly, and felt reassured by our belief in the DOH's system of partner notification of STIs. However, we learned that our state's process for contact tracing was different than we expected, and the wife would likely not be notified.

DISCUSSION: In Connecticut, new cases of reportable conditions are sent directly to the state DOH lab. For STI's there are defining qualifications that prioritize the identification and contact tracing of index patients (Figure 1)*. These currently include any cases of syphilis, the presence of HIV co-infection, men who have sex with men, individuals less than 20 years old, and residents of "core" (high-prevalence) geographic areas. Even among these priority cases, the only patients that currently trigger automatic partner notification services without a physician request are those involving syphilis. High priority cases are contact-traced with the ultimate goal of notifying and treating partners. Non-priority cases are rarely traced unless a physician request is submitted. With our patient's case not prioritized for partner notification through the DOH, more pressure was placed on us, his providers, to encourage him to disclose, or for us to tell his wife directly. We employed the Four Box method (Figure 2)* to help make our decision. We weighed the risk to the patient's wife out of our duty to prevent harm, against our duty to our patient's confidentiality and autonomy. We strongly encouraged the patient to disclose, and in doing so, we preserved his autonomy. The wife had an appointment with a gynecologist, where she ultimately received appropriate care. This case raises the concern that providers may be misinformed about the logistics of partner notification and contact tracing. Providers must understand the legal processes and the accompanying ethical concerns in order to make appropriate disclosure recommendations when contact tracing may not occur. *Figure 1: An algorithmic depiction of the state DOH partner notification system for 2008–2013. *Figure 2: The Four-Box Method of Ethical Analysis

A HYPERCALCEMIC CRISIS OF EPIC (PTH-RP) PORTIONS Thomas Wong; Cawin Wong-Mizuba; Kuo-Chiang Lian. University of Hawaii: John A. Burns School of Medicine, Honolulu, HI. (*Tracking ID #1935357*)

LEARNING OBJECTIVE 1: Recognize the classic constellation of signs and symptoms of hypercalcemic crisis.

LEARNING OBJECTIVE 2: Diagnose and clinically manage patients with humoral hypercalcemia of malignancy (HHM).

CASE: A 65-year-old woman with a past medical history significant for endometrial hyperplasia, diagnosed 6 years prior and treated exclusively by naturopathic medicine, presented to the emergency department with severe abdominal pain, rated 10 out of 10 and lasting for several hours. The patient stated that she had been experiencing similar cramping pain, albeit not as intense, for the past 4 months. She had not had a bowel movement in the past 10 days. The patient had also been experiencing pain in her coccyx making it excruciatingly painful to sit or lay supine. A review of systems was significant for increased frequency of urination, a forty-pound weight loss in the past 4 months, and diffuse muscle weakness in her extremities such that she had difficulty ambulating without the assistance of a walker. Upon evaluation, physical examination revealed a slightly distended abdomen with hypoactive bowel sounds, which was diffusely tender to palpation with multiple palpable firm masses. There was also a fixed, firm, peri-umbilical soft tissue mass consistent with the Sister Mary Joseph nodule. Computer tomography scan of the

abdomen revealed a large heterogenous mass within the uterine cavity with extensive metastasis to the peritoneum, sacrum, and right iliac bone. There was no evidence of bowel obstruction. Laboratory results were significant for an elevated calcium level of 15.5 mg/dL. Alkaline phosphatase was normal. Based on the patient's constellation of signs and symptoms, the patient was diagnosed with hypercalcemic crisis secondary to stage IV endometrial cancer. The patient was admitted to the telemetry unit for monitoring of possible cardiac arrhythmia. EKG revealed normal QTc, and she had no events on monitor. Aggressive hydration with normal saline was administered. Once the patient was fluid replete, furosemide was initiated on the second hospital day. A serum Parathyroid hormone related protein (PTH-rP) level was ordered to: 1) diagnose a component of humoral hypercalcemia of malignancy (HHM) responsible for the patient's high serum calcium given normal alkaline phosphatase; and 2) help guide therapy since studies have shown zoledronic acid to be more effective than other bisphosphonates in lowering calcium levels in HHM. The PTH-rP returned elevated at 77 pg/dL. Over the course of hospitalization, the patient's calcium level returned to normal and the patient's symptoms improved. In accordance with the patient's wishes, a palliative care plan was instituted for discharge.

DISCUSSION: This case is a classic example of hypercalcemic crisis, which when recognized promptly can lead to early interventions that prevent the life-threatening consequences of elevated serum calcium. Moreover, as a review of the current literature suggests, this patient suffered from a rare example of humoral hypercalcemia of malignancy due to advanced endometrial cancer. The PTH-rP responsible for this paraneoplastic syndrome has been recognized as a product of hyperplastic endometrial cells. Serum PTH-rP levels, in addition to its diagnostic value can play a role in guiding therapeutic options for hypercalcemia of malignancy. Furthermore, research interest continues to grow in the potential role of PTH-rP as a tumor marker and as a prognostic indicator of median survival time and response to bisphosphonate therapy. Hopefully, the knowledge gained from these studies will help guide future management of such challenging oncologic cases.

A MASS OF MUCOR Devika Nair; Sarah Moore; Deepa Bhatnagar. Tulane University Health Sciences Center, New Orleans, LA. (*Tracking ID #1924929*)

LEARNING OBJECTIVE 1: Recognize that Mucormycosis should be suspected in patients with diabetic ketoacidosis, sinusitis, and evidence of thrombosis.

LEARNING OBJECTIVE 2: Discuss the management and complications associated with Mucormycosis

CASE: A 21-year-old man with Type 1 diabetes presented with a four-day history of unilateral blurry vision and rhinorrhea. Vital signs consisted of a temperature of 97 F, heart rate of 118 beats/min, respirations of 22/min, blood pressure of 166/108 mmHg, and oxygen saturation of 98 % on room air. He had proptosis of his left eye and a fixed and dilated left pupil. Extra-ocular movement testing showed a palsy of cranial nerves two, three, four, and six of his left eye. The patient also exhibited tenderness over his sinuses bilaterally. Right eye movement was normal. Laboratory findings were suggestive of diabetic ketoacidosis with a glucose above 500, pH of 7.0 and an elevated anion gap. MRI of the brain with and without contrast revealed cavernous sinus thrombosis as well as thrombi of the left ophthalmic vein and artery. Given the presence of cavernous sinus thrombus in the setting of diabetic ketoacidosis, invasive fungal infections were chief on the differential. The patient was started on fluids, heparin, and insulin, and intravenous amphotericin B, followed by debridement of the infected tissue. Pathology confirmed invasive mucormycosis caused by Mucor. On hospital day three, the patient experienced a hemorrhagic stroke, likely due to septic emboli. Due to this complication, anticoagulation had to be withheld. Despite further treatment and optimization of medical management, the patient passed away due to complications of his stroke.

DISCUSSION: Diabetes is one of the most common illnesses in the United States, and patients with Type 1 diabetes are more prone to developing diabetic ketoacidosis. Acidosis and hyperglycemia have been shown to impair phagocyte function. Moreover, acidosis disrupts the ability of transferrin to bind iron, a growth factor for many bacteria. Malignant otitis externa, bacterial sinusitis, and invasive fungal infections are some of the most common head and neck infections that occur in diabetic patients. However, the presence of carotid artery occlusion or cavernous sinus thrombosis suggests the presence of an invasive fungal infection. In such patients, fungal infections can present as rapidly progressive rhino-orbital-cerebral disease, most commonly caused by Rhizopus, Absidia, or Mucor. Prompt diagnosis is imperative, as overall mortality ranges from 30 to 70 %. Treatment consists of intravenous amphotericin B and surgical debridement. Our patient experienced one of Mucor's most feared complications: spread to the cavernous sinus causing thrombosis. Current practice supports the early use of antifungals. Anecdotal evidence points to a benefit of corticosteroids

to reduce orbital inflammation, but the risks of this must be weighed in the setting of sepsis. The decision to anti-coagulate is more controversial, as septic emboli are an important cause of mortality. Case reports suggest that anticoagulation is most beneficial in earlier stages of the disease. All studies indicate that early recognition is paramount to treatment, and our case highlights a number of the challenges in management.

A MASSIVE DVT IN A PATIENT WITH ULCERATIVE COLITIS ON ADALIMUMAB Reuben Abraham; Craig Gluckman; Todd B. Linden. Beth Israel Medical Center, New York, NY. (*Tracking ID #1934956*)

LEARNING OBJECTIVE 1: Recognize that venous thromboembolic disease may be an adverse effect seen in patients treated with adalimumab for ulcerative colitis

CASE: We present a 61 year old female with a massive DVT, which was first appreciated approximately 2 weeks after beginning therapy with adalimumab for steroid refractory ulcerative colitis (UC). The patient has a history of UC for the past 9 years. She had none of the co-morbid risk factors seen in most reports of DVT in IBD. Her physical exam was normal except for marked swelling of her right lower extremity to above the knee. A CT scan of the chest was negative for PE but her abdominal/pelvic CT showed an intraluminal thrombus within the right deep and superficial femoral veins which propagated superiorly into the IVC. Colonoscopy showed pancolitis which was severe on the left and mild in the proximal colon.

DISCUSSION: While thrombo-embolic events are a widely recognized complication of inflammatory bowel disease, they are rare in the absence of overt risk factors. Although the package insert for adalimumab does list "thrombosis leg" in the section "Less Common Adverse Reactions in Rheumatoid Arthritis Clinical Studies" and "deep vein thrombosis" in the section "Post marketing Experience"; the incidence of these events appears to be exceedingly low. The US FDA Adverse Events Reporting System lists 325 "adalimumab related thrombosis adverse events". Seventy-eight were in patients with Crohn's and 13 were in patients with UC. Published data on adalimumab in Crohn's and UC in IBD do not describe any DVT in 6944 patients (12,925 patient-years). Data from adalimumab use in multiple trials of different autoimmune disease did not report DVT in 23,458 patients. The finding of a DVT in a patient with Ulcerative Colitis on adalimumab has not been previously described in the literature. There are 13 reports in the FDA adverse events database but none have been published. Our patient did not have any of the overt risk factors that are almost always associated with thromboembolic disease in IBD. In addition, the temporal association of an approximately 10 day lag between initiation of adalimumab therapy and onset of lower extremity edema is highly compelling. We recommend that although the incidence of this complication must be vanishingly small, clinicians be aware that it is a possibility that should be considered if appropriate symptoms appear after initiation of therapy with adalimumab.

A MIMIC OF A RHEUMATOID ARTHRITIS FLARE Paul Koffer; Zachary D. Horne; Benjamin Lloyd. Reading Hospital, West Reading, PA. (*Tracking ID #1938324*)

LEARNING OBJECTIVE 1: Recognize the potential for polyarticular septic arthritis in a patient with rheumatoid arthritis

CASE: A 63 year old woman with a past medical history of severe Rheumatoid Arthritis (RA) with bilateral metacarpal (MCP) prostheses on chronic prednisone presented to the emergency department with pain, stiffness, and warmth of her 1st and 2nd MCP joints of the left hand, the 3rd through 5th MCP joints of the right hand, and left ankle. The patient had complained of subjective fevers and chills over the past 2 days and stated the symptoms were similar to her previous RA flares. Her temperature was 37.3° Fahrenheit, heart rate was 90 beats/min, and she had a white blood cell count of 7.5 (nl: 4.8–10.80 cmm). On physical exam, she had warmth, erythema, swelling, and mildly decreased range of motion of the 1st and 2nd MCP joints of the left hand, the 3rd through 5th MCP joints of her right hand as well as swelling and warmth around the medial malleolus of the left ankle. The patient had been seen earlier in the day by her rheumatologist who took an aspiration of her 1st left MCP joint and increased her prednisone dose for a presumed RA flare. The patient was given 125 mg IV solumedrol in the emergency department for presumed RA flare and started on Vancomycin until septic arthritis could be ruled out. The left MCP joint aspiration grew Methicillin Sensitive Staphylococcus Aureus (MSSA) as did blood cultures and the patient was switched to Cefazolin. The patient's left ankle was aspirated during her hospitalization which was also positive for MSSA. Patient was also found to have bilateral paraspinal abscesses on MRI of the lumbar spine during the hospital admission. The paraspinal abscesses were drained and cultures

were positive for MSSA. The patient was discharged home after her hospitalization to complete a 42 day course of antibiotics.

DISCUSSION: This case demonstrates the potential for polyarticular septic arthritis superimposed on chronic RA. It is critical to keep your clinical suspicion for septic arthritis high in the setting of patients with RA even when the initial clinical presentation is suggestive of an RA flare, as the mortality of polyarticular septic arthritis in patients with RA has been reported to be as high as 50 % (1). Fifteen percent of all patients with septic arthritis have involvement of two or more joints and case series suggest that more than 50 % of patient with polyarticular septic arthritis suffer from underlying RA (1). Other factors predisposing patients to polyarticular septic arthritis are bacteremia from a secondary cause, immunosuppression, and prosthetic joints and clinical suspicion should be raised in these patient populations. (1) Dubost, J. J., I. Fis, P. Denis, R. Lopitaux, M. Soubrier, J. M. Ristori, J. L. Bussiere, J. Sirot, and B. Sauvezie. "Polyarticular septic arthritis." Medicine 72, no. 5 (1993): 296.

A MISLEADING PRESENTATION OF HYPERSENSITIVITY PNEUMONITIS Nadia D. Ali; Darlene LeFrancois. Montefiore Medical Center, New York City, NY. (*Tracking ID #1928197*)

LEARNING OBJECTIVE 1: Review the utility of measuring serum troponin and creatine kinase levels in the diagnosis of acute myocardial infarction as well as other cardio-pulmonary etiologies.

LEARNING OBJECTIVE 2: Diagnose hypersensitivity pneumonitis based on a collection of history, physical and radiographic data.

CASE: A 51 year old female with a history of seasonal allergic rhinitis, no known chronic respiratory or cardiac disease presented with progressive dyspnea, chest tightness, and post-tussive emesis for 1 day. Patient reports severe shortness of breath and multiple episodes of post-tussive emesis that began several hours prior to admission. On arrival she was found to be hypoxic to 88 %, tachypneic and moderately hypertensive. Troponin T levels were elevated to 1.38 ng/ml with concordant CK-MB to 36.7 mg/ml. Mild kidney injury with creatinine elevated to 1.6 mg/dl up from 1.1 1 year ago. No EKG changes. Cardiac exam was remarkably normal with no volume overload. V/Q scan and echocardiogram were normal. Lung exam was significant for crackles halfway up both lung fields that remained unchanged after administration of IV furosemide. Throughout her stay serum troponin and CK-MB remained elevated. A CT thorax showed diffuse bilateral centrilobular ground glass pulmonary nodules with focal ground glass and small patchy bilateral alveolar infiltrates as well as small mediastinal lymph nodes. Further history indicated that patient had progressive worsening dyspnea on exertion for the past 1–2 months. Notably patient's place of employment was under construction to rebuild after hurricane Sandy. Pulmonary function tests revealed mild restrictive disease with no bronchodilator response and a reduced DLCO of 36 %. A transbronchial lung biopsy revealed chronic inflammation with a proliferation of lymphocytes, plasma cells, histiocytes, eosinophils and type II pneumocytes hyperplasia consistent with hypersensitivity pneumonitis. On day five following bronchoscopy patient was started on high dose, slow prednisone taper and discharged. Patient followed up outpatient continued to improve clinically and on repeat pulmonary function testing.

DISCUSSION: Serum biomarkers including troponins and creatine kinase - MB are used to confirm the diagnosis of a suspected acute myocardial infarction. Two criteria are important to fulfill, an elevation above the 99th percentile of normal and a rise or fall in troponins in at least two serum levels 6 h apart. Troponin levels begin to rise 2–3 h after infarction, peaking in 1–2 days depending on the size of the infarct followed by a reliable downward trend. A persistent elevation in troponins without evidence of a rise or fall and lack of EKG or echocardiogram abnormalities indicates the need for further work to explain the troponemia. Multiple disease processes have been described with an inexplicable rise in troponins. One theory is that troponin release in the absence of necrosis may occur in conditions that produce increased myocyte membrane permeability. There are 3 ways to classify non-ACS troponemia: Myocardial damage related to 1) secondary myocardial ischemia (i.e. pulmonary embolism, heart failure); 2) non-ischemic causes (i.e. kidney disease and inflammatory syndromes such as sepsis, myocarditis and hypersensitivity pneumonitis); or 3) multifactorial causes. Hypersensitivity pneumonitis (HP) is a well described disease with a broad spectrum of clinical presentation and severity. The classic clinical finding is progressive cough and shortness of breath with exposure to an offending antigen which can be acute, sub-acute or chronic. Diagnosis is based on history, clinical exam and either bronchoscopy or high resolution CT thorax. Although it is primarily a pulmonary disease it is an inflammatory disorder and can be mistaken for a primary cardiac etiology.

A NIGHT OF EXCESS LEADS TO A NEAR DEATH EXPERIENCE Yoo Mee Shin. Emory University, Atlanta, GA. (*Tracking ID #1938877*)

LEARNING OBJECTIVE 1: Review the physiology of Wolff-Parkinson-White syndrome and its associated risk of tachyarrhythmias.

LEARNING OBJECTIVE 2: Recognize that recreation drug abuse is associated with arrhythmias.

CASE: 38 year old male was brought to the emergency department after being found unresponsive by his wife. EMS found the patient unresponsive and in ventricular tachycardia at his house. He underwent cardiac defibrillation and returned to sinus rhythm. He was given naloxone and was transported to the emergency department. He denied chest pain, palpitations, or shortness of breath prior to the event. Medical history was negative and social history was notable for a new, unknown recreational drug that he took prior to the event. Blood pressure was 144/81, heart rate was 100, respiratory rate was 6–12 breaths/min and oxygen saturation was 100 % on nonrebreather mask. Patient was somnolent but oriented. He had regular rate and rhythm with no murmurs or gallops. The rest of the physical examination was unremarkable. Initial venous blood gas showed respiratory acidosis with pH of 7.17 and PCO₂ of 76 mmHg. Urine drug screen was positive for opiates and cocaine. Troponin levels were normal. EKG showed sinus tachycardia and an accessory pre-excitation pathway. He underwent an electrophysiology study that confirmed Wolff-Parkinson-White (WPW) syndrome and had a successful ablation procedure.

DISCUSSION: Wolff-Parkinson-White syndrome (WPW) is a pre-excitation syndrome that develops from the presence of an abnormal accessory pathway between the atria and ventricles. It is most classically known to increase the risk of developing an atrioventricular reentrant tachycardia as the accessory pathway is utilized in the origination and propagation of the arrhythmia. The incidence of WPW is between 0.1 % and 0.3 % in the general population. Albeit rare, it is associated with sudden cardiac death due to tachyarrhythmias with an incidence of less than 0.6 %. In our case, ventricular tachycardia as a presenting arrhythmia in a healthy person without structural heart disease would be highly unusual, even in the presence of WPW. However, recreational drug use likely contributed to this patient's presentation. Cocaine induces a hyperadrenergic state and blocks sodium channels blockade which can lead to ventricular arrhythmias. Cocaine induces a hyperadrenergic state and blocks sodium channels blockade which can lead to ventricular arrhythmias. Narcotics increase parasympathetic activity, reduce sympathetic activity, and release histamine from mast cells. This produces bradycardia and enhanced automaticity which can precipitate an increase in ectopic activity, atrial fibrillation, or ventricular tachyarrhythmias. In turn, WPW significantly increases this patient's arrhythmogenic potential due to the presence of the accessory pathway and localized ion channel blockade. Our case illustrates two important points. First, recreation drug use is associated with cardiac arrhythmias via multiple mechanisms. Second, WPW increases the risk for other arrhythmias beyond supraventricular tachycardias. The dual-hit of drug overdose and WPW can potentiate the risk for serious arrhythmias and sudden cardiac death.

A NON-HEALING WOUND THAT IS NOT SKIN CANCER! Maen Abdelrahim^{1,2}; Glynda Caga-anan^{1,2}. ¹Baylor College of Medicine, Houston, TX; ²Michael E. Debakey VA Medical Center, Houston, TX. (*Tracking ID #1938953*)

LEARNING OBJECTIVE 1: Recognize that cutaneous metastases from hepatocellular carcinoma (HCC) can be the first clinical sign of HCC

LEARNING OBJECTIVE 2: Recognize the different cutaneous manifestations of hepatocellular carcinoma

CASE: Mr. W is a 66 y.o. white man who presented with a 6 month history of a rapidly growing abdominal wound and abdominal pain. He has a history of myeloproliferative disease (MPD) and had a prior ventral hernia repair in 2001, which was complicated by an infected mesh later removed in 2004, with the abdominal wound allowed to heal by secondary intention. His wound persisted since but eventually decreased to approximately 4 cm×4 cm in size. Over the past 6 months, the wound progressively enlarged, associated with new purulent drainage and worsening right upper quadrant abdominal pain. Exam showed an obese, soft abdomen, with tenderness at the right upper quadrant. A 14×14 cm supraumbilical wound was present, with mild bleeding and purulent discharge. Laboratory data showed leukocytosis (30,000/cmm) and thrombocytosis (993,000 /cmm) which were greatly above Mr. W's chronically elevated baseline levels due to his underlying MPD. Alkaline phosphatase was also elevated at 270 IU/L. CT abdomen showed multiple hypodense, poorly defined liver lesions, concerning for hepatic abscesses versus metastatic squamous cell skin cancer (SCC), seeding from the wound. Broad spectrum antibiotics were begun. The fine needle aspiration of the liver masses were consistent with hepatocellular carcinoma (HCC), an unexpected finding in this patient

who does not have a history of cirrhosis, viral hepatitis, or past alcohol abuse. Liver mass cultures remained negative. The abdominal wound pathology showed metastatic poorly differentiated carcinoma, with similar morphology to the liver findings. His carcinoembryonic antigen (CEA) was 1.55, and alpha fetoprotein (AFP) was 1.4. The wound culture grew pseudomonas aeruginosa, treated with 14 days of meropenem. After a multidisciplinary tumor board discussion, the conclusion was made that the morphological and immunohistochemistry aspect of the liver biopsy and abdominal wound biopsy were more likely consistent with poorly differentiated, metastatic hepatocellular carcinoma, with Mr. W's future treatment to include sorafenib.

DISCUSSION: Hepatocellular carcinoma (HCC) most often metastasizes to the lungs, abdominal lymph nodes, or bone (1). Cutaneous metastases from HCC are very rare but can be the first clinical sign of HCC (6,8). Prior reports have described these skin lesions to be rapidly growing, firm, painless, nonulcerative, 1–2.5 cm nodules, found mostly on the face, scalp, chest, and shoulders (1,2). These lesions may appear singly or in multiples. Some lesions have a pyogenic granuloma-like or a hemangiomatic character (1,3). In one study (4), skin metastases were shown to account for only 2.7 % of cirrhotic HCC's with no cases found in noncirrhotic HCC (like our case). There have been reports of cutaneous metastases due to direct implantation from a procedure, such as a biopsy or ablation of HCC. One report (5) described a nodule presenting at the injection site of a percutaneous ethanol injection therapy performed 3 months previously. Here, we report HCC metastasizing to a chronically unhealed abdominal wound. Usually, a non-healing wound transforms into squamous cell skin cancer. The possibility of skin metastases should be considered in patients with HCC who present with new skin nodules or non-healing wounds, with diagnosis later confirmed by biopsy. In our review of the literature, this is the first reported case of metastatic HCC to a non-healing skin wound.

A NOVEL CASE OF CRYPTOCOCCAL IMMUNE RECONSTITUTION INFLAMMATORY RESPONSE SYNDROME IN A PATIENT WITH MULTIPLE SCLEROSIS Heena A. Birbal Jain; Jacquiline Fischer; Saurabh K. Bansal. University of Illinois College of Medicine at Peoria at Saint Francis Medical Center, Peoria, IL. (*Tracking ID #1901785*)

LEARNING OBJECTIVE 1: Recognition of Cryptococcal Immune Reconstitution Inflammatory Response Syndrome associated with natalizumab

CASE: A 49 year male, on natalizumab the past 2 years for multiple sclerosis, presented with progressive weakness, headache and vomiting. Magnetic resonance imaging (MRI) of the brain revealed chronic multiple sclerosis-consistent findings without change since prior study. Cerebrospinal fluid (CSF) analysis showed white blood cells (WBC) 12/mm³ (67 % lymphocytes), protein 63 mg/dl and positive cryptococcal antigen. Both CSF and blood cultures grew Cryptococcus neoformans. CSF was negative for JC virus, West Nile virus and herpes simplex 1 and 2. Serum HIV and hepatitis serologies were negative. A diagnosis of cryptococcal meningitis was made. The meningitis was felt related to the immune suppressant effects of natalizumab. Natalizumab was discontinued and a 28 day course of amphotericin and flucytosine was given. Substantial clinical improvement occurred and the patient was discharged to home on daily oral fluconazole. At discharge, CSF cryptococcal antigen titer was 1:512. One month later the patient was rehospitalized with unilateral ptosis, left sided facial droop and transient dysarthria. MRI brain showed new areas of enhancement in the perivascular spaces, right occipital lobe, right calcarine gyrus, left occipito-parietal confluence, and leptomeninges. CSF cryptococcal titre had decreased to 1:128 but both the CSF protein (85 mg/dl) and WBC (35/mm³) had increased. The patient was diagnosed with immune reconstitution inflammatory response syndrome (IRIS) associated cryptococcal meningitis; the IRIS being attributed to the recent discontinuation of natalizumab. Treatment with methylprednisolone, amphotericin and flucytosine was given and the patient's clinical symptoms improved. At the completion of this second treatment course, CSF cryptococcal antigen titer had fallen to 1:64.

DISCUSSION: Immune reconstitution inflammatory syndrome (IRIS), first described in the early 1990s, is seen most classically in HIV patients following initiation of highly active antiretroviral therapy (HAART). HAART-related immune recovery may result in a heightened inflammatory host response toward any harbored pathogens. Natalizumab is a humanized antibody against alpha-4 integrin receptors and is FDA approved for multiple sclerosis and Crohn's disease. We believe our patient experienced IRIS upon the discontinuation of his natalizumab. Despite the successful initial treatment of our patient's cryptococcal meningitis, he was rehospitalized with progressive cryptococcal disease as evident by worsening neurologic, CSF, and imaging findings. Because the CSF cryptococcal titer at this time had fallen, we feel that natalizumab-discontinuation IRIS best explains the clinical features seen. To our knowledge, ours is the first reported case of cryptococcal meningitis as associated with natalizumab-discontinuation IRIS. Review

of the literature revealed no cases of cryptococcal meningitis or cryptococcal IRIS as associated with natalizumab. Data from the phase III randomized trial of natalizumab safety and efficacy in relapsing remitting MS (AFFIRM) yielded no information about cryptococcal meningitis as an adverse event of treatment.

A PARADOXICAL MANIFESTATION OF BACLOFEN TOXICITY Rachel Jantea. University of Pittsburgh Medical Center, Pittsburgh, PA. (*Tracking ID #1939449*)

LEARNING OBJECTIVE 1: Recognize an unusual sign of baclofen toxicity

LEARNING OBJECTIVE 2: Identify patients at increased risk of renal insufficiency, and therefore baclofen toxicity

CASE: An 84 year old Caucasian male presented to his PCP with new onset neck pain, for which he was prescribed acetaminophen 1 g orally three times daily, in addition to as-needed diclofenac 75 mg orally up to twice daily and baclofen 10 mg orally up to twice daily for neck pain. The patient proceeded to take all three medications in a scheduled manner. Three days later, he was brought to the emergency department by his daughter with complaint of confusion and abnormal movements. On exam, the patient was hemodynamically stable. He was slightly confused and oriented only to person. His neck was supple but mildly tender to palpation of the paraspinal muscles. He exhibited irregular involuntary purposeless jerking movements of the face, mouth, neck, shoulders, and upper extremities, characterized by repeated flexion and extension of the arms and neck, head turning, and shoulder shrugging. He did not have increased tonicity on passive movement of the extremities, and the remainder of the neurologic exam was unremarkable. CT head and MRI brain were unremarkable, and basic labs revealed acute renal insufficiency with a BUN/Cr of 38/2.2 (GFR 26 by Modification of Diet in Renal Disease formula) up from his baseline of 14/1.1. Diclofenac and baclofen were both discontinued, and acetaminophen was continued for pain control. He was given IV fluids for hydration in the setting of renal insufficiency. Over the next 3 days, the patient's renal insufficiency resolved, his mental status returned to baseline, and the abnormal movements diminished and subsequently disappeared.

DISCUSSION: Baclofen is a GABA-agonist used as a muscle relaxant to treat spasticity among other things. Baclofen withdrawal has widely been associated with dyskinesias and other neurologic manifestations. However, baclofen toxicity has only rarely been reported to result in movement disorders, a peculiar effect for a muscle relaxant. Usual signs of baclofen toxicity include central nervous system depression, confusion, hypotonia, ataxia, and hypotension. The present case was characterized by the more typical altered mental status, but also exhibited the unusual and paradoxical manifestation of dyskinesia. Movement disorders secondary to baclofen toxicity have rarely been reported in the literature, and when reported, have mostly been associated with intrathecal baclofen treatment of complex regional pain syndrome and/or dystonia. This case was unique in that it occurred with use of oral baclofen and in a previously neurologically normal patient. Baclofen is 90 % renally excreted, and toxicity when reported, has largely occurred in the context of renal insufficiency. Most case reports of baclofen toxicity in the setting of renal failure involve patients with known chronic kidney disease on or off hemodialysis. The patient in the present case had a previously normal GFR, and was found to have acute renal insufficiency secondary to NSAID-induced nephropathy at the time of presentation. There is one report of oral baclofen toxicity in a patient with partial spinal cord injury occurring in the setting of ibuprofen-induced renal insufficiency. However, the manifestations were more typical, including altered mental status and hypotension, and again, this occurred in a patient with a prior neurologic disorder. This unusual presentation of baclofen toxicity illustrates the importance of recognizing that baclofen is renally excreted, and renal function should be assessed prior to initiating this drug. Furthermore, it should be used cautiously in patients with chronic renal insufficiency or patients at increased risk of renal insufficiency, especially geriatric patients and patients using nephrotoxic drugs, such as NSAIDs. This is an especially important point, in treating patients with spinal musculoskeletal symptoms, when baclofen and NSAIDs are commonly co-prescribed, as in this case.

A PATIENT WITH PRURITIS, EOSINOPHILIA, AND A PAINFUL RED EAR Morgan Soffler; Christopher Sankey. Yale New Haven Hospital, New Haven, CT. (*Tracking ID #1939267*)

LEARNING OBJECTIVE 1: Establish a differential for pruritus and eosinophilia.

LEARNING OBJECTIVE 2: 2. Understand the diagnostic strategy for cutaneous T-cell lymphoma. 3. Recognize polychondritis as a potential manifestation of hematologic malignancy.

CASE: Mr. F is an 84 year-old man with a history of atrial fibrillation and stroke who presented with a 2-month history of failure-to-thrive and pruritus. Mr. F reported poor appetite accompanied by a 10-lb weight loss. He had not been taking his medications, which included Coumadin and aspirin. His pruritus began 2 months prior to presentation and was associated with an erythematous rash on his chest and back, though the pruritus was diffuse. He tried steroid cream and Benadryl without effect. A review of systems was otherwise notable for fatigue, global weakness, and depressive symptoms. His exam was notable for a temp of 96.1 F, heart rate of 84, BP of 112/76, respiratory rate of 14 with an O₂ sat of 95 % on room air. He was cachectic with temporal wasting. His abdomen was scaphoid without organomegaly. Lymph node examination revealed a 1-cm, non-tender, mobile, left-sided axillary lymph node. Neurologic exam revealed diffuse weakness. On skin exam there was an erythematous, non-blanching, maculopapular rash on his chest and back. Initial lab results revealed WBC 4.6 with 19 % eosinophilia, hematocrit 25, MCV 105, platelets 250, creatinine 0.7, ESR>120, ferritin 1350 and prealbumin 3.3. Urinalysis was bland. Blood smear revealed macrocytosis with increased eosinophils. On repeat CBC, eosinophilia increased to 30 %. His rash had resolved prior to biopsy, however, an area of inflammation on his forearm was biopsied which showed non-specific inflammation. Work-up for eosinophilia included a negative stool O&P, negative strongyloides antibody, and mildly elevated IgE level. A bone marrow biopsy revealed hypercellular myeloid-predominant marrow with eosinophilia. T cell lymphocytes ratios revealed CD4+/CD8+ elevated at 22. There were no monoclonal T cells or T-cell re-arrangements. Given the elevation in CD4+/CD8+ ratio, a presumptive diagnosis of Cutaneous T Cell Lymphoma (CTCL) was made. Several days into hospitalization, Mr. F developed a painful, swollen, left ear with sparing of the ear lobe. On further history, he reported he had swelling of his ears on and off for several months, suspicious for relapsing polychondritis.

DISCUSSION: Mr. F's presentation was highly concerning a systemic catabolic and inflammatory process such as malignancy. In formulating a differential diagnosis for this patient, pruritis and eosinophilia were findings useful in directing our work-up. The approach to the differential diagnosis of eosinophilia (defined as a eosinophils >500cells/microL) involves broad categorizations including infection, allergic disorders, hematologic malignancies, and rheumatologic disorders. A negative parasite work-up eliminated infection as our primary suspicion. A mildly elevated IgE and low tryptase level made an allergic process less likely. An ANA of <1:40 was inconsistent with rheumatologic disease. Hematologic malignancy was left as the likely cause of Mr. F's wasting syndrome, inflammatory process, and eosinophilia. An elevated CD4+/CD8+ gave rise to the concern of a T-cell lymphoma. Cutaneous T-cell lymphoma is a form of non-Hodgkin's lymphoma that is caused by a mutation of T cells that migrate to the skin. Pruritis is the most common presenting symptom. Other clinical signs of CTCL include lymphadenopathy and visceral involvement. Pathologic features can be found in skin biopsy, lymph node biopsy, and peripheral blood. Skin biopsy findings are often non-specific but include T-cell inflammation and clonality of TCR gene rearrangement. Lymph nodes can show anything from non-specific reactive changes to frank lymphoma. "Sezary cells" on blood smear are described as large atypical mononuclear cells with grooved nuclei. TCR gene rearrangement clonality is also suggestive of CTCL. Diagnosis is based on clinical, pathologic, and hematologic factors. Recurrent red swollen ears raised suspicion for Relapsing Polychondritis (RP). Relapsing polychondritis is an immune-mediated condition associated with inflammation of cartilage, most often within the ear. Approximately 1/3 of RP cases are associated with a systemic process. The association between RP and CTCL has been examined in the literature, though the more common hematologic process associated with RP is myelodysplastic syndrome.

CONCLUSION: In patients with pruritis and eosinophilia with evidence of systemic inflammation, hematologic malignancies such as CTCL should be considered. In cases with diagnostic uncertainty, a thorough history may reveal symptoms, as in our case evidence of polychondritis, which may further support the clinical suspicion of hematologic malignancy.

A PUZZLING CASE OF HYPOCALCEMIA! Venu M. Ganipisetti; Hitu Khaira; Samaneh Dowlatshahi; Pratyusha Bollimunta; Sanjolee Mangat; Erica Sinsheimer. Presence Saint Francis Hospital, Evanston, IL. (Tracking ID #1927988)

LEARNING OBJECTIVE 1: Recognize that Pseudohypoparathyroidism can present with life-threatening complications like seizures and bronchospasm, due to severe hypocalcemia. Hence, early diagnosis and treatment are warranted.

LEARNING OBJECTIVE 2: Recognize that bilateral basal ganglia calcification is one radiological feature that can be associated with pseudohypoparathyroidism.

CASE: A 24-year-old Hispanic male presented to our Emergency Department with multiple syncopal episodes over a period of 2 days. Witnesses reported that he was violently shaking all his limbs during the episodes, which lasted about 20 s each. Patient had no recollection of any of these events. No postictal confusion, bowel or bladder incontinence, or tongue-biting were reported. His past medical and family histories were noncontributory. He reported a three-year history of difficulty lifting heavy objects along with pain and cramping in his hands and arms with repetitive use. Initial labs revealed severe hypocalcemia (calcium level-5.6, ionized calcium-0.55) and hyperphosphatemia (phosphorus levels-6.1). Remaining lab tests including urine toxicology and alkaline phosphatase were normal. Physical exam was normal except for reportedly positive Trousseau and Chvostek signs. A CT of the head revealed bilateral, symmetric and diffuse calcification in the basal ganglia and the dentate nucleus of cerebellum, otherwise negative. A further workup showed elevated PTH (157), low 25-OH Vitamin D (15.5), and low 24-hour urine calcium. He received a preliminary diagnosis of pseudohypoparathyroidism with a coexisting Vitamin D deficiency. Patient was started treatment on both IV and PO supplemental calcium, and ergocalciferol. Despite ongoing supplementation of calcium, he continued to experience these seizure-like episodes for the next few days. The sleep deprived and extended EEGs were negative. Calcitriol and Keppra were later added to the treatment plan. The patient stopped having any further episodes on day 10 of admission, and his calcium levels reached the near normal range.

DISCUSSION: The main differential diagnoses for hypocalcemia in our patient were a Vitamin D deficiency and PTH resistance. With normal alkaline phosphatase, elevated phosphorus levels, and a lack of symptoms associated with osteomalacia, a Vitamin D deficiency was unlikely the sole cause of hypocalcemia. The presence of hyperphosphatemia, hypocalcemia and elevated PTH with normal morphologic features, points more to a diagnosis of PHP type 1b or type 2. Also, bilateral basal ganglia calcification is one radiological feature that can be associated with pseudohypoparathyroidism and might suggest that he had this condition for a long time. Pseudohypoparathyroidism (PHP) is a rare, heterogeneous group of disorders characterized by hypocalcemia, hyperphosphatemia, and increased PTH. This condition is caused by a dysfunctional Gs protein at the receptor level, conferring resistance to the biologic activity of PTH. There are three known subtypes of PHP—types 1a, 1b, and 2. Type 1a is characterized by morphologic abnormalities, whereas the other two subtypes are not. In this condition, hypocalcaemia can often present with life threatening complications like seizures, bronchospasms, laryngospasms, and arrhythmias. Hence, early diagnosis and prompt treatment are essential. The treatment usually consists of maintaining calcium levels to near normal with supplemental elemental calcium, along with an active form of Vitamin D analogue. A close outpatient monitoring of calcium levels is recommended.

A RARE CASE OF ATAXIA AND RAPIDLY PROGRESSING DEMENTIA

Sara Patrawala¹; Maryam Soltani¹; Mara Zulauf². 1UCSD, San Diego, CA; 2VA Healthcare System, San Diego, CA. (Tracking ID #1934106)

LEARNING OBJECTIVE 1: Recognize Creutzfeldt-Jakob Disease (CJD) and its variant forms

LEARNING OBJECTIVE 2: Counsel and assist in end-of-life care in fatal neurodegenerative diseases

CASE: A 69-year-old male veteran with a history of diabetes and cardiovascular disease presented to the hospital with a several week history of slurred speech and imbalance and was admitted to the neurology service for an acute stroke evaluation. Vital signs were normal. Neurologic exam revealed decreased attention, left-sided pronator drift, abnormal coordination, peripheral neuropathy and an unsteady, broad-based gait. CT head and basic laboratory results were unremarkable. The patient's presenting symptoms improved with hydration and he was discharged home. Two weeks later, he returned to the hospital with perceived left-sided weakness, multiple falls, confusion and word-finding difficulties. His examination revealed impaired language output, a child-like affect and truncal ataxia. Reversible causes of dementia and polyneuropathy including vitamin and mineral deficiencies, HIV infection, multiple myeloma and auto-immune diseases were ruled out. The neurology consultants were concerned for a heritable ataxia and recommended outpatient genetic testing. Three weeks later, the patient presented to the hospital with altered mental status and uncontrollable jerking. Neurologic exam revealed significant decline in speech production with inability to communicate within several days, and startle myoclonus in response to sound and touch. Electroencephalography (EEG), cerebrospinal fluid (CSF) testing for infectious etiologies and pan-CT imaging were unrevealing. An MRI was unable to be performed due to the presence of a pacemaker. His hospitalization was complicated by respiratory failure, myocardial infarction, arrhythmia, sepsis and progressive neurologic decline. In accordance with his family's wishes, he was transitioned to comfort care and passed away just over 2 months after

his initial presentation. Given the sub-acute decline in the patient's neurologic status with startle myoclonus and an otherwise unremarkable work-up, a diagnosis of CJD was suspected. Prion disease was later confirmed when 14-3-3 and tau proteins were discovered in his CSF. Final autopsy results are pending.

DISCUSSION: CJD is a fatal neurodegenerative disease caused by the accumulation of pathologic prion proteins in neuronal tissue with a prevalence of one case per million population. Classically, patients present with progressive dementia accompanied by startle myoclonus and mood lability with eventual progression to akinetic mutism and death. Most cases are sporadic but familial and iatrogenic cases do occur. Although cerebellar findings are common, a small subset of patients may present with an isolated cerebellar syndrome with cognitive decline seen weeks to months later. Some patients may even present with psychiatric symptoms prior to developing dementia and neurologic decline. Sporadic CJD is usually characterized by older age, periodic sharp wave complexes on EEG, an abnormal MRI signal in the putamen and head of the caudate, and positive 14-3-3 proteins on CSF analysis. In the variant forms of CJD, patients are typically younger, EEG changes are only seen in the later stages, CSF 14-3-3 proteins are not consistently present, and MRI may show signal hyper-intensity in the pulvinar nuclei of the thalamus. Recognizing nuances in presentation and testing is important when considering a diagnosis of CJD. As there is no known cure or intervention to slow the progression of this disease, early recognition is crucial so that internists may provide patients and their families with counseling and resources to allow for appropriate expectations of disease progression. With this prognostic information, families and patients may choose to pursue palliative and hospice care in efforts to reduce hospitalizations and potentially uncomfortable or harmful procedures at the end of a patient's life. In our patient's case, higher suspicion of CJD initially may have led to earlier discussion with him of his likely progressive neurologic deterioration and allowed for him to express his end-of-life wishes while he was still able, to his family.

A RARE CASE OF BACTEREMIA WITH SPHINGOMONAS PAUCIMOBILIS IN A PATIENT WITH ALLOGENIC STEM CELL TRANSPLANTATION Vikas Singh, SUNY Upstate medical university, Syracuse, NY. (*Tracking ID #1936954*)

LEARNING OBJECTIVE 1: Sphingomonas paucimobilis, is a yellow-pigmented, aerobic, non fermentative, gram negative motile bacillus. *S. paucimobilis* which is widely found in nature and hospital environments rarely cause serious or life threatening infections. In this report, a case of bacteremia with *S. Paucimobilis* secondary to line infection in a patient with stem cell transplant and immunosuppression is presented.

CASE: This is a 43 yo M with h/o AML complex cytogenetics s/p matched unrelated donor allogenic peripheral blood stem cell transplant with fludarabine/mechphalan preparatory regimen, 5 months ago, who was admitted with bacteremia. Pt recently went to see his primary oncologist for a follow up visit. His subclavian central line (Hohn catheter) was found to be uncapped and hence blood cultures were drawn from the line. The preliminary culture showed gram variable rods most likely corynebacterium species, with final culture eventually showing *Sphingomonas Paucimobilis* in the aerobic bottle. The anaerobic culture bottle didn't show any growth. He was hospitalized, re-cultured at our facility (Upstate Medical University Hospital) treated with IV vancomycin and Zosyn (total for 5 days) till final cultures came back as *Sphingomonas Paucimobilis*. Fortunately, patient remained asymptomatic during the entire course of hospitalization. His central line was removed and discharged to home with Amoxicillin for 10 days.

DISCUSSION: This case is reported to emphasize that *S. paucimobilis* should be kept in mind as a infectious agent in patients with immunosuppression and long term vascular access lines. Central venous catheter infections in hematopoietic SCT recipients may be associated with the development of bacteremia, septic complications, and death, particularly in neutropenic. Cure of such infections requires not only the administration of appropriate antibiotic therapy but also the early removal of the infected intravascular catheters

A RARE CASE OF COMPLETE HEART BLOCK Xuanjing Zhou1; Nicholas S. Amoroso2. 1Beth Israel Medical Center, New York, NY; 2Beth Israel Medical Center, New York, NY. (*Tracking ID #1901894*)

LEARNING OBJECTIVE 1: Recognize the potential for cardiac involvement in patients with neurodegenerative disorders in the absence of cardiac risk factors.

CASE: A 56 year old white male with hereditary spastic paraparesis and depression reports acute shortness of breath that awoke him from sleep. The wife reports that for the past 2 days, the patient appeared to have some difficulty breathing while lying down. The

patient denies a history of chest pain, fever, cough, nausea, diaphoresis, recent infection, toxic ingestions or family history of cardiac disease. Upon arrival to the emergency room, the patient was AAO \times 3, normotensive, with a heart rate of 26, and saturating 95–98 % on 2 l nasal cannula. The physical exam revealed prominent weakness and spasticity of the lower extremities with clonus and bilateral Babinski. The initial electrocardiogram showed complete heart block with a ventricular rate of 25 beats per minute and nonspecific intraventricular conduction delay. His serum electrolytes were within normal limits and cardiac enzymes were negative. B-type natriuretic peptide was 9.7 pg/ml. Chest x-ray showed clear lungs without pulmonary edema or evidence of calcification. Atropine 0.5 mg IV was given without change in ventricular rate. A transthoracic echocardiogram revealed mildly reduced left ventricular systolic function but was otherwise unremarkable. The patient was admitted to the coronary care unit where a temporary transvenous pacemaker was placed. The patient had 100 % paced rhythm, so a dual lead permanent pacemaker was placed the following day.

DISCUSSION: Hereditary spastic paraparesia (HSP) is a clinical diagnostic designation for those neurological syndromes in which bilateral lower extremity weakness and spasticity are the dominant manifestations and for which gene mutation is the major causative factor. It is well known that cardiac involvement is typical in neuromuscular diseases such as Duchenne muscular dystrophy and myotonic dystrophy. However, it has not been described in HSP. This case illustrates the potential for cardiac involvement in HSP patients in the absence of ischemic symptoms, known ischemic history or other cardiac risk factors. The pathogenesis that explains this cardiac involvement is unknown but endocardial biopsy of patients with similar neurodegenerative disorders have shown interstitial fibrosis of the right atrium and ventricle, as well as electron microscopical findings of myosin filament loss, and mitochondrial and Z-band alterations in degenerated myocytes (Takahashi et al. 2006, Roos et al. 2009). This suggests that an organic or functional lesion in the atrium, ventricle, or anywhere along the atrioventricular conduction system may contribute to a common pathway. Although the complete heart block seen in this patient is rare, it is a possible non-neurologic manifestation of HSP. Early recognition of this syndrome is critical to institution of appropriate monitoring and therapy.

A RARE CASE OF GROUP B STREPTOCOCCAL SEPTIC ARTHRITIS WITH A FLARE OF GOUT Phillip Aleksiejuk; Emily R. Haggerty. SUNY Upstate Medical University, Syracuse, NY. (*Tracking ID #1939376*)

LEARNING OBJECTIVE 1: Recognizing Streptococcus Agalactiae as an infrequent cause of septic arthritis in the elderly.

CASE: A 73 year-old man with multiple medical comorbidities presented with severe left knee pain of 3 days duration. He has a history of bilateral knee osteoarthritis and gout affecting his wrists and ankle joints. He denied any recent trauma to the knee, fever or additional joint pain. The physical exam revealed an exquisitely tender, warm, swollen left knee, without erythema. Labs were significant for a WBC of 13.5, CRP 21.8, ESR 116, and Uric acid of 9.2. Left knee x-ray demonstrated degenerative changes and a large effusion. Synovial fluid analysis showed a leukocytosis of 53000, with a moderate amount of monosodium urate crystals. Blood and synovial cultures returned positive for group B streptococcus (GBS). The patient was diagnosed with acute on chronic gout flare with superimposed septic arthritis secondary to GBS. He was treated with Ceftriaxone, Prednisone and Colchicine because of poor baseline renal function. The knee was irrigated and debrided several times to prevent recurrent infection. The remainder of the patient's hospital course was uneventful, and his condition improved thereafter with many hours of physical therapy.

DISCUSSION: This case illustrates the unique presentation of GBS induced septic arthritis in the setting of an acute gouty flare in an elderly patient. Literature shows an increasing incidence of GBS, and remains a serious cause of morbidity and mortality in nonpregnant adults. It is therefore crucial that clinicians maintain a high index of suspicion for GBS not only in pregnant females, but also in the elderly patient with multiple comorbidities. Increasing the awareness of GBS infection of septic arthritis will not only hasten diagnosis, but will improve clinical outcomes and the quality of life in the geriatric population.

A RARE CASE OF PRIMARY CARDIAC LYMPHOA Jason Sayanlar1; David DeMaria1; Ana Barac2. 1Georgetown University Hospital, Washington, DC; 2Medstar Washington Hospital Center, Washington, DC. (*Tracking ID #1942107*)

LEARNING OBJECTIVE 1: To understand the impact of Primary Cardiac Lymphoma as a rare but clinically important extranodal manifestation of Non-Hodgkin Lymphoma limited to the heart and pericardium.

LEARNING OBJECTIVE 2: To highlight the mainstays of therapy for Primary Cardiac Lymphoma

CASE: A 66 year-old female with no past medical history initially presented to her physician with unilateral facial swelling. A CT scan revealed a stone within the parotid gland, as well as the incidental finding of a pericardial effusion. A transthoracic echocardiogram was done, which demonstrated a large effusion with minimal right ventricle (RV) systolic collapse as well as left ventricle (LV) borders "suspicious for sarcoma". The patient underwent a pericardial window and ultimately a pericardectomy, after the fluid re-accumulated. Pathological specimens obtained were initially negative for malignancy. Four months later, the patient again presented with recurrent dyspnea and fatigue. A cardiac MRI showed an infiltrating epicardial mass extending from the anterior base of the left ventricle into the lateral wall. The patient underwent a cardiac biopsy, which was consistent with large B-cell lymphoma. The patient was diagnosed with stage IIE cardiac lymphoma and was started on a chemotherapy regimen consisting of etoposide, prednisone, oncovin, cyclophosphamide, and doxorubicin (EPOCH) with rituximab. An MRI after her first round of chemotherapy showed a significant reduction in tumor size.

DISCUSSION: Primary cardiac lymphoma (PCL) is a rare manifestation of Non-Hodgkin Lymphoma (NHL) characterized by extranodal lymphoma limited to the heart and pericardium. PCL represents approximately 1 % of all cardiac tumors and only 0.5 % of all extranodal lymphomas.⁴ Most cardiac tumors are metastases, followed by myxomas, which make up 75 % of primary cardiac tumors. Among malignant primary cardiac tumors, sarcomas are approximately 20 times more common than lymphomas. Patients with PCL typically present in the sixth decade of life, with a 3 to 1 male predominance. Sixty-nine percent of all PCL cases involve the right sided chambers of the heart, with the right atrium being the most common site of incidence. Left heart involvement is exceedingly rare and is usually limited to tumors extending from the right side of the heart. Bone marrow and superficial lymph nodes are free of lymphoma in nearly all cases. Symptoms are non-specific, therefore most patients are diagnosed incidentally or after advanced clinical presentation. Idiopathic recurrent pericardial effusion is a common feature of many PCL cases. Biopsy is the gold standard for diagnosis, but is usually accompanied by preceding echocardiography and/or cardiac MRI. If a pericardial effusion is present, a sample should be sent for immunohistochemistry. Therapeutic options include chemotherapy, radiation and surgical resection. Many cases include a combination of chemotherapy and radiation, however, treatment is case-specific and largely depends on the anatomic characteristics and biologic features of the tumor. In extremely rare cases, heart transplant has also been performed. Stem cell therapy may prove to be a treatment option for refractory cases. Like the treatment of other lymphomas, chemotherapy for PCL typically consists of EPOCH or CHOP (cyclophosphamide, hydroxydaunorubicin, oncovin, prednisone) and rituximab. Given its cardiotoxicity, the use of doxorubicin is controversial, but has not shown to decrease survival. Prognosis is variable and depends on the progression of disease at the time of diagnosis, as well as the patient's response to chemotherapy. For cases with advanced disease secondary to diagnostic delay, the median survival is 7 months.

A RARE CASE OF PROXIMAL MUSCLE WEAKNESS Ronak Shah; Reena Agarwal. Montefiore Medical Center, New York, NY. (*Tracking ID #1930431*)

LEARNING OBJECTIVE 1: Distinguish Lambert-Eaton Myasthenic Syndrome [LEMS] from its differential diagnosis of proximal muscles weakness.

LEARNING OBJECTIVE 2: Recognize the clinical presentation of LEMS and the importance of early diagnosis because of its high rate of association with malignancy.

CASE: A 60 year-old man presented with 8 months of progressive weakness. Initially, he had significant difficulty getting up from his chair and walking up a hill. His symptoms slowly progressed to having a hard time washing his hair and swallowing solid foods. He denied any muscular pains, tingling or numbness. But he did have dry mouth, erectile dysfunction and mild constipation. He had left eye ptosis, which did not worsen with sustained upward gaze and ocular movements were normal with no signs of fatigue. The strength of all his muscle groups was 5/5, except for the deltoids and hip flexors, which were 4/5 bilaterally. Patient had diminished to absent deep tendon reflexes and struggled to stand up from his chair. Initial laboratory studies revealed a creatine phosphokinase [CPK] of 124 U/L [normal range 20–200 U/L]. He underwent electromyography and nerve conduction studies [EMG / NCS], which were consistent with Lambert-Eaton Myasthenic Syndrome [LEMS]. The patient also had positive voltage gated calcium channel [VGCC] antibodies and a negative acetylcholine receptor antibody, which confirmed the diagnosis of LEMS. CT of the thorax, abdomen and pelvis did not reveal any masses. The patient was given 5 days of IV immune globulin [IVIG] and started on high dose prednisone and pyridostigmine daily. With this treatment, his symptoms of proximal muscle weakness, swallowing and dry mouth slowly resolved. The patient remains free of any evidence of malignancy.

DISCUSSION: Weakness is a common complaint in the outpatient setting. It is often confused with functional limitation due to pain or stiffness. After objectively identifying true weakness, the key in finding the underlying lesion or etiology is figuring out the pattern of distribution. Proximal muscle weakness is particularly important as it narrows the differential to neuromuscular junction disorders like myasthenia gravis [MG] or LEMS, inflammatory myopathies, such as polymyositis or dermatomyositis, and certain motor neuron diseases, like amyotrophic lateral sclerosis. Lambert-Eaton Myasthenic Syndrome is a rare neuromuscular autoimmune disease with an annual incidence of 0.48 per million that is thought to be caused by auto-antibodies against VGCC. The VGCC antibodies block the influx of calcium in the pre-synaptic membrane, which leads to a reduction in the acetylcholine that is released. The classic symptoms of LEMS are proximal muscle weakness, diverse autonomic features such as dry mouth [most common], erectile dysfunction, constipation, and decreased or absent reflexes. EMG studies show an increase muscle action potential after brief isometric exercise, known as post-exercise stimulation. The post-exercise stimulation helps differentiate between LEMS and MS as it has 84–96 % sensitivity and a 100 % specificity for LEMS. Therefore, the clinical signs, positive VGCC antibodies and EMG studies all help in diagnosing LEMS. Early recognition and diagnosis of LEMS is paramount because nearly 50 % of patients with LEMS have an associated malignancy, mostly commonly small cell lung cancer [SCLC]. Clinical symptoms of LEMS are usually present before SCLC is detected, making it important to distinguish LEMS from other disease entities that cause proximal muscle weakness. Myasthenia gravis is the most common etiology that is confused with LEMS, especially when the oculobulbar muscles are involved. But MG patients usually show oculobulbar symptoms first, in contrast to LEMS patients, who initially present with lower extremity weakness. In addition, most MG patients do not have autonomic symptoms or absent reflexes. And unlike inflammatory myopathies, patients with LEMS do not have pain or elevated CPKs. Management of LEMS must incorporate an aggressive screening process for SCLC. Additional treatment consists of symptomatic relief with medications, such as 3,4-diaminopyridine [3,4-DAP] and pyridostigmine that increase the acetylcholine at the post-synaptic membrane. For more refractory or significant symptoms, a trial of IV immune globulin [IVIG] and/or other immunosuppressive agents, like high-dose prednisone or azathioprine, is usually considered. Reference: Titulaer, M et al. Lambert-Eaton myasthenic syndrome: from clinical characteristics to therapeutic strategies. Lancet Neurology. 2011; 10; 1098–1107.

A RARE CASE OF TOXIC EPIDERMAL NECROLYSIS (TEN) ASSOCIATED WITH THE USE OF AZITHROMYCIN Steve M. Antoine; Emerald Banas; Shane Keogh. Upstate Medical University, Syracuse, NY. (*Tracking ID #1934683*)

LEARNING OBJECTIVE 1: Recognize a rare presentation of Steven Johnson Syndrome/Toxic epidermal necrolysis

LEARNING OBJECTIVE 2: Distinguish when to use and not to use systemic steroids

CASE: A 19 year old previously healthy male presented with fever, dyspnea, productive cough, sore throat, oral blisters, diffuse maculopapular and bullous skin lesions. He sought medical consult a week prior for coryza and a productive cough, for which he was prescribed azithromycin. He denied taking any other over-the-counter drugs. Two days later, he woke up with dysphagia and odynophagia at which time he stopped taking the azithromycin. His symptoms progressively worsened; he experienced increased difficulty with swallowing and talking and also began to notice swelling of his tongue and painful blisters inside of his mouth. He then started developing diffuse maculopapular skin lesions over his face, torso and upper extremities, was subsequently rushed to the hospital. Past medical history was significant only for past allergic drug reaction to amoxicillin, which resulted in swelling of his lips. On arrival, he was noted to be febrile (40.5°C), tachycardic at 106 bpm and tachypneic. Examination of the skin showed diffuse maculopapular skin lesions from his face down to his upper thighs encompassing approximately 40 % of total body surface area as well as smaller vesiculobullous lesions which showed separation of the epidermis from the dermis. Head and neck exam revealed significant conjunctival injection, severe oropharyngeal swelling and blistering of lips, oral mucosa, and tongue. Routine chemistry studies were unremarkable. Hematologic studies were significant for leukocytosis at 12,600/mm³ with neutrophilic predominance; Chest xray didn't show any evidence of pneumonia. Patient was admitted to the medicine service for management of suspected SJS/TEN. He received supportive care with IV fluids, topical antibiotics, viscous lidocaine and prednisolone eye drops. Punch biopsy showed epidermal acantholysis with intraepidermal and suprabasal keratinocyte separation without immunoglobulin or complement deposition, consistent with SJS/TEN. Ophthalmology determined that his conjunctival injection was consistent with ocular manifestations of SJS/TEN. The use of systemic corticosteroids

was discussed, as suggested by many specialist consulted on the case; however we opted not to as there is limited evidence supporting it, and at that point, an infectious trigger was still being debated. The patient's oropharyngeal and mucocutaneous lesions slowly resolved with conservative care and topical antibiotics. All cultures came back negative. He was eventually transferred to the burn management team and discharged home on hospital day number 12.

DISCUSSION: Stevens-Johnson and toxic epidermal necrolysis (SJS/TEN) represent a spectrum of severe mucocutaneous reactions triggered usually by medications, leading to desquamation, skin necrosis and sometimes death. Multiple medications have been associated with SJS/TEN. There are only 2 reports in the literature associating SJS/TEN with azithromycin. SJS/TEN is associated primarily with medications, secondarily with infections. A thorough investigation has to be conducted to rule out the latter, which can alter treatment. In this case, azithromycin was the most likely culprit, given the onset immediately after use and lack of an identifiable source of infection. The use of steroids in SJS/TEN has been debated and remains controversial. Although it can slow down disease progression, it can be detrimental if infection control is a major concern. Furthermore, in our patient the large exposed lesions provided an accessible site of infection, thus the risks of systemic steroid outweighed the potential benefits.

A RARE CASE: PULMONARY BLASTOMA WITH FOCAL MELANOCYTIC DIFFERENTIATION Alexandre Zaharia. Allegheny General Hospital, Pittsburgh, PA. (*Tracking ID #1940190*)

LEARNING OBJECTIVE 1: Recognize the rare but highly aggressive form of primary lung malignancy that are pulmonary blastomas and thereby establish a prompt diagnosis.

LEARNING OBJECTIVE 2: Appreciate the heterogeneity in presentation and histopathology of pulmonary blastomas.

CASE: An 81 year old male with history of chronic obstructive pulmonary disease (COPD) and longstanding cigarette smoking, presented to the emergency department with new-onset dyspnea and atypical chest pain. An extensive work-up was undertaken, with computed tomography (CT) revealing a new right lower lobe 8.3 cm×7.2 cm necrotic mass with underlying COPD. After stabilization of his symptoms, the patient underwent CT-guided core biopsy, revealing poorly-differentiated adenocarcinoma without further classification. Positron emission tomography (PET) showed absence of distant metastasis. Given these findings, the patient underwent video-assisted thoracoscopic surgery (VATS) and right lower lobectomy with mediastinal lymph node sampling. Intraoperative specimens sent for pathology were consistent with pulmonary blastoma composed of fetal adenocarcinoma and primitive blastematosus stroma, with additional foci of squamous differentiation, with staining pattern suggestive of melanoma, yielding the final designation of PB with melanocytic differentiation. With no nodal metastasis found, adjuvant chemotherapy was opted against. In the meantime, the patient was discharged home. A surveillance CT at 3 months showed no evidence of disease recurrence. Unfortunately, the patient presented again with dyspnea 6 months post-surgery. A CT obtained then showed progressive metastatic PB with a new massive right pleural effusion and suspected liver metastases. In consultation with the patient and his family, the patient was made comfort measures only and transferred to hospice, where he expired shortly thereafter.

DISCUSSION: Pulmonary blastomas (PB) are rare (0.25–0.5 % of all lung malignancies) primary malignant epithelial lung tumors consisting of immature lung components that arise in young adults (median age=35.5 years old). They constitute a form of sarcomatoid adenocarcinoma (2004 WHO classification) and are further subdivided into two histopathological subtypes: 1) well-differentiated fetal adenocarcinomas (WDFA) that contain epithelial components only and 2) classic biphasic pulmonary blastomas (CBPB) that contain both epithelial and mesenchymal components. There exists no current consensus with regards to risk factors or presenting symptomatology. PB are highly aggressive and carry a poor prognosis (5 year survival=16 %). Presently, complete early surgical resection is the favored treatment approach. However, further modalities such as chemotherapy and/or radiotherapy have not yet been defined. The above case displays PB of the CBPB subtype in an elderly male with early relapse following prompt surgical resection. PB are an uncommon, perhaps underdiagnosed, lung tumor subtype. This case presents two additional atypical variants that have seldom been reported - 1) the melanocytic component noted on pathology and 2) the well-advanced age at time of presentation - and that speak to PB's heterogeneity. Lastly, it bears witness to the aggressiveness of PB and suggests surgical resection, albeit the current consensus treatment option, does not constitute an effective curative modality.

A RARE CAUSE OF GASTROENTERITIS Malav P. Parikh; Venu M. Ganipisetti; Sathish Kumar Krishnan; Venu Pararath Gopalakrishnan; John Vainder. Saint Francis Hospital, Evanston, IL. (*Tracking ID #1935674*)

LEARNING OBJECTIVE 1: Eosinophilic gastroenteritis (EG) is a rare condition of unclear etiology. It is characterized by gastrointestinal (GI) symptoms, peripheral eosinophilia and eosinophilic infiltration of the bowel to a variable extent and.

CASE: An 83 year old female presented with brownish, watery diarrhea, weight loss of 5 lbs and dull lower abdominal pain for about 2 weeks. The patient reported 7–8 episodes of diarrhea in a day, not associated with blood or mucus. She denied any fever, vomiting, recent travel, sick contact, antibiotic exposure or food intolerance. Patient had a colonoscopy 2 years ago, which was reported as normal. Laboratory studies showed white blood cell count of 21 k/mm³ and absolute eosinophil count of 4180 cells/mm³ (19 %). Stool studies were negative for clostridium difficile, ova and parasites. Colonoscopy showed diverticulosis of the colon and biopsy was consistent with marked eosinophilic infiltration of the colonic and ileal mucosa. Total IgE level was elevated to 159 Ku/L (normal: 2–114 Ku/L). Patient improved clinically with intravenous fluids and was discharged after 24 h. Steroids or antibiotics were not used. She remained asymptomatic at a follow up visit after 1 month.

DISCUSSION: EG is an uncommon cause of gastroenteritis. Symptoms of EG depend upon the layers of bowel affected by eosinophilic infiltration. Mucosal involvement results in nausea, non-specific abdominal pain, diarrhea, and malabsorption. Muscle layer involvement causes symptoms of intestinal obstruction, whereas subserosal infiltration causes eosinophilic ascites. Diagnosis of EG is confirmed by endoscopic biopsy and/or eosinophilic ascitic fluid. It is very important to rule out intestinal parasitic infection. Irritable bowel syndrome can present with similar clinical presentation and is one of the important differential diagnosis. Currently, treatment of EG is empiric and based upon severity of disease. Patients with mild and sporadic symptoms can be managed with reassurance and expectant observation. Patients with severe GI symptoms and malabsorption can be treated with systemic glucocorticoids. Sodium cromolyn, ketotifen and elimination diet may be useful in patients with history of allergic disorders. Surgical intervention is reserved for patients with obstructive symptoms.

A RARE CAUSE OF HEADACHE: SCEDOSPORIUM IN THE SINUS Aliza Norwood. UCSF, San Francisco, CA. (*Tracking ID #1934629*)

LEARNING OBJECTIVE 1: Identify the “red flag” headache symptoms that require imaging

LEARNING OBJECTIVE 2: Recognize fungal sinus infection as an uncommon cause of headache

CASE: A 55 year old woman with a past medical history of depression and no personal or family history of migraine presented with 3 months of a worsening “vice-like” headache. She reported constant left fronto-temporal pain and pressure. Her headache occasionally woke her from sleep and interfered with her ability to work. She denied fevers, chills, night sweats, vomiting, lacrimation, pulsatile sensations, or photophobia and she had no HIV risk factors. Her only medication was Celexa 10 mg by mouth daily. On physical exam, she appeared to be in acute pain, and was rubbing her right temple. Her vital signs were within normal limits. She had no papilledema or nuchal rigidity. Her neurological exam—including speech, cranial nerves, reflexes, strength, and gait—was normal. CBC and TSH were normal. A head CT was obtained and demonstrated ethmoid and sphenoid chronic sinusitis with recommendation for a dedicated sinus CT. CT of the sinuses revealed an interval increase in size of a soft tissue mass within the left sphenoid sinus. The patient underwent endoscopic sinus surgery and was found to have a left sphenoid and posterior ethmoid mycetoma (“fungus ball”), for which she underwent left total ethmoidectomy and sphenoidotomy. Pathology showed Scedosporium apiospermum.

DISCUSSION: Headache is a common primary care complaint, and it is important to determine when it may be treated conservatively and when more aggressive work up is needed. CT or MRI is indicated in patients who present with one or more “red flag” symptoms, which include the following: a new or different headache, a severe headache often referred to as the patient’s “worst headache of their life”, symptoms of systemic illness, seizures, or as in the case of this patient, onset of headache after the age of 50 and disabling headache. Key features on exam that suggest a secondary cause of headache include papilledema, nuchal rigidity, or focal neurological signs. A sphenoid mycetoma is a fungal sinus process and can be a rare cause of headache. The pathophysiology is thought to be due to deficient mucociliary clearance leading to sinus colonization and a chronic inflammatory response. Most cases of non-invasive sphenoid mycetoma are in immunocompetent older women. Patients with this condition usually presents with unilateral fronto-orbital headaches. Rhinological symptoms, including nasal congestion, post-nasal drip, cough, headache or facial

pain, occur in 20 % of patients. Approximately 15 % of patients with this condition are asymptomatic and the mycetoma is found during routine tests. Sphenoid mycetomas can lead to recurrent secondary bacterial infections and central nervous system complications but only in a minority of patients. Two thirds of patients have symptomatic improvement after surgery and this is considered the definitive therapy.

A RARE COMPLICATION OF A COMMON CONDITION: WHEN LYMPHEDEMA GETS WORSE Thomas Weart^{1,2}; Sean M. Lockwood^{2,1}. ¹University of Kentucky Medical Center, Lexington, KY; ²VAMC, Lexington, KY. (*Tracking ID #1940099*)

LEARNING OBJECTIVE 1: Review the epidemiology of lymphangiosarcoma and the Stewart-Treves syndrome

LEARNING OBJECTIVE 2: Describe the common clinical manifestations, treatment, and prognosis

CASE: A 46 year-old male with a history of congenital pelvic arteriovenous malformations (AVMs) resulting in chronic left lower extremity lymphedema presented with 1 week history of slowly progressive weakness, fatigue, and intermittent fevers with increased lower extremity edema. His past medical history was significant for multiple complications of his AVMs including high output heart failure and chronic gluteal skin wounds. Physical examination revealed normal vital signs, diffuse edema of his left lower extremity with chronic venous stasis changes but no new discrete skin lesion. Bilateral inguinal lymphadenopathy was present with the largest node measuring 2×3 cm. Laboratory studies revealed a white blood cell count of 3.0 k/uL, hemoglobin 11.8 g/dL, and platelet count 175 k/uL. Complete metabolic panel was normal. CT imaging revealed extensive lymphadenopathy of the pelvis and retroperitoneum. Excisional lymph node biopsy of the largest inguinal node revealed high-grade angiosarcoma. In a patient with chronic lymphedema, this finding is consistent with Stewart-Treves syndrome. The patient was enrolled in a clinical trial for experimental chemotherapy on recommendation of a multidisciplinary tumor board. Repeat imaging after initial treatment is suggestive of a positive response to therapy.

DISCUSSION: Stewart-Treves syndrome refers to angiosarcoma arising in the setting of chronic lymphedema. This condition was first described in 1948 in a case series of six patients who developed lymphedema following mastectomy. Overall, the incidence of Stewart-Treves remains low with approximately 400 cases reported in the literature. Only 0.3 % of patients 10 years status post mastectomy develop this condition. The incidence of lower extremity Stewart-Treves Syndrome is even rarer. The pathogenesis is believed to be due to the disruption of immunocompetent cell movement to the affected region while collateral lymph vessels and angiogenesis proliferate in a dysregulated manner. The typical time course for development of this malignancy is 5–16 years after radical mastectomy and/or the onset of lymphedema. Clinicians should consider Stewart-Treves Syndrome when a patient with chronic lymphedema presents with worsening swelling, lymphadenopathy or new skin changes in the affected area. These patients often have atrophic skin with chronic edema and erysipelas being common. However the lesions associated with angiosarcoma may begin as dark or purplish areas mimicking Kaposi's sarcoma. It may also present as a wound which bleeds easily or fails to heal. Lymphadenopathy is often a late and ominous finding. Early diagnosis is particularly important because the most effective treatment is surgical excision prior to proximal spread which may require amputation. Mean survival is 5–8 months without treatment. Chemotherapy and radiation therapy offer little benefit to overall survival with mean survival up to 20 months with maximal treatment. The need for early diagnosis underscores the importance for internists to recognize this rare but potentially treatable cancer in a patient with the common condition of lymphedema.

A RARE GLIMPSE WITH MULTIMODALITY CARDIAC IMAGING INTO AN EXPANDING LEFT VENTRICULAR OUTFLOW PSEUDOANEURYSM FROM ENDOCARDITIS Jon N. Quach^{1,2}; Katharine M. Borthwick²; Jeffery Gordon²; John Moriarty³; Murray Kwon⁴; Paul Finn³; Eric H. Yang². ¹University of California, Los Angeles Olive View Medical Center, Sylmar, CA; ²University of California, Los Angeles Medical Center, Los Angeles, CA; ³University of California, Los Angeles Medical Center, Los Angeles, CA; ⁴University of California, Los Angeles Medical Center, Los Angeles, CA. (*Tracking ID #1935025*)

LEARNING OBJECTIVE 1: Recognize the incidence and clinical features of left ventricular outflow tract (LVOT) pseudoaneurysms (PSAs) after endocarditis

LEARNING OBJECTIVE 2: Assess left ventricular outflow tract (LVOT) size and appropriate management using multimodality cardiac imaging (ie echocardiography, MRI, CT)

CASE: A 56-year-old Chinese female with a history of bicuspid aortic valve, underwent an aortic root replacement and mitral valve repair (21 mm CryoLife homograft, CryoLife Inc., Kennesaw, GA) and 32 mm Medtronic Future Band annuloplasty ring (Medtronic, Minneapolis, MN) for Enterococcus faecalis endocarditis secondary to a longstanding intrauterine device. The patient also received coronary artery bypass graft (CABG) with saphenous vein grafts of all three of her native coronary arteries. Intraoperatively the patient was noted to have a PSA in the LVOT but given the concern for friable and unstable myocardial tissue in light of her recent infection and thus suboptimal surgical repair, the decision was made to conservatively manage and monitor her PSA. A postoperative TTE and multidetector cardiac computed tomography (MDCT) confirmed the presence of her LVOT PSA (Figure 1A and B). The patient was subsequently lost to follow up from our hospital, with interim development of acute occlusion of one of her saphenous vein grafts requiring percutaneous coronary intervention. She also was found on outside testing to have exercise induced ischemia on stress echocardiography. The patient once again reestablished care at our hospital 10 months after her initial surgery. Multimodality imaging, including transthoracic and transesophageal echocardiography, MDCT, and cardiac magnetic resonance imaging performed at that time was significant for progression of her LVOT PSA. (Figures 1C-D, Figure 2) Given the rapidly progressing size of the patient's LVOT PSA, the patient underwent open surgical repair. Her aortic root was redone with a customized-made valve conduit utilizing a 19 mm Edwards Magna Ease pericardial tissue valve (Edwards Lifesciences, Irvine, CA). She also underwent a re-do CABG of her native coronary arteries. Repeat imaging confirmed surgical closure of the LVOT PSA and patent grafts. The patient did well and was discharged with outpatient follow up.

DISCUSSION: A left ventricular pseudoaneurysm occurs when cardiac rupture is contained by surrounding pericardium or scar tissue [1]. Left ventricular outflow tract (LVOT) pseudoaneurysms (PSAs) are related primarily to MI, however other common causes include surgical aortic root repair and mitral valve repair. Primarily, patients present with symptoms of heart failure, chest pain, and shortness of breath; however >10 % of patients remain asymptomatic. The diagnosis of LVOT pseudoaneurysm remains difficult, however angiography is considered the best available diagnostic test. 2D Transthoracic echocardiogram remains a viable and less invasive option, but results in a definitive diagnosis in only 26 % of patients. With optimal medical management, LVOT PSA has a 35–40 % risk of rupture as well as a 50 % mortality rate [2]. Early identification and surgical repair is essential to improving patient outcomes. Patients generally do well after surgical repair, however perioperative risk of death is approximately 30 % [3]. There is some evidence suggesting that PSA can be conservatively managed with optimal medical therapy, but these results may be skewed by publication bias [4]. Our case shows the significant spatial resolution and ability to reconstruct 3-dimensional aspects of a cardiac PSA using sophisticated modern imaging techniques in evaluating the progression in size of a LVOT PSA. It highlights the importance of early detection and repair in this uncommon sequelae of infective endocarditis utilizing the advantages of multimodality cardiac imaging. 1. Dachman AH, Spindola-Franco H, Solomon N. Left ventricular pseudoaneurysm. Its recognition and significance. JAMA 1981;246:1951–3. 2. Frances C, Romero A, Grady D. A RARE OCCURRENCE: GRAVE'S OPHTHALMOPATHY IN A PATIENT WITH HASHIMOTO'S THYROIDITIS Mohammed W. Imam; Hiba Hadid; Rashim Gupta; Yogin Patel; Mona Hassan. Henry Ford Health System, Detroit, MI. (*Tracking ID #1938559*)

LEARNING OBJECTIVE 1: Through this case report, we hope to shed light on the importance of recognizing the possibilities of Grave's disease and Hashimoto's thyroiditis occurring consecutively or simultaneously.

LEARNING OBJECTIVE 2: We also aim to highlight the importance of recognizing Grave's ophthalmopathy with vision compromise as an ophthalmologic emergency that requires immediate intervention.

CASE: We report a case of a 55-year old male with a medical history significant for Hashimoto's disease for 13 years and type I diabetes mellitus, presenting with severe exophthalmos, eye swelling, near complete vision loss, and pretibial myxedema.

Orbital CT imaging, revealed severe optic nerve compression. Steroids were promptly initiated and the patient was emergently taken to the OR for orbital decompression.

DISCUSSION: The development of hypothyroidism after Grave's disease is well documented in the literature. However, the occurrence of Grave's disease after chronic thyroiditis is rare. Patients may become hypothyroid, euthyroid, or hyperthyroid and the occurrence of each is determined by the balance between the stimulating and blocking antibodies, and by the functional state of the thyroid gland. The interval between the onset of these two disease states could range from weeks to decades. There are only a few cases reported in the literature in which Grave's disease follows hypothyroidism. Through this case report, we hope to shed light on the importance of recognizing the possibilities of these two diseases occurring consecutively or simultaneously. We also aim to highlight the importance of recognizing Grave's ophthalmopathy as an ophthalmologic emergency that requires immediate intervention, when vision is compromised.

A RASH DECISION Shara I. Epstein^{1,2}; Sheira Schlar^{1,2}. 1Montefiore Medical Center, Bronx, NY; 2Albert Einstein College of Medicine, Bronx, NY. (*Tracking ID #1936875*)

LEARNING OBJECTIVE 1: Recognize various dermatological manifestations of strongyloidiasis

LEARNING OBJECTIVE 2: Distinguish signs and symptoms of acute versus chronic strongyloidiasis

CASE: A 39 year-old woman presented with a rash on her right buttock recurrent for two and a half years. She initially presented with a non-painful, non-pruritic rash on her left shoulder 3 months ago and a new rash on her breast, abdomen and legs. On physical exam she had mild erythema of the upper chest and erythematous plaques without scaling of the medial breasts. There was streaky erythema at the waistline. The left shoulder and the right buttock revealed annular, atrophic, non-scaling erythematous plaques as well. The bilateral medial buttocks were noted to have multiple track-like lesions. The right shin had two more plaques. Past labs were notable for a white blood cell count of 5.3, with 0.3 eosinophils (upper end of normal). She was initially treated with ketoconazole for disseminated tinea versicolor, with no improvement. The patient remembered spending some time in upstate New York and a concern for lyme disease developed. She was treated empirically with a 4 week trial of doxycycline, without any improvement. A shave biopsy of the left shoulder revealed peri-infundibular, superficial perivascular and interstitial dermatitis with eosinophils. Ultimately, laboratory tests revealed a positive Lyme antibody titer but with negative western blot. A strongyloides titer was ordered in light of the biopsy's eosinophils and found to be positive. On further questioning, patient stated that she had lived in Greece in the past and takes yearly trips to rural villages there. She was treated with albendazole with complete resolution of the rash.

DISCUSSION: General internists see many types of rashes in their practice and should consider the epidemiology of various eosinophilic rashes, especially for travelers. It is estimated that 30–100 million people are infected with *Strongyloides* worldwide via fecal-oral contamination, on all continents except Antarctica, and especially in the tropics. Typical presentation is with nonspecific symptoms that span a wide spectrum from abdominal pain and bloating to arthritis and rash, which may appear immediately following exposure or years later. Acute strongyloidiasis is characterized by a pruritic rash at the location of skin penetration followed by other non specific symptoms. Chronic strongyloidiasis, as this patient had, is usually asymptomatic, but can eventually manifest with either gastrointestinal or cutaneous symptoms. *Strongyloides* can complete its entire lifecycle in the human. The filariform larvae can penetrate the skin and it is often during this phase that they cause the larva currens rash, the pathognomonic rash of strongyloidiasis. However, various other rashes have been described. A diffuse purpuric and petechial rash can occur in disseminated strongyloidiasis, especially in immunocompromised patients. Other allergic type rashes have been seen, more rarely, as was likely the case in this patient with her eosinophil predominant rash. For cutaneous manifestations, treatment is one to two doses of ivermectin or albendazole twice daily for 7 days, while ivermectin is the preferred treatment for intestinal strongyloidiasis. Our patient received albendazole with full recovery. In conclusion, general internists are the first line for many patients with rashes, and it is always important, especially in a practice with patients frequently traveling internationally to rural areas, to consider parasitic causes for their rashes, especially those that are found to be eosinophil-predominant.

A RASH ON THE PALMS AND SOLES—AND EVERYWHERE IN BETWEEN Navya Nambudiri³; Vinod E. Nambudiri^{1,2}; Sandy Tsao². 1Brigham and Women, Brookline, MA; 2Massachusetts General Hospital, Boston, MA; 3Cochin Medical College, Cochin, India. (*Tracking ID #1936592*)

LEARNING OBJECTIVE 1: Recognize the clinical presentation of guttate psoriasis and the features which distinguish it from other cutaneous eruptions.

LEARNING OBJECTIVE 2: Treat and counsel patients diagnosed with guttate psoriasis.

CASE: A 23-year-old previously-healthy man presented for evaluation of a new rash. He had moved from France to the United States 8 weeks earlier. One week after arriving in the United States, he noted a sore throat associated with pain on swallowing as well as mild subjective fevers. The sore throat resolved after 10 days. Two weeks later, he noted the development of a papular eruption that started on his hands and feet as “many small pink spots.” He denied any arthralgias, myalgias, pruritus, pain or other systemic symptoms with the rash. He had previously been in a monogamous relationship with his girlfriend in France and had a recent negative HIV test. He took no medications, had no known allergies, and no close contacts with a similar rash. There was no family history of a similar eruption. He was evaluated at an outside urgent care provider 1 week following the onset of the eruption. The rash was noted to be predominantly on the palms and soles and was spreading to involve the arms and legs. Titers for Rocky Mountain Spotted Fever (RMSF) as well as Coxsackie virus were sent. He was treated empirically for RMSF with 7 days of doxycycline without improvement. Over the next 2 weeks, the rash progressed to involve the body diffusely. He presented to our institution for further evaluation when he noted the eruption was spreading to his face and becoming mildly pruritic. Titers for both RMSF and Coxsackie virus had returned as negative. He continued to deny fever, chills, or systemic symptoms. On examination, hundreds of 2–3 mm pink papules with silvery scale were noted on the face, arms, chest, back, legs, feet and hands, to the point of coalescence on the palms. Koebnerization of lesions in an area of linear excoriation on the upper arm was appreciated. Anti-Streptolysin-O titer was elevated at 695 IU/mL (normal <530) and Anti DNase-B titer was markedly elevated at 706 IU/mL (normal <300). A skin biopsy demonstrated psoriasiform hyperplasia, confirming the clinical diagnosis of guttate psoriasis. He was treated with topical triamcinolone acetonide 0.1% cream with good effect.

DISCUSSION: Guttate psoriasis is a benign inflammatory skin eruption characterized by numerous individual papules and plaques distributed over the trunk and extremities. The name ‘guttate’ is derived from the Latin term ‘gutta’ - meaning ‘a drop’—as the clinical appearance is of individual raindrop-like skin lesions that present in an eruptive manner. While it may occur at any age, guttate psoriasis is more common in children and young adults. The cutaneous lesions may begin as thin pink plaques which develop increasing scale, reflective of the epidermal hyperplasia and hyperkeratosis seen on skin biopsy. Koebnerization—the development of skin lesions in sites of trauma—is a characteristic finding in psoriasis and was noted in this patient’s clinical presentation. This finding helps distinguish guttate psoriasis from differential diagnoses such as an acute viral exanthem, eczema, morbilliform drug eruption, or pityriasis rosea. Guttate psoriasis is unique among other forms of psoriasis as it is often associated with preceding streptococcal infection. Family history of psoriasis and stressful life events have also been associated with the disease’s onset in case-control studies. The classic history is of a streptococcal pharyngitis preceding the onset of the eruptive rash by a few weeks, consistent with our patient’s history. The elevated Anti-Streptolysin-O and Anti-DNAse B seen in our patient confirm a streptococcal cause for his recent sore throat symptoms. Epidemiologic studies suggest patients in whom the development of guttate psoriasis is associated with a streptococcal infection have more rapid and more long-term clearance of the skin than those without evidence of associated streptococcal infection. Treatments for guttate psoriasis remain an ongoing area of investigation in the medical literature. Studies do not suggest any benefit of anti-streptococcal treatments for skin clearance in individuals with guttate psoriasis. Commonly reported treatments for guttate psoriasis include topical corticosteroids (as in our patient), topical Vitamin-D analogues, and ultraviolet-B phototherapy. The prognosis of guttate psoriasis is generally favorable with a self-limited disease course, though a substantial percentage of individuals ultimately develop chronic plaque psoriasis. Clinicians should suspect guttate psoriasis in patients who present with a new eruptive rash following a recent pharyngitis.

A RETRO COLLECTION Talal Hilal; Andrew Hoellein. University of Kentucky, Lexington, KY. (*Tracking ID #1937688*)

LEARNING OBJECTIVE 1: Identify the possible etiologies of retroperitoneal fibrosis

LEARNING OBJECTIVE 2: Outline medical management of retroperitoneal fibrosis

CASE: A 58 year-old woman reported 6 weeks of dull, bilateral flank and lower back pain along with progressive fatigue and weakness. She noted anorexia and weight loss over the past 4 weeks and intermittent subjective fever and chills. She has a

history of coronary disease requiring stenting over 10 years ago and peripheral arterial disease requiring aortobifemoral bypass grafting 4 years ago. She is a smoker with a 100 pack-year history. Her family history is unremarkable. Physical exam found a thin lady, normal vital signs, tenderness over the flanks, and palpable kidneys. Her metabolic panel revealed BUN 114 mg/dL, creatinine 11 mg/dL, potassium 5.7 mEq/L and bicarbonate 12 mEq/L. A CT of the abdomen and pelvis found severe bilateral hydronephrosis with dilatation of the ureters to the level of the iliac arteries. The patient underwent bilateral percutaneous nephrostomy tube placement with subsequent post-obstructive diuresis. Her BUN and creatinine trended down to 29 mEq/L and 3.3 mEq/L, respectively. It was felt that the bilateral proximal ureteral obstruction was secondary to retroperitoneal fibrosis related to aortobifemoral bypass grafts. Surgical correction of the strictures was not an option due to the close proximity of the grafts and the risk of graft infection and/or fistulization. She was discharged with nephrostomy tubes in place and follow-up was arranged for further outpatient management.

DISCUSSION: Retroperitoneal fibrosis is a slowly progressive condition characterized by deposition of fibro-inflammatory tissue in the retroperitoneal space, usually covering the infrarenal abdominal aorta, and extending into the ureters. Symptoms are usually vague including dull, non colicky pain in the lower back, flank and lower abdomen, and patients tend to present late with complications. Most cases are idiopathic (60–70 %), while a minority appear to be secondary to regional inciting events such as malignant disease, surgery, radiation and chronic inflammatory conditions. Principles of treatment involve suppressing the inflammatory process and preserving renal function. Patients with ureteral obstruction should have emergent relief of the obstruction by percutaneous nephrostomy but long-term pharmacologic therapy should be instituted once diagnosis is confirmed. This is usually in the form of corticosteroids with or without immunosuppressive agents (azathioprine, cyclophosphamide and mycophenolate), or tamoxifen. A prospective study comparing a corticosteroid taper with tamoxifen for maintenance therapy concluded that the relapse rate with tamoxifen was significantly higher at 8 months compared to corticosteroids. The addition of mycophenolate to corticosteroids has shown significant benefit in long-term stabilization of disease in a small sample of patients, but randomized controlled trials to define optimum treatment are lacking. The duration of therapy for most taper regimens is 2 years with patients sometimes requiring further treatment. Patients who do not respond to medical therapy may require surgical intervention to treat ureteral obstruction. A multidisciplinary approach needs to be instituted to manage not only the disease but the complications that tend to coexist. Follow-up is essential and prognosis is usually good.

A STRONG MAN POWERLESS: A PERPLEXING CASE OF GENERALIZED WEAKNESS Nivedita Gunturi; David C. Demoise; Brian S. Heist. UPMC Presbyterian Shadyside, Pittsburgh, PA. (Tracking ID #1938353)

LEARNING OBJECTIVE 1: To recognize cervical intervertebral disc herniation in the absence of typical symptomatology

LEARNING OBJECTIVE 2: To manage cervical disc herniation with early imaging and prompt referral for surgical intervention

CASE: A 54 year old obese African American man with poorly controlled type 2 diabetes mellitus and hypertension presented to our clinic with generalized weakness and fatigue progressive over the previous 1–2 months. The patient worked as a sanitation worker and bus driver, and reported his symptoms prevented him from performing daily tasks. Medications consisted of long standing amlodipine, hydrochlorothiazide, lisinopril, metformin, glyburide, and aspirin. He had a 30 pack year smoking history and did not use alcohol or recreational drugs. Physical examination revealed a large obese and muscular man (weight 148 Kg, BMI 44) with blood pressure of 160/100 and was otherwise unremarkable. Laboratory data included hemoglobin A1C of 6.8 % and normal complete blood count, comprehensive metabolic panel, and thyroid stimulating hormone level. He was advised to exercise, improve his diet, and monitor blood pressure and blood glucose. The patient returned 4 weeks later perseverating on loss of power, and with new complaint of diffuse myalgias, but no focal pain. He denied other neurological symptoms including tremors or urinary/fecal incontinence. He denied mood instability, anxiety and depression. Physical exam was remarkable for perceived diffuse 5-/5 strength, though assessment was compromised by his large physique. Sensation to pain and light touch was intact in bilateral upper and lower extremities, but plantar sensation was absent on monofilament testing. Gait was normal. To check for polymyositis and polymyalgia rheumatica, ESR and CPK were obtained and were within normal limits. Per instruction, a week later the patient again returned to clinic. He appeared fatigued and reported nearly collapsing upon rising from his waiting room chair. On physical exam, sensation exam was unchanged, patellar reflexes were mildly increased, and upper extremity reflexes were normal. Proprioception testing was

normal. Strength testing results were unchanged, though patient felt he was weaker. Based on suspicion of axonal neuropathy and possible neuromuscular junction disorder, nerve conduction studies were performed and showed evidence of sensory motor polyneuropathy of upper and lower extremities. Cervical magnetic resonance imaging (MRI) showed large C3–C4 disc herniation with significant myelomalacia and cord displacement and a smaller disc herniation at C6–C7. MRI brain, obtained per neurology recommendation, showed no acute changes. A methylprednisolone taper was prescribed, with no symptomatic improvement. The patient was then referred to neurosurgery, and underwent C3–C4 anterior cervical discectomy with bony fusion and plating. On 4 week post-operative follow up, patient reported significant symptomatic improvement. He started physical therapy and 2 weeks later demonstrated further improvement of weakness and imbalance. He plans to continue physical therapy for another month and then return to work.

DISCUSSION: This case demonstrates a unique presentation of cervical disc herniation and myelomalacia, which can be difficult to diagnose due to myriad modes of presentation. Symptoms of cervical disc herniation may be mistaken for those of diabetic neuropathy, rheumatological conditions or cerebrovascular accident, among others. As there are no pathognomonic features that can direct diagnosis, the astute physician must be aware of subtle symptomatology that may point to disc herniation, including gait abnormality and unilateral or bilateral hyperreflexia, and obtain appropriate imaging early in the clinical course. Failure to recognize signs and symptoms of cervical disc herniation may delay early surgical intervention, which is associated with significant changes in neurological prognosis, including spastic paraparesis. The risk of spinal cord injury with minimal trauma is also higher in patients with cervical myelopathy, which is of particular concern in this patient, whose occupation requires extensive manual labor. The clinician's ability to suspect cervical spondylopathy due to disc herniation, diagnose with appropriate imaging and make an early referral for surgical intervention will serve to provide rapid symptomatic relief and avoid further complications, as seen in the case of this patient.

A SUPRATHERAPEUTIC INR FROM AN UNCOMMON INTERACTION

Eiran A. Warner; Christopher Taurani; Kristen Coffey; ZuJun Li. Beth Israel Medical Center, New York, NY. (Tracking ID #1939669)

LEARNING OBJECTIVE 1: Recognizing that cisplatin can interact with patients on warfarin

LEARNING OBJECTIVE 2: Understanding the mechanism of cisplatin and warfarin interaction

CASE: A 65 male with locally advanced oropharyngeal squamous cell carcinoma and a history of deep vein thrombosis, on long-term warfarin, was referred to the emergency room (ED) by his oncologist for an INR level of 10. The patient had an INR of 3.7 2 weeks earlier for which his daily warfarin dose of 5 mg was stopped for 2 days and restarted at 5 mg daily for 6 out of 7 days a week. One week prior to ED arrival the patient had started radiation therapy and was given a single dose of cisplatin 40 mg per square meter. Baseline hemoglobin was 13.3 g/dL and serum creatinine was 1.0 mg/dL. Prior to receiving his second weekly dose of cisplatin, the patient's INR was noted to be 10, with a creatinine of 3.7 mg/dL, a hemoglobin of 11.4 g/dL and normal liver function tests. The patient's blood pressure was 88/52. He admitted to having several episodes of epistaxis over the previous few days but denied easy bruising, melena or hematochezia. Other medications included fluticasone/salmeterol, tiotropium bromide, lansoprazole and ondansetron, the latter started with the cisplatin. The patient denied any over the counter supplements or change to his diet of 4 cans of Jevity per day via PEG tube. Vitamin K 2 mg IV and 2 L normal saline were given prior to transport to the ED. The patient was given a further 5 mg IV vitamin K in the ED (repeat INR was 8.8) and was admitted. There were no further bleeding episodes and INR returned to under 2 within 72 h of admission. With hydration during hospital stay, the patient's creatinine returned to baseline. The patient was discharged on his usual dose of 5 mg warfarin daily and after discussion with his oncologist cisplatin was discontinued.

DISCUSSION: Long term anticoagulation is the standard of care for patients with conditions such as recurrent deep vein thrombosis or atrial fibrillation. Warfarin is the anticoagulant traditionally used with a target INR of 2 to 3. Cisplatin is a chemotherapy drug with activity against a wide range of malignancies. It is very commonly used either as a single agent radiosensitizer or as part of combination chemotherapy in the adjuvant, neoadjuvant and palliative treatment settings. Because both cancer and conditions that require anticoagulation are more common in older adults, and because recurrent thromboses are a complication of many malignancies, the prescription of cisplatin for a patient already on chronic warfarin therapy is likely a fairly common occurrence. The acutely elevated INR observed in our patient on a previously stable dose of warfarin is not traditionally recognized as a side effect of cisplatin. Warfarin consists of a racemic mixture of 2 enantiomers (R and S forms).

Cyp3A4 and CYP2C9 are involved in the metabolism of R-warfarin and S-warfarin respectively with the latter playing the larger role in warfarin's metabolism. Recent evidence *in vivo* suggests that cisplatin has CYP2C9 inhibitory activity. Several recent case studies have, as well, suggested a possible interaction between cisplatin and warfarin. These case studies involved a combination of chemotherapy drugs in addition to cisplatin, with the latter implicated as it was the only drug common to all cases. The fact that our patient only received cisplatin removes any confounding factors and greatly increases the likelihood that the cisplatin-warfarin interaction is real. Our patient's other medications were all long-standing with the exception of ondansetron. Although ondansetron is a weak CYP2C9 inhibitor, it is unlikely to have been the cause of the acutely elevated INR as the patient continued to take ondansetron during his hospital stay and after discharge with return of his INR to baseline. Moreover, ondansetron is used more commonly than cisplatin and no case of a clinically significant interaction with warfarin has ever been reported. Nevertheless, a small contribution of the ondansetron in this case cannot be excluded. The fact that the interaction between warfarin and cisplatin has not been reported more often based on the expected frequent co-prescription of these drugs, suggests that susceptibility to this interaction may be a function of individual pharmacogenetics and occurs only in patients who have inherited alleles with reduced CYP2C9 activity. Patients on concurrent warfarin and cisplatin should have their INR carefully monitored. If an equally suitable chemotherapeutic drug cannot be substituted, a switch to another anticoagulant such as a low molecular weight heparin should be made at the first sign of a rise in INR.

A SURPRISING CAUSE OF ACUTE KIDNEY INJURY IN A HEALTHY YOUNG MALE Halis K. Akturk. Creighton University Medical Center, Omaha, NE. (*Tracking ID #1926128*)

LEARNING OBJECTIVE 1: Recognize rare causes of acute kidney injury.

LEARNING OBJECTIVE 2: Diagnose fecal impaction and treat immediately.

CASE: A 19-year-old man presented with abdominal pain and decreased urine output. He also mentions that he has been constipated for about 10 days. The patient was afebrile, tachycardic and tachypneic. He was in acute distress due to severe pain. Physical exam revealed lower abdominal tenderness and palpable abdominal mass. Lab work showed signs of acute kidney injury with increased creatinine of 3.4 mg/dL and blood urea nitrogen of 44 mg/dL. Other routine blood tests were normal. Urine output was less than 10 cm³/h. Urine analysis was unremarkable and urine drug screen was positive for Tetrahydrocannabinol (THC). Computed tomography revealed rectal mass measuring approximately 13×10×19 cm (Anteroposterior × Transverse × Craniocaudal). There is noticeable mass effect on the bladder with near total collapse of the bladder without hydronephrosis. The patient was not on any medications and there was no previous or family history of severe constipation. He had no underlying disease and no history of abdominal surgery. Patient was admitted to hospital and treated with intravenous hydration, mineral oil enema and several manual disimpactions. After treatment, kidney function returned to normal dramatically.

DISCUSSION: Fecal impaction is a solid bulk of stool, mostly develops in the rectum due to severe constipation. Risk factors are age, chronic narcotic use, immobility and Hirschsprung's Disease. Massive fecal ball, Fecaloma is a rare entity that may cause mass effect to adjacent structures. A few case reports have been reported that fecaloma caused hydronephrosis in elderly population with mass effect. Fecaloma can cause obstruction, ulceration and perforation and rarely mass effect to adjacent structures. Fecal ball should be considered in the differential diagnosis of patients who have a history of constipation and present with decreased urine output and abdominal mass.

A SWEET RHYTHM David Kitchell¹; Helen Tsai²; Eugenia Tsai¹. ¹Montefiore Medical Center, Bronx, NY; ²St. George's University, True Blue, Grenada. (*Tracking ID #1936455*)

LEARNING OBJECTIVE 1: Recognize etiologies of hyperkalemia

LEARNING OBJECTIVE 2: Identify EKG changes in hyperkalemia

CASE: A 52 year old gentleman with hypertension, diabetes mellitus type 2 (hemoglobin A1c 11) and obesity presented with weakness, nausea and vomiting for 2 days. Home medications included enalapril and canagliflozin, a new antidiabetic agent which he recently started. Initial vitals were significant for hypotension (BP 90/58 mmHg), bradycardia (HR 46–52 bpm) and hyperglycemia (fingerstick glucose 450 mg/dL). Serum chemistry was notable for potassium of 7.5 meQ/L, glucose of 231 mg/dL, BUN of 56 mg/dL and creatinine of 1.8 mg/dL (reported baseline of 1.5 mg/dL 2 weeks prior to presentation). Complete blood count was unremarkable. Initial electrocardiogram (EKG) revealed junctional rhythm (HR 49 bpm). The patient

was treated for hyperkalemia with polystyrene sulfonate, insulin and sodium bicarbonate. Clinical symptoms rapidly resolved with treatment; a repeat serum chemistry showed improvement of hyperkalemia (K+ 5.2 meQ/L) and a repeat EKG showed normal sinus rhythm. Canagliflozin was discontinued during the hospital course and replaced with long-acting insulin for diabetes management. Serum creatinine returned to baseline within 2 days and the patient had no further episodes of hyperkalemia.

DISCUSSION: Canagliflozin (Invokana) is a relatively new antidiabetic agent that works as a sodium-glucose cotransporter 2 (SGLT2) inhibitor. It blocks glucose transport at the level of the proximal tubule in the nephron thereby increasing glucose excretion in the urine. Clinical trials have demonstrated canagliflozin as non-inferior to glimepiride. Studied side effects include urinary tract infection, postural dizziness, orthostatic hypotension and less frequently, syncope. Commonly reported side effects include renal insufficiency and hyperkalemia. Hyperkalemia, defined as serum potassium (K+) >5.5 meQ/L, is a commonly encountered clinical problem. Clinical manifestations may be nonspecific and include neuromuscular complaints such as weakness, generalized fatigue or fasciculations. GI symptoms such as abdominal cramping, nausea, and vomiting, or cardiac symptoms such as slow, weakened or absent pulse may also occur. Due to the lack of characteristic symptoms, hyperkalemia can be easily and dangerously overlooked. Maintaining a high clinical suspicion for hyperkalemia and recognizing associated EKG changes, particularly in those with renal dysfunction or with history of medication and supplement use, is thus vital. The majority of hyperkalemia cases result from impaired urinary excretion as a result of acute or chronic kidney failure. Hyperkalemia can also be caused by the redistribution of potassium from intracellular to extracellular space, as observed in metabolic acidosis, uncontrolled diabetes, rhabdomyolysis, hemolysis, burns or trauma. Importantly, iatrogenic causes such as the use of ACE inhibitors, NSAIDS, potassium-sparing diuretics and other medications can precipitate hyperkalemia by affecting renal excretion of potassium. In addition to evaluating a patient's risk factors, EKG findings can clue in a hyperkalemia diagnosis. Hyperkalemia can present with cardiac arrhythmias such as sinus bradycardia, sinus arrest, ventricular tachycardia, ventricular fibrillation and even asystole. Conduction abnormalities may also be seen and can include right or left bundle branch block, bifascicular block and advanced atrioventricular block. Rapid onset hyperkalemia is more likely to demonstrate EKG changes. These changes often correlate with serum potassium concentration. Classic narrow, tall peaked T waves are often seen with mildly elevated K+ (5.5–6.5 mEQ/L). This is due to the extracellular potassium effects on the repolarization phase of the cardiac action potential. Loss of the P wave and widening of the QRS complex can be seen with K+ >6.5 mEQ/L. This reflects the greater sensitivity of the atrial tissue than the sinoatrial node to elevated serum K+. The sinoatrial node maintains function as the pacemaker of the heart but directly stimulates ventricular depolarization. At K+ >8 meQ/L, a sine wave pattern (fusion of the QRS complex and peaked T wave) can be seen, which can quickly develop into ventricular fibrillation. Nevertheless, a normal EKG does not exclude hyperkalemia. Hyperkalemia is a condition frequently encountered by the general internist. Severe hyperkalemia (K+ ≥7.0 meQ/L) can lead to arrhythmias and conduction abnormalities thus must be quickly identified and treated to prevent fatal complications.

A SWING AND A MISS: HEPARIN INDUCED THROMBOCYTOPENIA (HIT) WITH AN INITIALLY NEGATIVE ANTIBODY SCREEN Kirtan Nautiyal^{1,2}; Jeffrey T. Bates^{1,2}. ¹Baylor College of Medicine, Houston, TX; ²Michael E. DeBakey VA Medical Center, Houston, TX. (*Tracking ID #1939797*)

LEARNING OBJECTIVE 1: Apply the "4 Ts" clinical scoring system to estimate the pre-test probability of Heparin-induced Thrombocytopenia (HIT) in a patient prior to serologic testing

LEARNING OBJECTIVE 2: Recognize that HIT can occur despite the ELISA for the HIT antibody initially returning negative.

CASE: A 54-year-old male with diabetes mellitus, hypertension, hyperlipidemia, and peripheral arterial disease was admitted for cellulitis. On the second hospital day, Doppler ultrasound could no longer identify a pulse in the patient's left dorsalis pedis artery. CT runoff showed acute thrombosis of the left superficial femoral artery extending into the popliteal, anterior tibial, and peroneal arteries; platelet count at this time was normal. He was started on IV heparin and was taken to the operating room 6 days later, where he underwent a left femoral-popliteal bypass. A completion angiogram in the operating room showed a patent graft and the heparin was re-started post-procedurally. On the first post-operative day, the patient again lost distal pulses in his left foot. He was taken back to the OR, where he was found to have complete thrombotic occlusion of his vascular graft. By this time, 7 days following the initiation of heparin, the patient's platelets had fallen 30 % from their peak. Though an immediate ELISA for the HIT antibody returned negative, the patient was switched

from heparin to bivalirudin due to the continued high clinical suspicion for HIT and was subsequently bridged to warfarin. A repeat ELISA was sent 8 days after the first negative result and this time returned positive, thus confirming the diagnosis of HIT.

DISCUSSION: HIT is an immune-mediated thrombocytopenia associated with heparin therapy typically caused by the development of IgG antibodies to the complex of unfractionated heparin (UFH) and platelet factor 4 (PF4). These antibodies subsequently bind to platelets, causing their activation and aggregation and leading to the clinical manifestations of the disorder. The pre-test probability of a HIT diagnosis prior to serologic testing can be estimated using the “4 Ts” clinical scoring system, in which patients are assigned zero, one, or two points in each of four categories—degree of thrombocytopenia, timing of platelet fall, thrombosis, and absence of other causes of thrombocytopenia. Our patient had a “4Ts” score of six (one point for 30–50 % drop in platelet count, two points for the platelets falling between 5 and 10 days after the initiation of heparin, two points for a clinically apparent thrombosis, and one point for the recent surgery being an alternative cause of thrombosis), thus giving him a high pre-test probability for HIT. The ELISA-based screening assay typically used has a very high sensitivity (95–100 %) but a lower specificity (~80 %), thus this testing is best performed on patients with a high pre-test probability (greater than six points) to minimize the risk of a false positive result. The serotonin release assay, which is much more specific than the ELISA screen, is still not widely available in hospitals without specialized coagulation laboratories. In patients such as ours, the pre-test probability is high enough that a single negative HIT antibody ELISA is not enough to rule out the condition. There are several scenarios in which a patient may initially have a negative ELISA but still experience HIT. First, as seen in our case, the assay, though extremely sensitive, may not be able to detect the low antibody titers very early in the disease course. Second, a small subset of patients experience clinical HIT due to anti-IL8 or anti-neutrophil activating peptide antibodies, rather than usual anti-PF4/UFH antibody detected by the ELISA. Third, some patients express a large amount of platelet associated PF4 and can thus develop clinically apparent HIT with levels of anti-PF4/UFH antibodies low enough to evade the screening ELISA test. A recent retrospective chart review identified cases of repeat HIT antibody testing following an initial negative result. While 12 % of these repeat tests returned positive, mainly among those patients whose initial ELISA was borderline, the only four who actually developed thrombotic complications were the same four patients whose pre-test “4 Ts” score had also increased in the interim, thus suggesting a true change in their clinical situation. In these patients, the positive ELISA merely confirmed the increased clinical suspicion raised by the climbing “4 Ts” score. This finding reinforces the notion that the occurrence of symptomatic HIT is best predicted through accurate assessment of the clinical situation; the ELISA test remains an adjunct and should be reserved for confirmation of the diagnosis in patients with a high pre-test probability.

A TATTOO PAINTS A PICTURE OF SARCOID David A. Rand¹; Julie Lin²; Elizabeth Zeeck³; Deborah Cook⁴. ¹University of Vermont, Burlington, VT; ²University of Vermont, Burlington, VT; ³University of Vermont, Burlington, VT; ⁴University of Vermont, Burlington, VT. (*Tracking ID #1939857*)

LEARNING OBJECTIVE 1: Recognize that tattoo reactions can be a manifestation of systemic sarcoidosis

CASE: A 30 year old Caucasian male presented with a 10 day history of progressively worsening discomfort and irritation at multiple tattoo sites. Severe pain surrounding his leg tattoos limited his ability to ambulate and prompted a visit to the emergency department. All tattoos were placed professionally 10 years prior though one tattoo had been touched up with black, orange, and red pigment 4 months before presentation. The patient had a history of hyperlipidemia, hypothyroidism, as well as systemic sarcoidosis with associated hilar adenopathy and anterior uveitis, asymptomatic since remicade infusion therapy 2 years prior. On examination, all black tattoos were inflamed and raised with erythematous margins and superficial scaling. Areas with non-black pigmentation were completely spared. The result of a punch biopsy was notable for multinucleate giant cells consistent with granulomatous dermatitis. The patient was prescribed 60 mg of prednisone daily which was tapered over 4 weeks. His symptoms subsequently resolved completely and the appearance of the tattoos returned to baseline.

DISCUSSION: Sarcoidosis is a granulomatous disease of unknown etiology which involves the skin in up to one third of cases (1,2,3). Indeed, the word sarcoid originated from the Greek sarkodes, coined by the Norwegian Dermatologist Casear Boeck to describe “fleshy” skin findings resembling sarcoma (4). The presence of granulomatous reactions within tattoos has been reported since 1952 (5). In this case vignette, we report the case of a patient with known sarcoidosis presenting with granulomatous infiltration of multiple tattoos. While this patient had previously been diagnosed with systemic sarcoidosis, prior case reports have described the presence of non caseating granulomas within a tattoo as the initial presentation of systemic sarcoidosis (6,7,8). However, the presence of histologically identical granulomatous

disease may also be associated with a foreign body reaction caused by a tattoo or scar, unrelated to sarcoidosis (9,10). Hence, identification of a non-caseating granuloma in the skin should be followed by a thorough workup for systemic sarcoidosis. In this case, the long latency period between placement of the tattoos and the granulomatous reaction likely suggests a sarcoidosis flare. However, the role of exposure to foreign bodies in sarcoidosis is still unknown and it is possible that the flare represents a delayed foreign body reaction. Also unclear is why only the black pigmented regions were affected (4). It is important for internists who care for patients with sarcoidosis to recognize its dermatologic manifestations in addition to the more common pulmonary and ocular presentations. This is especially relevant given the popularity of cosmetic tattooing. 1. Hanno R; Needelman A; Eiferman RA et al. A TEMPERATE CLIMATE PATIENT PRESENTING WITH A TROPICAL DISEASE: A CASE OF BACTERIAL PYOMYOSITIS SECONDARY TO COMMUNITY ACQUIRED MRSA Grant Boschult; Jonathan S. Kurman; Kurt J. Pfeifer. Medical College of Wisconsin, Milwaukee, WI. (*Tracking ID #1927281*)

LEARNING OBJECTIVE 1: Enhance clinical awareness of the increasing incidence of pyomyositis in temperate climates.

LEARNING OBJECTIVE 2: Consider the presence of pyomyositis in patients who present with localized musculoskeletal complaints in the setting of bacteremia.

CASE: A 28-year-old African American female with a past medical history of hypertension presented with 2 days of persistent, left-sided, “burning,” chest pain exacerbated by palpation, deep breathing, and lying supine. While in the emergency department the patient was found to be afebrile and tachycardic with a mild leukocytosis of 14,700/uL. A chest X-ray was performed, and no abnormalities were noted. Computed tomography (CT) of the chest with contrast was negative for pulmonary emboli or other pathology. The patient was subsequently discharged home with a presumed muscle strain, only to return to the emergency department 2 days later with complaints of worsening left-sided chest pain. The patient had a temperature of 100.1 F and a worsening leukocytosis. An electrocardiogram showed sinus tachycardia, and a chest x-ray was unremarkable. The patient was admitted for further evaluation and management. Two days after admission, blood cultures returned positive for methicillin-resistant *Staphylococcus aureus* (MRSA). The patient was subsequently started on intravenous vancomycin. Transthoracic and transesophageal echocardiograms were performed and showed no valvular or other abnormalities. An indium-tagged white blood cell scan showed an area of intense uptake in left mid-anterior hemithorax, consistent with the distribution of the chest pain. A repeat CT scan revealed an ill-defined mass-like inflammatory lesion in the left anterior chest wall extending into the intercostal fat, mediastinal fat, and pleural spaces, with some compression of the right ventricular outflow tract, as well as a moderate left-sided pleural effusion. A thoracentesis produced 250 mL of exudative and culture-negative fluid. Surgical drainage of the affected muscle was considered, but not performed, as a focal fluid collection or abscess was not identified. The patient was continued on IV vancomycin for a total 4 weeks and her symptoms gradually improved. A repeat chest CT was performed at the end of therapy, which showed resolution of the inflammatory mass and pleural effusion.

DISCUSSION: Pyomyositis is a purulent infection involving skeletal muscle associated with bacteremia and abscess formation. Classically seen in the tropics, this disease has been recognized with increasing frequency in temperate climates. Pyomyositis is often not an early diagnostic consideration due to its rarity in temperate climates and non-specific presenting signs and symptoms (fever, muscle pain and leukocytosis), often delaying initiation of appropriate therapy. If not recognized and treated in a timely manner, pyomyositis can progress to septicemia and septic shock. Predisposing factors include immunodeficiency, trauma, intravenous drug use and malnutrition. The most common associated pathogen is *Staphylococcus aureus*, responsible for approximately 95 % of tropical and 70 % of temperate cases. Treatment includes drainage of abscesses and empiric intravenous

antibiotics, initially directed against MRSA and adjusted according to gram stain and culture results. It is generally recommended to continue IV antibiotics for 4 weeks and to repeat imaging at the end of therapy. This case illustrates the importance of considering the diagnosis of pyomyositis in patients who present with persistent fever, leukocytosis and focal muscle cramping and tenderness.

A TIGHT SQUEEZE Rebecca L. Hostetler¹; Jeremy S. Markowitz². ¹University of Pittsburgh Medical Center, Pittsburgh, PA; ²VVA Pittsburgh Healthcare System, Pittsburgh, PA. (*Tracking ID #1938174*)

LEARNING OBJECTIVE 1: Recognize the clinical features of constrictive pericarditis and distinguish it from restrictive cardiomyopathy

LEARNING OBJECTIVE 2: Determine the best diagnostic workup for constrictive pericarditis

CASE: 46 year old man with a history of class III obesity and coronary artery disease status post coronary artery bypass graft 3 years prior transferred from an outside hospital with a 4 month history of increasing ascites, worsening dyspnea on exertion, jaundice, and a 50 lb weight gain. He had been intubated for increasing respiratory distress prior to arrival, after a large-volume paracentesis failed to sufficiently improve his respiratory status. His exam was notable for central venous pressure of 30, massive ascites, and 4+ lower extremity edema. His labs showed an acute liver injury in a cholestatic pattern and kidney injury of unknown duration. On arrival, the team initially attempted fluid removal with repeated large-volume paracentesis and IV diuretics; however, he developed refractory ascites, renal failure, and eventually shock requiring CVVHD and pressors. His liver failure continued to worsen, and peaked with a total bilirubin of 11.4 mg/dL, direct bilirubin 7.0 mg/dL, ALT 236 IU/L, AST 265 IU/L, and alkaline phosphatase 953 IU/L. Workup for the cause of his liver failure revealed negative testing for viral hepatitis, primary biliary cirrhosis, primary sclerosing cholangitis, and autoimmune hepatitis. Right upper quadrant ultrasound disclosed no focal liver lesions, mild cirrhosis and patent vessels. Transjugular liver biopsy showed sinusoidal dilatation, moderate bridging fibrosis, and transhepatic gradient of 6 mmHg without significant portal hypertension. TTE showed normal systolic function with borderline pulmonary hypertension. Left and right heart catheterization were notable for four-chamber equalization of pressures, and CT chest revealed pericardial thickening with calcifications, confirming the diagnosis of constrictive pericarditis with hepatic congestion. Unfortunately, he was unable to be stabilized in order to perform a pericardectomy and passed away after being terminally extubated.

DISCUSSION: Our patient presented with constrictive pericarditis from cardiac surgery. The most common causes of constrictive pericarditis are viral/idiopathic, post-surgical, and post-radiation. Constrictive pericarditis complicates 0.2–0.3 % of cardiac surgeries. This case illustrates common challenges in diagnosing constrictive pericarditis, which include distinguishing congestive hepatopathy from primary liver disease, and distinguishing constriction from other causes of right heart failure, especially restrictive cardiomyopathy. Historical clues that aid in the diagnosis include prior cardiac surgery or chest radiation. Exam findings of constrictive pericarditis include signs of right heart failure (elevated JVP, ascites, pulsatile liver, peripheral edema.) Transthoracic echocardiography can exclude other more common causes of right heart failure (such as left heart disease and pulmonary hypertension) and sometimes shows characteristic findings of pericardial constriction such as ventricular interdependence. Pericardial thickening and calcifications on chest X-ray, chest CT, or cardiac MRI are also characteristic findings. Distinguishing constrictive pericarditis from restrictive cardiomyopathy usually requires simultaneous left and right heart catheterization to evaluate hemodynamics, cardiac CT/MRI to find the location of structural abnormalities, or both. Despite being a rare condition, there is a definitive treatment (pericardectomy), increasing the importance of early recognition.

A TREMOR WITH GRAVE CONSEQUENCES Asad Jehangir; Bilal Shaikh; Ahmed Salman; Anthony Donato. Reading Health System, West Reading, PA. (*Tracking ID #1927856*)

LEARNING OBJECTIVE 1: Recognize Graves' disease in patients with complaint of intention tremor.

CASE: A 34 -year-old-male presented to an urgent care center with a chief complaint of tremors for the last 3 months. Vitals revealed tachycardia with heart rate of 120, prompting them to refer him for emergency care. Exam showed mild diffuse enlargement of his thyroid gland to two times normal size without nodules and an associated thyroid bruit. Hyperreflexia was also noted, but ophthalmoplegia and

dermopathy were absent. A high-frequency, low amplitude tremor was present that worsened with intention. Labs revealed TSH of 0.01 uIU/mL (normal: 0.3–5.0 uIU/mL), free T4 of 5.59 ng/dl (normal: 0.58–1.64 ng/dl) and total T3 of 8.1 ng/mL (normal: 0.9–1.8 ng/mL). TSI and thyroid receptor antibody were positive, confirming Graves disease. He was started on methimazole and propranolol and referred for follow up with an endocrinologist. Patient has been maintained on methimazole and is awaiting definitive therapy at this time.

DISCUSSION: Graves' disease is the cause of 60–80 % of cases of hyperthyroidism and usually presents with multiple symptoms including sweating, palpitations, tremors, weight loss, diarrhea and tachycardia as well as unique Graves' disease findings of lid-retraction, proptosis and pre-tibial myxedema. However physicians should recognize it even when patients do not have overt symptoms of hyperthyroidism. This case demonstrates that patients can present with a solitary complaint of tremors as the presenting sign of hyperthyroidism. A new tremor is a symptom that can be a benign finding or it can serve as a harbinger for underlying systemic disease. The presence of a high-frequency, low-amplitude tremor should raise essential tremor, catecholamine excess (including alcohol withdrawal) and hyperthyroidism on a differential. The presence of weight loss or abnormal thyroid examination should prompt serum testing of thyroid function.

A TRICKY CLICKING: A CASE OF PULSATILE TINNITUS Alison R. Landrey. University of Vermont/Fletcher Allen Medical Center, Burlington, VT. (*Tracking ID #1937486*)

LEARNING OBJECTIVE 1: Recognize and evaluate for vascular etiologies of pulsatile tinnitus.

CASE: CC: left ear clicking HPI: A 79-year-old man presents with a constant "clicking" sound in his left ear progressing over 7 weeks. He states it is "like a ticking clock" and seems to be timed with his pulse. It is worse when supine and better when leaning his head back while sitting or standing. He also complains of episodic lightheadedness and nausea progressing over 4 weeks. The lightheadedness and nausea are worse with standing or sitting up from a supine position and better with lying down. He also endorses a mild intermittent non-throbbing frontal headache for 5–6 days. He denies ear pain, neck pain, eye pain, nasal congestion, sinus pressure or vision changes. He had been seen 1 month prior for the same complaint. He was noted at this visit to have been seen 6 weeks prior for ear fullness, which resolved with ear irrigation for cerumen impaction, but was associated with clicking in the left ear when opening his jaw. His ear canals this time were clear but he was thought to have a mild effusion behind the left tympanic membrane. Auscultation was not performed. He was prescribed a nasal corticosteroid for possible Eustachian tube dysfunction as a cause of the tinnitus. He stopped it after a week because he thought it was making the lightheadedness and nausea worse and did not seem to be helping the clicking. Past medical history: Prostate cancer, T2, gleason grade 9. Treated at age 75 with radiation and androgen deprivation therapy Osteoporosis Osteoarthritis Hyperlipidemia Current medications: Atorvastatin 10 mg daily Latanoprost eye drops Multivitamin daily Social history: He has never smoked. He currently drinks on 10 alcoholic drinks per week. He is a retired banker and lives with his wife. Family history None pertinent Physical Exam BP 160/75 | Pulse 68 | Temp (Scr) 36.7 °C (98.1 °F) (Tympanic) Constitutional: He is oriented ×3. He appears well-developed and well-nourished. No distress. Head: Normocephalic and atraumatic. Right Ear: Tympanic membrane, external ear and ear canal normal. Left Ear: Tympanic membrane, external ear and ear canal normal. Nose: normal. Mouth/Throat: Uvula is midline, oropharynx is clear and moist and mucous membranes are normal. Eyes: EOMI, PERRLA, normal fundoscopic exam Neck: Normal range of motion. Neck supple. Cardiovascular: Normal rate and regular rhythm. 2/6 diastolic murmur 2nd intercostal space, right sternal border Radial pulses 2+ bilaterally Loud left carotid bruit Pulmonary/Chest: Effort normal and breath sounds normal Neurological: He is alert and oriented to person, place, and time. No cranial nerve deficit. Gait normal. Workup and Diagnosis: The patient was suspected of having a vascular etiology for his pulsatile tinnitus. A CT angiogram and an echocardiogram were ordered. He was also started on lisinopril for his elevated blood pressure. CT arteriography showed early venous opacification at the skull base to the left of midline about the left vertebral artery and epidural space, suspicious for an arteriovenous fistula. Echocardiogram showed a normal left ventricle and systolic function with mild aortic stenosis and moderate aortic regurgitation. A conventional angiogram confirmed a dural arteriovenous fistula originating in the left vertebral artery. The patient then underwent an uncomplicated coil embolization of the fistula. He had complete resolution of the clicking sound and dizziness.

DISCUSSION: Pulsatile tinnitus is the perception of a rhythmic noise timed with the pulse and is a relatively uncommon complaint in the primary care setting. It is most suggestive of a vascular etiology such as AV malformation, arterial stenosis, or compression of a blood vessel by a mass. Other etiologies include pseudotumor

cerebri and Eustachian tube dysfunction. In our case, the diagnosis was missed on the first examination. The fact that the patient did have a prior visit for ear fullness with similar left ear clicking may have confounded the assessment, although the clicking was not pulsatile when associated with the ear fullness. It is important for the general internist to be aware of pulsatile tinnitus as a distinct presentation and to perform an appropriate exam and workup for vascular causes. This includes auscultation for bruits, which may have accelerated the diagnosis and treatment for our patient had it been done at the initial visit for his complaint.

A TWENTY-NINE-YEAR-OLD MAN WITH AN UNUSUAL CAUSE OF AN ABSCESS Shivangi Vachhani; Anne Cioletti. George Washington University, Washington D.C., DC. (*Tracking ID #1939152*)

LEARNING OBJECTIVE 1: Discuss an unusual cause of an abscess, which is a botfly infection

LEARNING OBJECTIVE 2: Remind the readers that travel history is an important aspect of the history taking.

CASE: A 29 year old healthy male presented to the clinic with a two-day history of a left scalp mass. Two days prior to his initial presentation, he noticed three scabs on his left scalp with associated pruritis. These symptoms progressed to left temporal edema and purulent drainage from his scalp on the day prior to presentation. He denied any fevers, chills or any pain. His past medical and family history was negative, and he was not on any medications. He denied any tobacco or drug use and drank alcohol only socially. He did report recent travel to Belize 2 weeks prior to his presentation. His review of system was otherwise negative. Upon presentation, his vital signs were within normal limits, and he was afebrile. His physical exam showed a firm abscess with purulent drainage on the left scalp as well as a left temporal edema. He was started on sulfamethoxazole and trimethoprim to treat for suspected MRSA abscess. He noticed improvement of the left temporal edema and decrease in purulent drainage upon starting the antibiotics. Over the next few days, the patient started experiencing alopecia around the abscess as well as occasional parasthesia leading to increased pruritis. Despite finishing the course of his antibiotics, his abscess and drainage persisted, so he was re-started on another course of sulfamethoxazole and trimethoprim and instructed to use warm compresses over the area. After restarting the antibiotics and warm compresses, the patient's wife tried to express purulent material when a larva was expressed instead. Analysis of this larva confirmed it was a larva of a bot fly. A total of three larvae were removed from his scalp. Upon the removal of the larvae, his symptoms improved, and he had complete resolution over the next few weeks.

DISCUSSION: This is a case of a young man with recent travel to Belize who presented with a two-day history of a scalp abscess and left temporal edema. He was appropriately started on sulfamethoxazole and trimethoprim to treat for community acquired MRSA with incomplete resolution of his symptoms; after a couple of weeks with attempts to drain the abscess, larvae of the human bot fly were extracted instead. The initial improvement of symptoms with antibiotics is believed to be due to a superimposed bacterial infection around the larvae, but without expression of the fly, symptoms would have persisted. The bot fly is a 12–18 mm in length bluish colored fly that resembles bumble-bee. The larva of this fly is known to infest the skin of mammals and live out the larval stage in the subcutaneous layer. The species of bot fly known to infect humans is called *Dermatobia hominis*. It is native to Central as well as South America. The adult fly lays its eggs on the abdomen of a mosquito where it hatches to form the first larval instar. When the mosquito bites the human, the larva penetrates the skin and burrows itself into the subcutaneous layers. As the larva burrows deeper, it feeds on the host's body and exudates. It uses spines on its body to anchor itself and breaths through posterior spiracles. The treatment is asphyxiation using either petroleum or a scotch tape which causes the larva to migrate out of its host. Although it is rarely fatal, the larva can live in subcutaneous layer for as long as 10 weeks and induces formation of a painful nodule. It can occur in any part of the body including eyes, ears, and nose. The exact prevalence of Botfly in United States is unknown; however given the increasing rates of travel to foreign countries, it is important to recognize the symptoms of this infection.

A UNIQUE CASE OF ACQUIRED PANHYPOPITUITARISM PRESENTING AS SYMPTOMATIC HYponATREMIA Brian Y. Park¹; Daniel I. Kim^{1,2}; Iqbal Munir^{1,2}. Loma Linda University, Loma Linda, CA; 2Riverside County Regional Medical Center, Riverside, CA. (*Tracking ID #1939505*)

LEARNING OBJECTIVE 1: Hypopituitarism is a clinical condition with impaired synthesis of pituitary hormone(s) which has variable presentation and often difficult

to diagnose. The clinical features of hypopituitarism depend on rapidity of onset of hormone deficiency and involvement of specific hormonal axis.

CASE: A 49-year-old female with a past medical history of hypertension and diabetes type II, presented with a one-month history of weakness, fatigue, and loss of appetite in our hospital. A detailed history revealed having no menstrual period since her last child birth in Mexico 20 years ago. Although her pregnancy was otherwise unremarkable, she had lactation failure after delivery. The patient was admitted to the hospital due to moderate hyponatremia (serum Na level 124 mEq/L). Her vitals were in the normal range; physical exam was normal except absence of axillary hair and very scant pubic hair. Clinically, she was euvolemic. Labs showed low T4 with inappropriately normal TSH. The patient was suspected to have pituitary failure and further labs were ordered, which showed low insulin-like growth factor, low dehydroepiandrosterone, and normal prolactin level. She also had very low follicle-stimulating hormone and luteinizing hormone levels. Her basal cortisol was low with a normal ACTH level, and cosyntropin test showed a sub-optimal rise of cortisol following administration of cosyntropin. An MRI of the pituitary gland showed an empty sella. Patient was diagnosed with panhypopituitarism (when three or more hormonal axis are deficient). She was treated with levothyroxine and hydrocortisone replacement with resolution of hyponatremia and improvement of clinical condition.

DISCUSSION: This is a unique case of panhypopituitarism presenting with hyponatremia. Etiology of hyponatremia for this patient is likely both adrenal and thyroid hormone deficiency. History of lactation failure and amenorrhea following last child birth points toward Sheehan's Syndrome. Sheehan syndrome occurs as a result of pituitary necrosis following severe postpartum hemorrhage. Empty sella in pituitary MRI, which is often a normal variant, may indicate a loss of pituitary tissue subsequent to Sheehan's Syndrome. This case is also unique having a delay of presentation of Sheehan's Syndrome.

A WEAK, EXCITED, AND DRUNK HEART Michael Zablow; Amir Latifi; Salman Haq. New York Methodist Hospital, Brooklyn, NY. (*Tracking ID #1923584*)

LEARNING OBJECTIVE 1: Recognize the etiology of cardiomyopathy and subsequent decompensations.

LEARNING OBJECTIVE 2: Recognize medication interactions, including those with diet and social habits

CASE: A 30 year old male with ADHD presented with 2 months of progressive shortness of breath and decreased exercise tolerance. He had generalized malaise, but denied fevers. His only medication was Adderall (Amphetamine/Dextroamphetamine), which he had been taking TID between 2006 and 2008, and again from 2010 to the present. While he denied tobacco and illicit drugs; he drank 1 bottle of wine 4–5 times weekly for 12 years. Family history was HTN in both parents. Physical exam was unremarkable. Chest X-ray had a small pleural effusion and cardiomegaly. Routine labs and cardiac enzymes were normal, ProBNP was 2,619 pg/ml. EKG showed sinus tachycardia, rate 125, left atrial enlargement, and left axis deviation. Echocardiogram found left ventricular ejection fraction to be 19 %. Cardiac MRI did not show infiltrative disease (i.e. amyloidosis, hemochromatosis, or sarcoidosis). Cardiac catheterization was negative for CAD. Anti-dsDNA, ANA, HIV, Hepatitis C and Parvovirus IgM were negative. Parvovirus IgG was 6.6 (normal 0.0–0.89) and Coxsackie B3 titer was 1:8 (normal <1:8). He was discharged on an ACE-I, beta blocker, and loop diuretic. There is a black box warning for Adderall and structural heart damage. He agreed to discontinue Adderall and abstain from alcohol. He was outfitted with an external defibrillator and plans for a follow up echocardiogram in 3–6 months. Should there be no improvement in LVEF, he will need permanent defibrillator placement and cardiac transplant evaluation.

DISCUSSION: The low Coxsackie titer and negative Parvovirus IgM imply the infections are not acute. Coxsackie B3 and Parvovirus are known causes of myocarditis, which can progress to idiopathic dilated cardiomyopathy (IDCM) through mechanisms that are not well understood. IDCM is the second leading cause of heart transplant; Androletti found Enterovirus RNA (i.e. Coxsackie) in 37.5 % of explanted hearts with IDCM. Amphetamines increase cardiac work through indirect sympathetic activation via noradrenaline, dopamine and serotonin. Dilated cardiomyopathy is an infrequent complication of Adderall, occurring in <1 % of patients. By itself, alcohol is unlikely the primary cause of the cardiomyopathy; MCV and LFTs were normal. However, alcohol inhibits the breakdown of amphetamines, and furthermore, is a vasodilator. When combined, the two substances can place tremendous stress on the heart. It is by exclusion that we hypothesize the decompensated IDCM was caused by two mechanisms. Viral myocarditis caused the dilated cardiomyopathy, which was well compensated until cumulative damage from amphetamine and alcohol lead to a decompensated state. This case exemplifies the need for a meticulous history and medication reconciliation. Without recognizing

the affect of Adderall and alcohol, cardiac damage and functional decline would have continued.

AWOLF IN SHEEP'S CLOTHING: HANSEN'S DISEASE MASQUERADE AS A VASCULITIC PROCESS Sumit R. Naig^{2,1}; Eunice Yu¹; Susan Rhee^{3,1}. ¹Johns Hopkins Bayview Medical Center, Baltimore, MD; ²Johns Hopkins Bayview Medical Center, 21224, MD; ³Johns Hopkins Bayview Medical Center, Baltimore, MD. (*Tracking ID #1939034*)

LEARNING OBJECTIVE 1: Recognize that steroid responsiveness does not confirm a primary vasculitic process and can delay diagnosis of an infectious process.

LEARNING OBJECTIVE 2: Recognize that Hansen's disease can present with vasculitic complications

CASE: Mr. S is a 28 year old man who presented with severe pain from bilateral lower extremity ulcers. The lesions began 1 year after he moved to the United States from Costa Rica as painless, red plaques below the knees. Oral prednisone led to rapid resolution. Eight months later, the plaques reappeared and were again successfully treated with steroids. The lesions appeared with increasing frequency before progressing to ulcers. Mr. S reported subjective fevers and weight loss of 30 lbs. He had no other medical history. His medications were intermittent steroids and ibuprofen for pain control. He tried a 3 month course of methotrexate for the lesions without success. Family history was significant for 'colitis' in his mother although he denied such symptoms. Mr. S did not smoke, drink alcohol, or use illicit drugs. Physical exam was pertinent for a thin man in no acute distress, moon faces, and loss of lateral eyebrows and eyelashes. He had a normal neurologic exam except for decreased sensation in a median nerve distribution of the left hand. Below the knees, patient had multiple punched-out ulcers with wavy, violaceous borders that ranged from 4 to 12 cm in size. Bloodwork showed sedimentation rate of 47 mm/h and C-reactive protein of 9 mg/L. Mr. S had negative anti-nuclear antibody and anti-nuclear cytoplasmic antibody, making rheumatologic process unlikely. Hepatitis C and cryoglobulins were also negative. Multiple skin biopsies of the ulcers showed heavy acid-fast bacilli (AFB) positive staining, and a deep wedge biopsy showed heavy AFB+ bacilli within bubbly macrophages and nerves, as well as changes of small vessel vasculitis.

DISCUSSION: The morphology of the ulcers and a history of response to steroids suggested a vasculitic process. Unfortunately, skin biopsy was never pursued as an outpatient due to presumptive diagnosis of scleroderma vs. pyoderma gangrenosum and inconsistent follow-up, delaying diagnosis. The deep wedge biopsy that demonstrated AFB+ bacilli in nerves was critical to establish the diagnosis of Hansen's disease. Hansen's disease is a chronic granulomatous disease caused by *Mycobacterium leprae* or *Mycobacterium lepromatosis* that affects the skin and peripheral nerves. A variety of the diffuse lepromatous form is characterized by necrotic ulcerations of the skin of the lower extremities from reactive vasculitis, alopecia of the eyebrows and eyelashes, and is epidemiologically linked to Central America. Following diagnosis, steroids were restarted and the patient was referred to the National Hansen's Disease Program for further treatment with dapsone, rifampin, and clofazimine.

A WOMAN AND HER ACUTELY UNSUSPECTING HEART Eugenia Tsai; Jenny Johnson; Darlene LeFrancois. Montefiore Medical Center, Bronx, NY. (*Tracking ID #1939371*)

LEARNING OBJECTIVE 1: Recognize clinical manifestations of toxic shock syndrome

LEARNING OBJECTIVE 2: Diagnose endocarditis based on its risk factors and clinical presentation

CASE: A 23 year old woman with no significant medical history presented with 1 week of fever and rhinorrhea accompanied by diffuse myalgias. She had no history of congenital heart disease, rheumatic fever or intravenous drug use (IVDU). Her last menstrual period was 3 weeks prior to presentation and she denied any recent tampon use. Vital signs were notable for temperature 102°F, HR 130 bpm and BP 109/56 mmHg. She had injected conjunctiva, a diffuse macular rash and early necrosis of the right index finger. Cardiac exam revealed a 3/6 diastolic murmur at the right sternal border with radiation to the carotids. On hospital day 10, patient had desquamation of her palms. Blood work on presentation showed creatinine 1.6 mg/dL, AST 155 U/L and ALT 145 U/L. CBC revealed WBC 16.5×10⁶/L, platelet count 34×10⁹/L. Other notable labs included CRP 111 mg/dL, ESR 51 mm/h and CPK 596 U/L. A full infectious panel, including syphilis and HIV were negative. Multiple blood cultures grew methicillin-sensitive *S. aureus*. Transesophageal echocardiogram revealed a 0.6 cm round mobile vegetation on the aortic valve and moderate aortic valve regurgitation without any abscess formation; the remainder of the endocardium was unremarkable. The patient fulfilled diagnostic criteria for non-menstrual

Staphylococcal toxic shock syndrome (TSS), complicated by infective endocarditis (IE). She was treated with a 6-week course of nafcillin and gentamicin. Three days after initiation of antibiotic therapy the patient was no longer bacteremic.

DISCUSSION: Toxic shock syndrome (TSS) is a toxin-mediated, potentially life-threatening condition that is typically associated with tampon use during menstruation. Pathogens include *S. aureus*, where TSS is caused by enterotoxin type B, and *S. pyogenes*. However one-half of reported TSS cases are non-menstrual. Diagnosis is made based on clinical features of fever, diffuse rash, hypotension, desquamation of the palms and soles and multiorgan involvement. Three of seven organ systems must be affected to meet criteria: GI (diarrhea or vomiting), muscular (myalgia or elevated CPK), mucous membrane (vaginal, oropharyngeal or conjunctival hyperemia), renal (elevated BUN or creatinine), hepatic (elevated transaminases or total bilirubin), hematologic (platelet <100×10⁹/L) or CNS (altered consciousness). Endocarditis, or inflammation of the endocardium, is the result of aggregation of platelets, fibrin and inflammatory cells. IE by bacterial or fungal species involves direct adherence by more virulent species to the endocardium. Alternatively, microorganisms in the blood may attach to sites of nonbacterial thrombotic endocarditis (NBTE) and lead to infective endocarditis. In acute endocarditis rapid structural cardiac damage ensues, often leading to metastatic infection and fatal if left untreated whereas subacute endocarditis slowly damages the heart and rarely has hematologic seeding. Although many bacteria can cause endocarditis, only a few cause the majority of cases. *S. aureus*, streptococci and coagulase-negative staphylococci are the pathogens in a majority of acute bacterial endocarditis cases. IE more often occurs in those with underlying cardiac structural abnormalities including congenital or rheumatic heart disease. Patients with intracardiac devices may also be predisposed to endocarditis. Risk factors include IVDU, indwelling catheters, poor dental hygiene or HIV infection. As this case demonstrates, however, IE due to *S. aureus* can occur in patients with normal hearts and without risk factors. The most common presenting features of IE are fever and heart murmur, each clinically seen over 80 % of the time. Other features such as chills, myalgias, arthralgias and malaise, are also nonspecific and can suggest any number of diseases. Although seen in only 2–8 % of acute cases, clinical findings can include Osler nodes (tender subcutaneous nodules usually in the hands and feet), splinter hemorrhages (dark-red, linear lesions in the nail beds), Roth spots (retinal hemorrhages) and Janeway lesions (nontender rash on the palms and soles). Alarming sequelae include neurological complications such as stroke or encephalopathy. Diagnosis requires fulfilling 2 major, 1 major and 3 minor or 5 minor Duke criteria. This patient met the 2 major Duke criteria: persistently positive blood culture with a typical IE organism and a valvular mass on echocardiogram. Minor criteria include predisposition, fever, evidence of embolism, immunologic problems (e.g. Osler's nodes), and a positive blood culture that does not meet major criteria. It is important for internists to maintain a high degree of suspicion for infective endocarditis, despite the lack of classic risk factors, as delay of treatment can lead to significant sequelae.

A YOUNG MAN WITH FEVER AND DIFFUSE MUSCLE PAIN Priti Dangayach; Lee Lu; Vagish Hemmige. Baylor College of Medicine, Houston, TX. (*Tracking ID #1926379*)

LEARNING OBJECTIVE 1: Recognize the clinical features of tropical pyomyositis.

LEARNING OBJECTIVE 2: Diagnose and treat tropical pyomyositis promptly for better outcome.

CASE: A previously healthy 43-year-old construction worker presented with fever and muscle pain for 8 days. His initial symptoms included a high fever up to 102°F with left hip pain radiating down his leg. Two days prior to presentation, he noticed left shoulder pain and right elbow pain with redness, swelling, and warmth. His pain was worsened by movement. He denied muscle trauma. His fever continued to spike daily to a maximum temperature of 105°F. He was monogamous, married, and denied any new sexual partners, penile discharge, or skin lesions. On examination, he was febrile to 102.9°F, tachycardic to heart rate in the 120 s, and normotensive. He had limited range of motion of his left shoulder, most pronounced with abduction, and of the left hip, mainly with flexion. There was left sided gluteal point tenderness. The right elbow was erythematous and warm without palpable effusion. There were no rashes, lesions, or open wounds. His WBC was 21.6 (91 % neutrophils) with ESR 71 mm/h and CRP 32.9 mg/L. The focal muscle tenderness on exam prompted further studies. CT imaging showed fluid collections in the left iliacus muscle (2.4×8 cm), left piriformis muscle (1.2 cm×1.5 cm), and the subdeltoid bursa. The left iliacus abscess was drained, and cultures yielded *Staphylococcus aureus*. An attempt to drain the subdeltoid bursa was unsuccessful. Blood cultures grew methicillin susceptible

Staphylococcus aureus. His transthoracic echo was negative for endocarditis. He was diagnosed with tropical pyomyositis and was initially started on intravenous vancomycin, which was changed to cefazolin when susceptibilities returned. He completed 6 weeks of therapy with resolution of all abscesses.

DISCUSSION: Isolated bacterial infection of the muscles has been named “tropical pyomyositis” due to its higher incidence in equatorial regions. In the tropics, most cases occur in young healthy males. In temperate regions, the associated risk factors are immunocompromised state, intravenous drug use, or significant medical comorbidities. The most common pathogen for tropical pyomyositis is *Staphylococcus aureus*, with increasing reports of methicillin resistant *Staphylococcus aureus*. Other described pathogens are streptococci, pneumococci, enteric gram negatives, and mycobacteria. Approximately 20–50 % of cases are associated with previous muscle trauma. The commonly affected muscles include quadriceps, glutei, pectoralis major, serratus anterior, biceps, iliopsoas, gastrocnemius, abdominal and spinal muscles.

A YOUNG WOMAN WITH CHEST PAIN AFTER A SORE THROAT AND FEVER Richard Wang. NewYork-Presbyterian Hospital Weill Cornell Medical Center, New York, NY. (*Tracking ID #1936849*)

LEARNING OBJECTIVE 1: Recognize the features of carditis in acute rheumatic fever

LEARNING OBJECTIVE 2: Recognize the diagnostic error of premature closure

CASE: A 33 year old woman with no significant medical history was admitted at this hospital with diffuse chest, abdominal, and back pain. Two weeks prior to presentation, the patient had had a sore throat with fever. These symptoms resolved after 1 week. Five days prior to presentation, the patient developed severe abdominal, chest, and back pain associated with fever, chills, and rigors. The pain was diffuse and often pleuritic. She took large doses of ibuprofen, up to 800 mg four times daily, with minimal improvement in symptoms. She was prescribed azithromycin at an urgent care center 1 day prior, but her symptoms persisted and she presented at the Emergency Department for further evaluation. On presentation, the patient was afebrile, tachycardic to 102 beats per minute, tachypneic to 26 breaths per minute, and normotensive. Her physical examination was otherwise normal. A complete blood count was remarkable for a leukocytosis of 23,400. Her serum creatinine was 5.89 mg/dL. The serum level of troponin I was 4.28 ng/mL. EKG showed normal sinus rhythm with no ST depressions or elevations. Urine toxicology screen was negative for all tested substances. Serum CRP was 10.95 mg/dL. ASO titer was elevated to 687 IU/mL (normal is <144 IU/mL). Throat culture was negative for Streptococcal species. Blood culture was positive for *Streptococcus pyogenes*. Accounting for her history of a sore throat and a positive streptolysin titer, the patient was diagnosed with acute rheumatic fever based on 1 major Jones criterion (carditis) and 2 minor Jones criteria (history of fever and elevated CRP). An echocardiogram was normal and showed no significant valvular disease. Her acute kidney injury was attributed to NSAID nephrotoxicity and resolved with intravenous fluids. The patient was initially treated with vancomycin, piperacillin-tazobactam, and penicillin VK, then subsequently narrowed to amoxicillin-clavulanate. Her pain was treated with ibuprofen and hydromorphone. She was discharged on the fifth day of her hospitalization with instructions to complete a 14-day course of amoxicillin-clavulanate. Two days after discharge, the patient returned to the Emergency Department with severe pleuritic back and chest pain. A chest X-ray was abnormal with a new opacification of the right lower lobe concerning for collapse. CT of the chest revealed an empyema of the right posterior thorax. The patient's diagnosis was revised from acute rheumatic fever to streptococcal toxic shock syndrome from empyema. The patient subsequently underwent video-assisted thoracoscopic surgery for drainage and lung de-cortication. After a 14 day course of IV antibiotics, the patient made a full recovery.

DISCUSSION: The misdiagnosis in this case resulted in part from a misunderstanding and misapplication of the Jones criteria for the diagnosis of acute rheumatic fever. On physical examination and on echocardiographic imaging, the patient did not have any evidence of the valvular injury that is characteristic of carditis from acute rheumatic fever. In the absence of valvulitis, the patient was unlikely to have acute rheumatic fever. Moreover, it was incorrect to attribute the patient's pain symptoms and elevated serum troponin to rheumatic carditis, and pre-mature closure prevented a search for alternative etiologies. In retrospect, the patient had low pre-test likelihood for acute rheumatic fever because initial attacks of acute rheumatic fever are rare in adults. Her history of sore throat 2 weeks prior to hospitalization was ultimately a red herring. A series of cognitive errors resulted in the failure to recognize and treat the correct diagnosis in this case, streptococcal toxic shock syndrome.

A-KNEE-MIA: BLOOD WHERE IT DOESN'T BELONG Jonathan T. Cheah; Jason A. Korcak. Montefiore Medical Center, Bronx, NY. (*Tracking ID #1940577*)

LEARNING OBJECTIVE 1: Recognize hemarthrosis as a potential cause of acute monoarthritis.

LEARNING OBJECTIVE 2: Describe the etiology and risk factors, including systemic anticoagulation, for the development of hemarthrosis.

CASE: A 67-year-old woman presented with 3 days of right leg pain that began while walking and was exacerbated by movement. The patient denied any history of antecedent trauma. Past medical history was significant for bilateral hip replacement and atrial fibrillation on systemic anticoagulation with Warfarin. Temperature was 100.5 F and other vital signs were normal. There was swelling of the right lower extremity most prominent at the knee, as well as overlying ecchymosis. The knee and proximal lower extremity were warm and tender to palpation. Both active and passive movement of the knee were markedly reduced secondary to pain. Hemoglobin was 7.5 g/dL (the baseline was 10.0 g/dL), white blood cell count was 9.7 k/µL, INR was 6.4, and C-reactive protein was 223 mg/L. A radiograph of the right knee showed diffuse subcutaneous soft tissue edema and evidence of severe osteoarthritis. Knee aspiration revealed blood and blood clots, and cultures of the aspirate were without growth.

DISCUSSION: The complaint of joint pain is frequently encountered by the internist in both outpatient and inpatient settings. Although there is a broad differential, the most typical causes of acute monoarthritis include trauma, septic arthritis, and the crystal arthropathies, gout and calcium pyrophosphate dihydrate deposition disease. Less frequent causes include hemarthrosis, erosive osteoarthritis, reactive arthritis, and tumors. Hemarthrosis most commonly affects the knee. Risk factors for the development of hemarthrosis include trauma and bleeding disorders. Less common associated conditions include septic arthritis, tumors such as synovial hemangiomas and pigmented villonodular synovitis, and impaired sensation and proprioception leading to abnormal loading and injury. In cases of trauma, hemarthrosis may occur secondary to damage of any component structures of the knee joint, but often arises from ligament or meniscal damage. Furthermore, underlying joint disease, such as osteoarthritis in this case, may be a contributing factor due to the development of abnormal anatomy and vasculature. Bleeding disorders that cause hemarthrosis are typically acquired or congenital deficiencies of specific coagulation factors, such as the hereditary hemophilias, rather than defects of the vessel wall, platelets, or fibrinolysis. Acquired deficiencies of coagulation factors leading to hemarthrosis are predominantly due to the effect of systemic anticoagulants. Hemarthrosis is a complication of Warfarin therapy in up to 1.5 % of patients. In comparison, the overall hospitalization rate for any Warfarin-related hemorrhage has been estimated at 3.8 % per person year. Hemarthrosis has also been documented with the use of the newer oral anticoagulants, including Rivaroxaban for the prophylaxis of venous thrombosis after knee and hip surgery. In conclusion, hemarthrosis should be considered in the differential diagnosis of acute monoarthritis, especially in individuals receiving systemic anticoagulation.

ABDOMINAL COMPARTMENT SYNDROME FROM MASSIVE PANCREATIC PSEUDOCYSTS Jianhua A. Tau^{1,2}; Jeffrey T. Bates^{1,2}. ¹Baylor College Of Medicine, Houston, TX; ²Michael E. DeBakey VA Medical Center, Houston, TX. (*Tracking ID #1940161*)

LEARNING OBJECTIVE 1: Diagnose the abdominal compartment syndrome (ACS) as a cause of end-organ failure in patients with acute pancreatitis.

LEARNING OBJECTIVE 2: Recognize the utility of bladder catheter transduction to diagnose ACS and that rapid decompression of increased abdominal pressure is the mainstay of therapy.

CASE: A 46-year-old male with a PMH of alcohol dependence was admitted to the intensive care unit with hypotension, acute abdominal pain and distention, and severe dyspnea requiring intubation. Physical examination revealed diffuse rales and a tense and tender abdomen. Laboratory studies were significant for a lipase >2000 U/L, and a CXR showed diffuse infiltrates. Abdominal CT revealed multiple fluid collections and large peripancreatic pseudocysts. He was diagnosed with severe pancreatitis and the acute respiratory distress syndrome (ARDS), and his hypotension was treated with rapid volume expansion. Initial renal function was intact, but by the fifth hospital day the renal function began to deteriorate; peak and plateau lung pressures were also increasing despite a protective ventilator strategy. Serial CT scans confirmed enlarging abdominal fluid collections. Abdominal compartment pressure (ACP) was measured every 6 h via bladder catheter transduction and was persistently greater than 25 mmHg. He was diagnosed with abdominal compartment syndrome (ACS), based on the combination of new organ dysfunction in the setting of an elevated ACP. Over the course of 63 days, he received six transcutaneous abdominal drains for decompression, which were effective in reducing his abdominal pressure below 20 mmHg. His renal function and inspiratory pressures

improved within 48 h of each successful drainage; they ultimately returned to normal. The patient never required decompressive laparotomy.

DISCUSSION: Abdominal wall compliance initially reduces the degree to which an increasing abdominal girth can elevate the intra-abdominal pressure. However, when a critical abdominal girth is reached, abdominal wall compliance decreases abruptly. Further increases in abdominal girth beyond this critical level result in a rapid rise of intra-abdominal pressure and can result in abdominal compartment syndrome (>25 mmHg). ACS can cause ischemic compression of visceral organs, cardiovascular collapse from decreased venous return, and high peak and plateau lung pressures leading to barotrauma. ACS is often related to the need for and extent of volume resuscitation—creating a difficult balancing act in patients with severe pancreatitis, who require significant volume resuscitation. ACS may be underrecognized because it affects patients who are already critically ill and whose organ dysfunction may be incorrectly ascribed to progression of the primary illness—such as ARDS, sepsis, or pancreatitis itself. Since treatment can improve organ dysfunction, it is important that the diagnosis be recognized in critically ill patients with severe acute pancreatitis.

ABDOMINAL COMPARTMENT SYNDROME: A DEADLY CASCADE Mandy S. Stull. Reading Health System, Ephrata, PA. (Tracking ID #1926050)

LEARNING OBJECTIVE 1: Abdominal Compartment Syndrome is a clinical entity resulting in organ dysfunction and multiorgan failure from elevated abdominal pressures. Abdominal compartment syndrome has a mortality that can range from 40 to 100 %.

LEARNING OBJECTIVE 2: Most patients who develop ACS have a tensely distended abdomen, significantly elevated intraabdominal pressures, progressive oliguria, hypotension, and increased ventilatory requirements.

CASE: 48 year male with diabetes, hypertension, and morbid obesity was admitted with tense scrotal and peripheral edema after stopping his furosemide 1 month prior. No evidence of heart failure on physical exam with normal chest radiography and BNP. No history of liver or kidney disease. His liver function tests, including albumin and INR were normal. No proteinuria on urinalysis with normal creatinine. On the second day of admission, the patient developed high pitched bowel sounds and a tense distended abdomen. CT scan of abdomen/pelvis showed no acute findings. Over the course of third hospital day; patient developed oliguria acute kidney injury; creatinine increased from 0.92 to 5.03. Patient then developed acute hypoxic hypercapneic respiratory failure which required BiPAP. He became progressively more hypotensive and ultimately required fluid resuscitation and vasopressors for blood pressure support. In setting of tense distended abdomen with oliguria, acute kidney injury, and hypotension, there was a concern for Abdominal Compartment Syndrome. The patient continued to decompensate requiring mechanical ventilation and multiple vasopressors. Foley catheter transduced pressures greater than 20 mmHg at range. Bladder pressures were consistent with intra-abdominal hypertension; patient had evidence of multi-organ failure as well. Patient continued to decompensate. Repeat CT of abdomen/pelvis demonstrated pneumoperitoneum. Surgery revealed perforated right colon requiring right hemicolectomy. The abdomen was left open for surgical decompression with dressings to bridge the fascial edges. Septic shock persisted. Multiorgan failure ensued with further kidney injury and bowel infarction, shock liver, myocardial infarction and ultimately death.

DISCUSSION: Abdominal Compartment Syndrome is a clinical entity resulting in organ dysfunction and multiorgan failure from elevated abdominal pressures. Failure to recognize abdominal compartment syndrome can lead to a deadly cascade of events. Clinicians must have a high degree of suspicion for this diagnosis and a low threshold to obtain bladder pressures to identify high risk patients. This clinical entity is gaining increased recognition among the medical community as it has a high morbidity and mortality.

ABSENCE MAKES THE HEART GROW FONDER Aimee E. Hiltbold; Catherine Jones. Tulane University Health Sciences Center, New Orleans, LA. (Tracking ID #1926970)

LEARNING OBJECTIVE 1: Recognize the clinical presentation and the appropriate treatment of cardiac tamponade.

LEARNING OBJECTIVE 2: Define the pathophysiology of classic cardiac exam findings.

CASE: A 58-year-old man presents with 2 weeks of progressively worsening dyspnea and chest pain. He has experienced severely decreased functional capacity and is now unable to walk 5 ft without becoming dyspneic. His pain is described as substernal without radiation, and unrelated to physical exertion. He has smoked two packs per day for the past 30 years. He is tachycardic at 118 bpm and tachypneic to 22 breaths per minute. Blood pressure is 128/

86 mmHg, but systolic blood pressure drops to 112 mmHg on inspiration. He appears uncomfortable, is sitting in the tripod position, and is unable to speak in full sentences. He has jugular venous distention to the angle of the mandible. Coarse breath sounds are auscultated bilaterally. He has distant heart sounds and the point of maximal impulse is difficult to locate. Chest radiograph reveals small bilateral pleural effusions, right interstitial and airspace disease, cardiac enlargement, and prominent right hilar lymphadenopathy, suggestive of malignancy. Electrocardiogram shows low voltage amplitude and electrical alternans. Bedside transthoracic echocardiogram revealed a large pericardial effusion. The patient was diagnosed with cardiac tamponade and an emergency pericardiocentesis was performed. Pathological evaluation of the fluid revealed hypercellular and atypical cells arranged in papillary groups. Immunohistochemistry was consistent with malignant papillary adenocarcinoma causing pericardial effusion and cardiac tamponade.

DISCUSSION: Chest pain is a common emergency encountered by internists. We often rely upon advanced tests and imaging for diagnosis. However, a thorough physical exam can focus the practitioner's differential and expedite diagnosis. Physical exam findings of cardiac tamponade include hypotension, jugular venous distention, and muffled heart sounds—collectively known as Beck's triad. A decrease in systolic blood pressure of greater than 10 mmHg with inspiration is known as pulsus paradoxus, and is highly suggestive of cardiac tamponade. Cardiac tamponade is caused by increased pressure on the heart, often from fluid accumulation within the pericardial space. Pericardial effusion may be secondary to infection, malignancy, ventricular rupture, trauma, or surgical procedures. Increased pressure limits diastolic filling, reduces cardiac output, and causes hypotension. The decreased forward flow of blood results in jugular venous distension. Auscultation reveals muffled heart sounds secondary to the accumulated pericardial fluid. Bedside transthoracic echocardiogram is useful in confirming fluid within the pericardial sac and can estimate the volume of effusion. EKG generally reveals diffuse low voltage complexes, with electrical alternans due to the pendular motion of the heart within the pericardial sac. Treatment of cardiac tamponade requires that the fluid surrounding the heart be evacuated via pericardiocentesis or a surgical pericardial window. When the tamponade is secondary to malignancy, treating the underlying malignancy is required. The internist should utilize physical exam findings, such as Beck's triad and pulsus paradoxus, in addition to bedside TTE and EKG findings to promptly diagnose cardiac tamponade.

ACCELERATED CALCIFICATION OF A BIOPROSTHETIC VALVE IN END-STAGE RENAL DISEASE Allison J. Kwong; Douglas B. Jacobs; Matthew Spinelli; Paul D. Blanc. University of California, San Francisco, San Francisco, CA. (Tracking ID #1937187)

LEARNING OBJECTIVE 1: To recognize end-stage renal disease as a risk factor for early calcification of prosthetic valves, and review the relevant literature.

CASE: Our patient is a 61-year-old transgender male-to-female with HIV/AIDS and anuric end-stage renal disease (ESRD) on hemodialysis, who underwent bioprosthetic mitral valve replacement in 2008 for endocarditis of her native valve. She presented in early 2013 with symptoms of progressive heart failure, including orthopnea, weight gain, and exertional dyspnea. Other co-morbidities included type 2 diabetes mellitus, coronary artery disease with history of stents, smoking, and peripheral vascular disease requiring bilateral below-the-knee amputations. Her end-stage renal disease was attributed to HIV and diabetes, and she had been on hemodialysis since 1999, with a history of failed renal transplant in 2004. Physical exam revealed bibasilar crackles, 13 cm jugular venous distention, an audible S3, and a 3/6 holosystolic murmur at the left lower sternal border. Upon admission to the hospital, her calcium was 9.0, phosphorus was 3.6, and PTH was 420 (normal 12–65). Her calcium-phosphorus product had been intermittently elevated—to as high as 90—in the preceding year, despite prescribed phosphate binder therapy. The most recent CD4 count was 174, with an undetectable viral load on anti-retroviral therapy. Her initial EKG showed evidence of an old anteroseptal myocardial infarction and left axis deviation. An echocardiogram obtained during her admission showed new severe mitral valve stenosis, mild mitral regurgitation, no paravalvular leak, and peak and mean transvalvular gradients of 21 mmHg and 14 mmHg, respectively. The ejection fraction was estimated to be 50–55 %. Given her co-morbidities, she was deemed ineligible for either percutaneous valvuloplasty or repeat surgical mitral valve repair/replacement. She has since had frequent admissions for volume overload and is currently in hospice care.

DISCUSSION: Structural valve degeneration, which includes stenosis and/or regurgitation, is a known long-term complication of bioprosthetic heart valves. In the mitral position, bioprosthetic valves have an expected lifespan of at least 10–20 years, and 5-year durability rates approach 100 %. Accelerated calcification of bioprosthetic valves in patients with dialysis-dependent renal failure has been long-assumed, but described only in isolated case reports, and usually in the tricuspid and aortic positions. The mechanism of this rapid calcification is thought to be due to

elevated calcium-phosphate product in the setting of end-stage renal disease and hyperparathyroidism. Though HIV and antiretroviral therapy could also be implicated in this case, these particular risk factors have yet to be associated with the accelerated calcification of non-native valves. Awareness of this potential early complication of bioprosthetic valves in patients with end-stage renal disease could lead to more timely diagnosis, management, and intervention. Strict control of hyperphosphatemia and hyperparathyroidism, as well as closer surveillance of valve function, is likely warranted among patients on hemodialysis with bioprosthetic valves. In this specific high-risk population, mechanical valves, which are less susceptible to calcification, may be a preferable option for those requiring valve replacement.

ACQUIRED ACRODERMATITIS ENTEROPATHICA: RECOGNIZING ZINC DEFICIENCY FOLLOWING GASTRIC BYPASS SURGERY Gautam Mankaney; Thomas Radomski; Kevin Kraemer. University of Pittsburgh Medical Center, Pittsburgh, PA. (Tracking ID #1939348)

LEARNING OBJECTIVE 1: Describe a classic presentation of zinc deficiency

LEARNING OBJECTIVE 2: Recognize the potential nutritional deficiencies following gastric bypass surgery

CASE: A 54 year-old Caucasian woman with a history of Crohn's disease, Roux-en-Y gastric bypass surgery, and chronic kidney disease, presented with a progressive skin rash for several months. The patient noted a red rash with cracked and sloughing skin around her groin, buttocks, and upper extremities. The rash did not resolve with the use of topical corticosteroids or both topical and oral anti-fungal agents. She denied any fevers or new medications, but did have several weeks of associated diarrhea. She underwent a Roux-en-Y gastric bypass surgery about 8 years prior and endorsed poor eating habits and compliance with her vitamin supplements. The physical exam revealed a middle-aged appearing female in no distress. She was afebrile with stable vital signs. She had an erythematous, desquamating rash associated with excoriations and honey-colored crusting. The rash was predominant over her perioral, lumbosacral and inguinal regions. Her distal extremities also displayed palmar erythema and fissuring. The remainder of her exam was unremarkable. A skin biopsy revealed non-specific histologic findings of parakeratosis, impetiginized regions, and chronic inflammation with dermal edema. A work-up for infections and autoimmune etiology was non-revealing. The patient was found to be nutritionally deficient with an albumin level of 1.4 g/dL. Further evaluation for micronutrient deficiencies revealed a markedly low plasma zinc level of 0.31 µg/ml (normal 0.55–1.50 µg/ml). She was diagnosed with acquired acrodermatitis enteropathica secondary to zinc deficiency and was started on zinc supplementation. A near-complete resolution of the rash was noted at follow-up 4 weeks later.

DISCUSSION: Bariatric surgery is one of the fastest growing surgical procedures in the United States. The Roux-en-Y gastric bypass surgery, the most commonly performed type of bariatric surgery, divides the stomach into two unequally sized pouches and connects the smaller pouch to the jejunum, effectively bypassing the duodenum and part of the proximal jejunum. Although intraoperative and early postoperative complications are rare and compare favorably with other frequently performed abdominal operations, late complications are becoming more visible. Micronutrient deficiencies are the most likely long-term complication and often present as clinical syndromes classic for the deficiency. Zinc is an essential cofactor for enzymes involved in keratinocyte maturation, among several other regulatory processes. Acquired acrodermatitis enteropathica, or zinc deficiency due to impaired metabolism, classically presents as a perioral, intertriginous, and acral dermatitis that may be associated with diarrhea, alopecia, and altered mental status. The dermatitis appears as erythematous patches of dry and scaly skin, an eczematous rash, or a vesiculopustular eruption. Several mechanisms contribute to the micronutrient deficiencies seen after bariatric surgery, including decreased oral consumption, impaired intestinal uptake, poor compliance with dietary supplementation, and pre-existing nutritional deficiencies seen in obesity. Zinc levels may be low pre and postoperatively; however, when symptomatic, oral repletion rapidly corrects symptoms, as in this patient. This case also illustrates the importance of recognizing nutritional deficiencies in patients who undergo bypass surgery. Other common deficiencies include vitamin B12, folate, iron, copper, calcium, and vitamin D. There are not any randomized-controlled trials that guide general practitioners on screening and supplementation; however, awareness of such deficiencies may lead primary care physicians to reinforce dietary compliance with their patients and more easily identify the signs and symptoms of micronutrient deficiencies when they occur.

ACRAL CD4 T CELL LYMPHOMA PRESENTING AS DUPYTUREN'S CONTRACTURE Ragisha Gopalakrishnan; Harris Naina. UT southwestern, Dallas, TX. (Tracking ID #1939624)

LEARNING OBJECTIVE 1: To recognize Acral CD4 T cell Lymphoma as a part of the differential diagnoses for Dupuytren's contracture.

CASE: A 90 year old Hispanic man with no medical history presented to his physician after developing redness and a knot like sensation in both of his hands for 1 year. On exam, there was erythema on the dorsum and palmar surfaces of both hands, but there was no evidence of lymphadenopathy, petechiae or ecchymosis. He denied any fevers, night sweats, pruritus, and weight loss. He was a former smoker, but denied any family history of malignancy. He was initially diagnosed with Dupuytren's contracture and treated with topical steroids and clobetasone. However, this provided little symptomatic benefit, and a subsequent MRI of his left hand showed a small 8 mm lesion between the epidermal and subepidermal tissue. A biopsy showed a nodular proliferation of medium-sized to large, cytologically atypical and immunophenotypically aberrant T-lymphoid cells which were consistent with acral CD4 positive T-cell lymphoma. Subsequent PET imaging showed no evidence of systemic disease. He underwent surgical resection of the 8 mm nodule of his left hand. However, the disease continued to spread to his right hand, and he developed gangrene of his thumb requiring amputation of his thumb. He underwent 35 cGy radiation to his right hand, but the disease recurred. He was treated with gemcitabine, with minimal response. His performance status declined rapidly and died on hospice care.

DISCUSSION: Acral CD4 T cell lymphomas (ACTL) are a rare form of cutaneous lymphomas. There are 15 cases of ACTL reported in literature, and all of these cases present in the lesions in the lower extremity, head or neck. Most patients diagnosed with ACTL have had an indolent clinical course with complete response rate greater than 80 % with local surgical therapy or radiation therapy. However, in 2 of the 15 cases of ACTL reported, systemic chemotherapy (vornistat or gemcitabine) was used when a patient could not qualify for local surgical or radiation therapy; this provided limited benefit, and both of these patients died. By presenting this case, we show for the first time that ACTL can present with lesions in the upper extremity. This suggests, that ACTLs can present as upper extremity lesions and should be considered as part of the differential of Dupuytren's contracture. In addition, in this case, the disease recurred multiple times and was resistant to all three treatment regimens currently available for ACTL. Given the aggressive course and number of recurrences of this patient's case, additional investigation is required to in additional treatment modalities when the existing treatment regimens fail.

ACRAL MELANOMA IN SITU Karen Y. Cheng; Victoria T. Liu¹; Pearl Yu². 1UCSD, San Diego, CA; 2University of California, San Diego, La Jolla, CA. (Tracking ID #1925625)

LEARNING OBJECTIVE 1: Recognize the parameters for assessing pigmented cutaneous lesions that require further evaluation by a dermatologist

LEARNING OBJECTIVE 2: Describe the risk factors and management for melanoma in situ

CASE: A 59 year old white male with past medical history of prostate cancer, hypertension, and hyperlipidemia presented with a pigmented lesion that was changing in appearance on the plantar surface of his left first toe. The patient stated that there had been a pigmented lesion on the plantar surface of his left first toe for about 5 years. In the few weeks prior to presenting in clinic, he had noticed that several other pigmented lesions had appeared around the original lesion. There was no associated pain or pruritis. On exam, it was noted that he had 3 areas of black pigmentation measuring 5×5 mm, 6×4 mm, and a larger area consisting of a very dark 5×4 mm patch and a lighter 15×8 mm patch. He was referred to dermatology, where two 2 mm punch biopsies were taken from different parts of the larger area: one from the more distal dark black patch and another from the more proximal lighter black patch. Both of these biopsies showed proliferation of atypical pigmented melanocytes at the dermal-epidermal junction consistent with melanoma in situ. Additional biopsies were taken from the two other areas of pigmentation on the great toe after the dermatopathology demonstrated melanoma in situ and the patient is scheduled to discuss wide excision with possible plastic surgery repair with the dermatology surgeon.

DISCUSSION: The incidence of malignant melanoma in situ has been increasing and represents about 40 % of all melanomas diagnosed in the United States. Malignant melanoma in situ is a non-invasive precursor lesion which accumulates mutations to gain the ability to invade the underlying dermis and become invasive and metastatic melanoma. Risk factors for melanoma in situ include: family history of melanoma, greater number of severe sunburns, greater susceptibility to sunburns, and natural red or blond hair color. Melanoma is suspected based on the well-known ABCDE parameters: asymmetry, border irregularity, color variegation, diameter >6 mm, and evolution. Biopsy with histopathological findings of proliferating melanocytes that migrate into the epidermis and architectural asymmetry within the lesion are diagnostic of melanoma in situ. Standard treatment is excision with margins of 0.5 to 1 cm. Although acral skin is the most prevalent site of melanoma in non-white populations, this case represents an atypical anatomic site of presentation since

white males typically have lesions on their trunk or back and the patient had no family history or other risk factors for melanoma in situ. However, the lesion did show asymmetry, irregular borders, color variegation, diameter greater than 6 mm, and recent change, demonstrating the necessity of having a high index of suspicion for melanoma when a lesion matches ABCDE criteria.

ACUTE AMIODARONE PULMONARY TOXICITY FOLLOWING LUNG RESECTION Opeyemi Fadahunsi; Mandy S. Stull; Shobhit Gupta. Reading Health System, Reading, PA. (*Tracking ID #1938472*)

LEARNING OBJECTIVE 1: Recognize that amiodarone pulmonary toxicity (APT) can occur any time after commencement of amiodarone and it is a diagnosis of exclusion

LEARNING OBJECTIVE 2: Recognize the increased risk of acute APT following lung resection

CASE: An 80-year-old male with a 15-pack-year cigarette smoking history and coronary artery disease underwent a right upper lobectomy for lung adenocarcinoma (T2A N0 M0, Stage 1b). Preoperative transthoracic echocardiography (TTE) showed normal left ventricular function. Preoperative pulmonary function tests (PFTs) revealed a forced expiratory volume in 1 s (FEV1) of 2.19 L (71 % of predicted), forced vital capacity (FVC) of 2.86 L (71 % of predicted), FEV1/FVC ratio of 77 %, total lung capacity (TLC) of 4.45 L (66 % of predicted) and a diffusion capacity for carbon monoxide (DLCO) of 13.5 mL/mmHg/min (59 % of predicted). Postoperative (postop) course was complicated by subcutaneous emphysema which necessitated prolonged intubation. On postop day 4, he developed paroxysmal atrial fibrillation with rapid ventricular rate and was loaded with IV amiodarone for rhythm control at a rate of 0.5 mg/min which was then converted to 400 mg tid orally on postop day 8. He was transferred to a rehabilitation center on postop day 12 in a relatively stable condition. On postop day 15, patient presented to the hospital with severe dyspnea, dry cough and syncope. He denied chest pain, diaphoresis, nausea or fever. He had received a total dose of 12.5 g amiodarone in the preceding 12 days. There were no known environmental exposures. On physical examination, patient had diffuse dry crackles and no wheezes. Neck veins were not distended and there was no pedal edema. Arterial blood gas showed hypoxemia without CO₂ retention. Cardiac enzymes were normal and there were no EKG changes. Laboratory studies showed a leukocytosis and elevated ESR. Chest CT scan revealed bilateral airspace opacities and mediastinal adenopathy. ACE level was normal and collagen vascular work up, including ANA, RF and ANCA, was negative. Blood culture did not grow any organisms. Postop PFTs revealed a severe restrictive disease: FEV1 of 1.24 L (41 % of predicted), FVC of 1.61 L (39 % of predicted), FEV1/FVC ratio of 81 %, TLC of 3.13 L (42 % of predicted) and DLCO of 6.5 mL/mmHg/min (24 % of predicted). TTE showed normal valvular and left ventricular function with elevated pulmonary artery (PA) pressure (80 mmHg). Cardiac catheterization which was done 7 months ago had shown normal PA pressure. Amiodarone was discontinued and he was started on prednisone due to suspicion for APT. He improved symptomatically and radiographically, however he was still requiring 3 L of intranasal oxygen. He was discharged home on oxygen and was placed on 1 month prednisone taper. On postop day 52 (4 days after completing steroid therapy), he again presented to the hospital with similar complaints of severe dyspnea with high oxygen requirements. Radiological findings were improved but not back to baseline. He underwent bronchoscopy which revealed normal bronchial mucosa. Bronchial washing cytology was negative for AFB or malignancy and there was no growth on culture. Microbiologic analysis of bronchial washing showed a neutrophilic leukocytosis. Clinically, he improved and he was discharged on a prolonged course of prednisone.

DISCUSSION: APT is the most severe adverse effect associated with the use of amiodarone. Pulmonary fibrosis following APT is irreversible, therefore anticipation and early detection of this potentially fatal side effect is important. Onset of APT has usually been observed after several months or years of amiodarone use. In the above case and a handful of other cases reported in literature, pulmonary toxicity can occur within a few days to weeks. The clinical findings in APT are non-specific and it remains a diagnosis of exclusion. The diagnosis of APT needs to be considered in high risk patients on amiodarone irrespective of dose, presenting with new or worsening respiratory symptoms or signs, new chest radiographic abnormalities or a decline in DLCO>20 %. Risk factors in our case include old age, pre-existing lung disease, thoracic surgery, intubation and amiodarone dose ≥400 mg/day. In a subset of patients undergoing thoracic surgery who are intubated and require high levels of oxygen, it has been postulated that the risk of developing APT is further heightened due to increased susceptibility for lung damage. Studies on risk factors for APT development have not been conclusive, however, in patients with multiple risk factors, there needs to be a discussion on the risks and benefits of amiodarone

treatment. Finally, management of APT requires discontinuation of amiodarone and commencement of steroids for greater than 6 months. As in the case presented, tapering steroids too early may lead to symptom recurrence.

ACUTE ANEMIA AFTER A URINARY TRACT INFECTION (UTI): A CASE OF HEMOLYTIC ANEMIA IN A NEWLY DIAGNOSED GLUCOSE-6-PHOSPHATE DEHYDROGENASE (G6PD) DEFICIENT PATIENT Irem Nasir. Greenwich hospital, Greenwich, CT. (*Tracking ID #1939299*)

LEARNING OBJECTIVE 1: 1) Recognize a case of acute nonimmune hemolytic anemia in a patient with a new diagnosis of G6PD deficiency.

LEARNING OBJECTIVE 2: 2) Name drugs contraindicated in patients with G6PD deficiency.

CASE: A 69 year old Hispanic female who had a recent UTI, presented to us with shortness of breath, fatigue, and malaise ×6 days. She also had jaundice and dark urine ×1 day. She had just completed an 8 day course of nitrofurantoin and phenazopyridine (a urinary tract analgesic) the day prior. She denied fevers, cough, chest pain, nausea, vomiting, and diarrhea. There were no tarry/black stools. Her dysuria had resolved. There was no recent travel, sick contacts, or insect bites. There was no history of IVDA or risky sexual behavior. There was no known family history of any blood dyscrasias. On physical exam, patient was afebrile, icteric, heart regular rate, lungs clear, abdomen soft, nontender. Guaiac was negative. There were no rashes or petechiae. Her labs were notable for wbc22, hgb6.8 (decreased from a hgb 12 a few months prior), platelets 280, Cr 1, and a lactate of 1.5. Both her reticulocytes and LDH were significantly elevated at 12 % and 700, respectively. Total bilirubin was elevated at 4 with an indirect bilirubin of 3. AST, ALT, and INR were normal. Haptoglobin was low at <7. Peripheral blood smear had no schistocytes. Urinalysis showed high urobilinogen. CXR was neg. A diagnosis of acute hemolytic anemia due to nitrofurantoin and phenazopyridine was made and both drugs were immediately stopped. Aggressive supportive care was initiated and 1u pRBC was transfused. Her hgb improved to 7.7. On further testing, direct coombs test, ANA, Parvovirus IgM and PCR, Cold agglutinins, Mycoplasma IgM, EBV, and CMV titers were all negative. Hgb electrophoresis was negative. Her RBC G6PD activity level was low at 2.5 (4.6 to 13 reference range). A diagnosis of G6PD deficiency was made. Two weeks later, her hgb was 11 and both the reticulocytes and LDH were normal at 2 % and 196, respectively. Patient and family were advised to avoid all foods and drugs with known oxidative potential, such as nitrofurantoin and phenazopyridine, which can trigger an episode of nonimmune hemolytic anemia.

DISCUSSION: G6PD deficiency, an X linked disorder, is the most common enzymatic disorder of RBC, affecting 400 million people worldwide. A diagnosis of G6PD deficiency is made when there is decreased activity of this enzyme in RBC. False negative results can occur if the G6PD level is checked immediately following hemolysis, since the most severely deficient RBC have been removed and young reticulocytes have higher G6PD levels. In those cases, retesting a few months later is recommended. A female can be heterozygous or homozygous, resulting in half or all of her RBC vulnerable to hemolysis, respectively. G6PD deficient cells are incapable of coping with oxidant stress. G6PD protects RBC by replenishing reducing equivalents, NADPH and Glutathione reductase. Nitrofurantoin inhibits glutathione reductase and decreases generation of reduced glutathione. Phenazopyridine, which should only be prescribed for 2–3 days, is a well known oxidative drug. Other commonly used drugs like fluoroquinolones, sulfa drugs, and even NSAIDS and acetaminophen in high doses can cause hemolysis. Even black and red henna tattoo and hair dyes have been implicated. Clinicians must maintain a high index of suspicion for G6PD deficiency in any individual presenting with an episode of nonimmune hemolytic anemia, especially if temporally related to a culprit drug.

ACUTE CHOLANGITIS, SANS CHOLE Aimee E. Hiltbold; Catherine Jones. Tulane University Health Sciences Center, New Orleans, LA. (*Tracking ID #1926993*)

LEARNING OBJECTIVE 1: Apply the Tokyo guidelines to diagnose a cause of abdominal pain

LEARNING OBJECTIVE 2: Discuss treatment goals for acute cholangitis

CASE: A 61 year-old woman presented with 3 days of worsening abdominal pain, fever, and jaundice. Additionally, she reported dizziness with periodic confusion. Abdominal pain was located in the right upper quadrant with radiation to her right scapula. She noted dark urine and yellowing of her eyes. Pertinent past medical and surgical history was significant for a history of gallstones, prompting a cholecystectomy, and a Roux-en-Y gastric bypass procedure 10 months ago. She was febrile at 103 °F, tachycardic at 111 bpm, tachypneic at 22 bpm, with a blood pressure of 85/58 mmHg after receiving 3 l of normal saline. She was slightly confused and in

moderate distress with severe 10/10 abdominal pain. She had scleral icterus and significant tenderness to palpation of the right upper quadrant with voluntary guarding. Laboratory findings included a leukocytosis of 20,000, 94 % neutrophils, bandemia, and prolongation of the PT to 12.3. Chemistry demonstrated BUN of 24 with a creatinine of 1.1. Liver panel evidenced an obstructive pattern with AST of 1030, ALT of 638, alkaline phosphatase of 1026, and total bilirubin of 5.8. Computed tomography revealed fluid in the gallbladder fossa with intra and extrahepatic biliary duct dilation. The patient met Reynolds' pentad of acute cholangitis; however, secondary to her gastric bypass surgery she could not undergo ERCP. Interventional radiology performed percutaneous cholangiography with biliary drain placement, where she was noted to have a 1 cm stone in the distal common bile duct.

DISCUSSION: It is imperative for the general internist to quickly diagnose acute cholangitis to prevent significant morbidity and mortality. Cholangitis is a clinical syndrome characterized by fever, jaundice, and abdominal pain, known as Charcot's triad. Confusion and hypotension may also occur in patients with suppurative cholangitis, producing Reynolds' pentad. The Tokyo guidelines propose definitive diagnosis of acute cholangitis if the patient exhibits Charcot's triad, or if there are two elements of Charcot's triad plus abnormal liver tests, imaging revealing biliary dilation, and evidence of an inflammatory response—leukocytosis or elevated CRP. Infection occurs when bacteria from the gut translocate into an obstructed biliary tree or after introduction via instrumentation. Primary causes of biliary obstruction include gallstones, acalculous stasis, and malignancy. Bile duct stones usually form in the gallbladder, but can also form spontaneously in the bile duct after cholecystectomy. Treatment of acute cholangitis is aimed at treating associated sepsis, providing empiric antibiotics to cover enteric pathogens, and visualizing and draining biliary obstruction. This is typically done by emergent endoscopic sphincterotomy with stone extraction via ERCP. ERCP is not technically feasible in some patients, including those who have undergone a Roux-en-Y gastric bypass. In this instance, biliary drainage should be attempted via percutaneous transhepatic cholangiography with biliary drain placement or open surgical decompression. Acute cholangitis is associated with significant morbidity and mortality, and internists must be adept at providing prompt diagnosis and treatment.

ACUTE DIFFUSE MACULOPAPULAR RASH: MAYBE NOT SO "SWEET."
Derek A. Pae; David Linz. University of Pittsburgh, Pittsburgh, PA. (*Tracking ID #1942112*)

LEARNING OBJECTIVE 1: Recall the differential diagnosis of acute febrile neutrophilic dermatosis

LEARNING OBJECTIVE 2: Diagnosis of Sweet's syndrome

CASE: A 29 year old man presented to his doctor with 1 week of fevers and a painful rash. The patient first experienced a fever to 101 associated with shaking chills and drenching sweats, followed the next morning by a rash on his chest and abdomen. Over the following few days, the rash spread all over his body with painful blisters, draining milky-yellow fluid and the fevers did not abate. The patient finally sought medical attention because of the intense pain of the blisters and was subsequently admitted to the hospital. Past medical history was significant for Crohn's disease diagnosed by colonoscopy 4 months prior. He worked as electrician, did not have any recent travel or sick contacts. His medications included azathioprine 200 XXX mg daily, which was initiated 4 months prior and 5 mg of prednisone daily, tapered from 40 mg daily over the past 2 months. Skin exam revealed multiple diffuse pustular lesions across neck, face, trunk and upper extremities sparing the palms and soles, multiple nodules on the lower extremities, and two painful erythematous nodules in groin and neck in various stages of healing. There were also two flaccid hemorrhagic bullae on the right shin. Labs revealed WBC of 21.5 and elevated ESR and CRP (99 mm/h; nl <23 and 22.5 mg/dL; nl <0.7 respectively). Blood and urine cultures were negative. CXR showed no evidence of pneumonia. Sigmoidoscopy showed severe inflammation with skip lesions and ulcers in the colon consistent with active Crohn's colitis. Skin biopsies revealed neutrophilic dermatosis with mild vasculopathy consistent with abscess forming neutrophilic dermatosis/atypical Sweets syndrome. Patient did not respond to broad spectrum antibiotics, but showed marked improvement after the initiation of high dose steroids, with decreased pain, absence of fevers, and normal WBC.

DISCUSSION: Fever, leukocytosis, or skin rash are common chief complaints for physicians but the combination of all three can be a puzzling triad. This patient presented with acute febrile neutrophilic dermatosis, which should prompt a differential diagnosis that includes infection, malignancy, and auto-immune disease. Empiric antibiotics to cover a broad spectrum of organisms could be warranted while awaiting final pathology results. In acutely ill patients like ours with fever and leukocytosis who are taking immunosuppressants, pseudomonas and fungal infection should be ruled out. Sweets syndrome is not uncommon, but the presence of abscess formation and hemorrhagic lesions in our case is exceedingly rare. The definitive way to diagnose this disease is through biopsy, as performed in this case. However, there

are several underlying systemic diseases to consider, including malignancy, in a patient with such a syndrome. In this case, patient was already diagnosed with IBD, and the repeated sigmoidoscopy was consistent with Crohn's flare. However, in another setting if such a patient presented with only the dermatological manifestation, investigation including sigmoidoscopy may be warranted. Taking into account patient age, investigation for malignancy should be considered. There have been several but not many case studies regarding association between atypical sweet's syndrome and myeloproliferative diseases, including leukemia. One final note is this patient was on azathioprine, which had been linked to sweet's syndrome, and discussion regarding discontinuing this medication and watchful observation should be considered.

ACUTE ENCEPHALITIS IN AN AFEBRILE YOUNG ADULT PRESENTING WITH HEADACHES AND MYALGIAS Sharon Chow; Jennifer Way; Adrienne L. Clark. UCLA, Los Angeles, CA. (*Tracking ID #1939510*)

LEARNING OBJECTIVE 1: Describe an atypical presentation of acute encephalitis in a young adult

LEARNING OBJECTIVE 2: Discuss the broad differential and work up of meningoencephalitis in a patient with atypical presentation

CASE: RL was a 21 year old previously healthy male with a history of ADHD, impulsivity, and migraines who was initially admitted to the hospital for 3 days of headaches and diffuse myalgias. On presentation, the patient was afebrile with normal heart rate and physical exam, and all studies, including CBC, BMP, CK and blood cultures, were unremarkable. He was initially treated with supportive management, including intravenous fluids and analgesics, for suspected migraine and somatization disorder given no evidence of an organic component to his symptoms. However the patient's mental status deteriorated on hospital day three following myoclonic-seizure activity and he became increasingly agitated and unable to follow commands with changes in his vitals including fever to a Tmax of 40.0C and tachycardia into the 160 s following a lumbar puncture (LP). He also developed severe muscle rigidity, opisthotonus, and upper motor neuron signs such as clonus and hyperreflexia on physical exam. MRI at that time showed subtle leptomeningeal enhancement and LP was significant for 104 RBC, 54 WBC (86 % lymphocytes, 14 % monocytes), glucose 103, and protein 288. He was intubated and sedated for airway protection and started on broad spectrum anti-infective agents including ceftriaxone, vancomycin, and acyclovir for suspected meningitis. Given the severity of his acute decompensation, atypical physical exam findings, and elements in his history such as recent travel to Sweden and questionable immunization profile, a broad differential for both infectious and non-infectious causes was considered that included tetanus, rabies, and anti-NMDA receptor encephalopathies. Anti-infective therapy was broadened with doxycycline to cover atypical infection including rickettsial disease and tetanus toxoid was administered. Following negative viral and bacterial CSF cultures, the decision was made to initiate treatment for anti-NMDA receptor encephalitis with five doses of solomedrol and IVIG with further work up (including NMDA receptor and paraneoplastic serologies) pending. The patient showed marked improvement, and was extubated on hospital day eight with improved mental status and physical exam. Eventual CSF studies all returned negative with the exception of Mycoplasma Pneumoniae and West Nile Virus IgG, both which resulted as positive. He was discharged home to complete a course of doxycycline for possible mycoplasma infection with close follow up in infectious disease clinic post discharge.

DISCUSSION: 1. Encephalitis can present with subtle neurologic symptoms including behavioral changes, agitation, and motor complaints such as paresis and myalgias without evidence of organic disease. High index of suspicion for CNS infection should be maintained for individuals with persistent symptoms. 2. Atypical causes of encephalitis including West Nile Virus and Mycoplasma Pneumoniae are difficult to diagnose based on laboratory data due to poor sensitivity and specificity of available studies. 3. Broad spectrum treatment for severe encephalitis should be initiated early as diagnostic results are often delayed. Furthermore, a confirmed etiology in most encephalitis cases is unable to be determined, thus illustrating the importance of prompt supportive management.

ACUTE HEPATITIS B INFECTION ASSOCIATED WITH RHABDOMYOLYSIS Marissa D. Friedman. New York Presbyterian - Weill Cornell Medical Center, New York, NY. (*Tracking ID #1911877*)

LEARNING OBJECTIVE 1: Recognize instances when a patient with acute hepatitis B infection should receive treatment with anti-virals.

LEARNING OBJECTIVE 2: Discuss the potential for myopathy with the use of statins in patients with acute liver dysfunction.

CASE: In this case, a 66 year old female originally from Italy, with a history of coronary artery disease status post three vessel coronary artery bypass graft, was admitted to the hospital with 3 weeks of malaise, fever, nausea, jaundice, and diffuse abdominal pain. Her medications included simvastatin 80 mg daily. On physical exam, her sclera were icteric, skin with jaundice, and she had right upper quadrant abdominal tenderness to palpation. Labs were significant for a transaminitis with values of 877/724 (AST/ALT). A hepatitis panel was obtained which revealed, hepatitis B surface antigen positive, hepatitis B core antigen IgM positive, and Hepatitis A IgM negative, indicating an acute hepatitis B infection. On her second day of admission, she reported that she could not move her legs and her arms also felt weak. Repeat exam revealed that strength was 3/5 in the lower extremities bilaterally and 4/5 in the upper extremities bilaterally. Creatine kinase (CK) level was found to be 5000. Over the next few days the CK continued to uptrend as did the transaminases, with peaks at 12,000, and 1300/1000 (AST/ALT) respectively. The patient also developed a rise in creatinine, thought to be secondary to rhabdomyolysis given presence of myoglobin in the urine. The patient remained bed bound, barely able to lift herself out of bed. Rheumatologic serologies were all negative, and the decision was made to begin anti-viral treatment with tenofovir and entecavir. A muscle biopsy was performed in attempt to rule out vasculitis, however the sample was too small, only revealing a small area of muscle necrosis. Overall, with anti-viral treatment, CK and transaminases started to downtrend. The patient slowly regained her strength and was discharged from the hospital.

DISCUSSION: This case presents a unique diagnostic dilemma as to the actual cause of the rhabdomyolysis and demonstrates instances when a patient with hepatitis B may benefit from treatment with anti-virals. Typical indications for treatment with anti-virals in acute hepatitis B include the presence of coagulopathy or encephalopathy. This patient had neither, however given the concurrent myopathy and an inability to fully rule out the hepatitis virus itself as potential cause, the decision was made to treat with anti-virals. Following initiation of tenofovir and entecavir, the patient did improve. Even so, the leading differential diagnosis for the cause of myopathy in this case was the patient's use of statin while concomitantly developing acute viral hepatitis. In the current literature the link between statin use in the setting of acute viral hepatitis has never been studied and thus is not associated with any known increased risk of myopathy. There is evidence that patients with existing liver disease are at increased risk to develop myopathy, therefore it can be inferred that an acute liver injury may invoke a similar mechanism leading to the same side effect. In considering this possibility, another interesting clinical practice question is raised as to whether or not patients on statins should receive a hepatitis B vaccination? Further research needs to be conducted to better elucidate the incidence of myopathy in patients on statins who develop acute viral hepatitis in order to answer this question.

ACUTE HEPATOTOXICITY: A COMPLICATION OF CHAPARRAL INGESTION Nicholas Tangchaivang, University of California, Los Angeles, Los Angeles, CA. (Tracking ID #1925982)

LEARNING OBJECTIVE 1: Recognize an unusual cause of hepatotoxicity that would not be recognized if not searched for

CASE: A 65-year-old man with no significant past medical history presented to the Emergency Department with a 1 week history of fevers up to 103 F and chills. He endorsed myalgia, nausea, anorexia, night sweats, and fatigue. He denied abdominal pain, diarrhea, melena, weight loss, or recent travel. The patient denied using any medications including supplements and herbs. He had been seeing an acupuncturist regularly. Physical exam was notable for a temperature of 38.1C, blood pressure of 78/58, heart rate of 130, a jaundiced general appearance, scleral icterus, dry mucous membranes, and hepatomegaly. The patient was given IV fluids with improvement in blood pressure to 116/73 and heart rate to 113. Laboratory work-up revealed elevated liver tests with an AST of 178 U/L, ALT of 342 U/L, Total Bilirubin of 4.3 mg/dL, and Alk Phos of 257 U/L. CBC, Basic Metabolic Panel, and INR were within the normal range. An abdominal ultrasound revealed an enlarged liver with mild perihepatic ascites and marked gallbladder wall thickening with no evidence of cholecystitis. A CT Abdomen and Pelvis with Contrast confirmed these findings. There was no evidence of drainable fluid collections. IV fluid resuscitation was continued. Empiric antibiotics were not given due to a lack of an infectious source, normal WBC count, and hemodynamic stability following IV fluid resuscitation. Acute hepatitis workup was negative for Hepatitis A, Hepatitis B, Hepatitis C, Autoimmune Hepatitis, and acetaminophen toxicity. An abdominal ultrasound with Doppler was negative for vascular occlusion. Over the next 48 h, the patient had complete resolution of his symptoms without additional intervention. Bacterial cultures returned negative and the patient's liver tests were downtrending. A call to the patient's acupuncturist revealed that the patient had been taking Chaparral to promote liver health.

DISCUSSION: The actual prevalence of herbal product use and incidence of acute herbal hepatotoxicity are unknown. Based on available data, herbal products are implicated as a cause of hepatotoxicity in up to 10 % of drug induced liver injury and acute liver failure cases. Chaparral-induced hepatotoxicity typically manifests with symptoms that include fatigue, abdominal pain, dark urine, light stools, nausea, and diarrhea. Most patients have marked jaundice and elevated liver tests. Although most cases of hepatotoxicity resolve following cessation of Chaparral ingestion, some evolve onto cirrhosis or develop acute liver failure. Chaparral is made from the leaves of the creosote bush or greasewood. It has been used for its claimed antioxidant and anti-ageing properties as well as for treatment of various conditions such as cancer and AIDS. The mechanism of Chaparral-induced hepatotoxicity is not known but may be related to inhibition of lipoxygenase and cyclooxygenase pathways, cytochrome P450 inhibition, or the estrogen activity of chaparral metabolites. In this case, our patient presented with acute hepatotoxicity with marked hypotension. This may have led to acute liver failure had prompt IV fluid resuscitation not been employed. Awareness that the ingestion of alternative medicines can lead to severe hepatotoxicity is essential in cases of unclear liver disease. This case also reminds us that inquiring about the use of alternative medicines is an important aspect of taking a thorough medication history.

ACUTE LIVER FAILURE AS INITIAL MANIFESTATION OF DIFFUSE LARGE B CELL LYMPHOMA Gargi Bajpayee; Matthew Kutner; Isabel Preeshagul; Alfred Burger; Lionel S. D'Souza; Franklin Kasmin. Beth Israel Medical Center of Mount Sinai, New York, NY. (Tracking ID #1940112)

LEARNING OBJECTIVE 1: Recognize Non-Hodgkin's Lymphoma as a rare presentation of acute liver failure

LEARNING OBJECTIVE 2: Understand that prompt recognition and appropriate treatment of this disease is essential in preventing devastating outcomes

CASE: A 77-year-old man with remote history of prostate cancer (in remission) and former alcoholic presented to the emergency department for worsening jaundice and malaise for 1 month. The patient denied any recent travel, fevers, abdominal pain, diarrhea, or constipation and was current with his hepatitis vaccinations. The patient's vitals were normal and physical exam was remarkable for diffuse jaundice, scleral icterus, and intermittent episodes of confusion. Laboratory work was significant for total bilirubin 17.3 mg/dL, direct bilirubin 14.5 mg/dL, AST 310 IU/L, ALT 232 IU/L, ALP 254 IU/L, albumin 2.6 g/dL, INR 1.9, LDH 2144 U/L, ferritin 663 ng/ml, ceruloplasmin 54 mg/dL, acetaminophen level <10 ug/ml and absence of hepatitis A, B, C, D, EBV, CMV, VZV and HIV. ANA (anti-nuclear antibody), anti-LKMI (liver-kidney microsome) and ASMA (anti-smooth muscle antigen) were negative. Right upper quadrant ultrasound revealed diffusely infiltrated liver with normal portal and arterial blood flow. The patient was started on Rifaximin and Lactulose for worsening hepatic encephalopathy. Liver biopsy revealed large, heterogeneous, neoplastic cells with vesicular chromatin and prominent nucleoli consistent with Diffuse Large B Cell Lymphoma. Shortly thereafter, the patient's clinical and laboratory status deteriorated, requiring transfer to the MICU. Unfortunately, 2 days after induction chemotherapy with CHOP, the patient developed tumor-lysis syndrome and expired.

DISCUSSION: Acute Liver Failure (ALF) is a rare condition characterized by rapid deterioration of liver function resulting in the development of encephalopathy and coagulopathy in a patient without preexisting cirrhosis and an illness duration <26 weeks. Annual incidence of ALF in the US is estimated at approximately 2000 cases per year with an overall mortality rate of 80 %. Drug-induced (primarily acetaminophen), infectious, and autoimmune liver disease represent the majority of ALF cases. As was the case for our patient, Non-Hodgkin's Lymphoma (NHL) is an extremely rare presentation of ALF, with less than 40 cases reported in the literature. Most diagnoses are confirmed by liver biopsy, however, are often made postmortem. In order to prevent devastating outcomes, it is essential to recognize that hepatic involvement from NHL is usually asymptomatic and should be suspected if liver enlargement and alterations in liver biochemistries, mainly ALP and GGT, are present. One should further suspect hepatic involvement if symptoms such as malaise, weight loss, and fever are present. Early diagnosis and initiation of appropriate chemotherapy are vital for prognosis; even with rapid introduction of therapeutic options, ALF secondary to NHL carries with it a mortality rate of greater than 90 %. In conclusion, this entity should be included in the differential diagnosis when evaluating a patient with rapidly progressive encephalopathy, coagulopathy and liver function derangement. Even when a common etiology seems likely (i.e. drug-induced or viral hepatitis), a thorough understanding of the wide differential diagnosis for acute liver failure, could result in early recognition and treatment of the disease thereby preventing adverse outcomes.

ACUTE MYOPERICARDITIS AFTER TETANUS, DIPHTHERIA, AND PERTUSSIS VACCINATION IN A HEALTHY ADULT Adrienne L. Clark¹; Laleh Boroujerdi-Rad². ¹University of California, Los Angeles, Los Angeles, CA; ²University of California, Irvine, Orange, CA. (*Tracking ID #1919044*)

LEARNING OBJECTIVE 1: Recognize that myopericarditis may rarely be observed after immunization

LEARNING OBJECTIVE 2: Weigh risks and benefits of invasive procedures such as cardiac angiography, particularly if alternatives are available

CASE: A previously healthy 28-year-old man presented with 1 day of sudden onset severe substernal chest pain, not associated with inspiration and improved by leaning forward. Three days prior he had received a single intramuscular tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis vaccine, and 2 days prior developed tactile fevers and myalgias. Vital signs and clinical exam were normal. He denied sick contacts, any history of vaccine reactions, or any cardiac risk factors apart from a 10-pack-year tobacco history. EKG showed diffuse upsloping ST segment elevations. Laboratory studies revealed WBC 13.3/mm³, troponin 9.1 ng/mL, creatinine kinase 372 IU/L, and C-reactive protein 79.3 mg/L. Two-dimensional echocardiography showed normal left ventricle size and function and no effusion. His symptoms were thought consistent with pericarditis and he was started on high dose aspirin and colchicine. Overnight he was febrile to 38.1°C, his troponin uptrended to 30.5 ng/mL, and his chest pain persisted. Cardiac catheterization showed normal coronary arteries. Several hours later he developed worsening chest pain and new, marked ST elevations in leads I, AVL, and V1-V6. Repeat angiography showed a newly dissected and occluded LAD, which was stented with restoration of TIMI 3 flow. He was discharged with an ejection fraction of 45 % on colchicine, clopidogrel, and aspirin. An infectious workup including Coxsackie B, echovirus, and adenovirus was ultimately negative, as were antinuclear antibody and rheumatoid factor. He re-presented several times over the next few months with atypical chest pain but normal cardiac enzymes and CRP. He underwent an exercise treadmill test-myoview and was able to exercise 10 min without EKG changes. Nuclear imaging showed a medium-to-large partially reversible perfusion defect in the apex and anteroseptal wall, but repeat catheterization showed a patent LAD stent and distal vasospasm. He was treated for vasospasm with isosorbide mononitrate and diltiazem.

DISCUSSION: Most U.S. cases of myopericarditis result from viral infection, although other pathogens, drugs, hypersensitivity, and autoimmune disorders are occasionally implicated. Cardiovascular complications due to vaccination are rare. Only two case reports of myopericarditis after Tdap vaccination exist, and of 20 million doses distributed from 2005 to 2007, three cases were reported in the U.S. postlicensure safety surveillance. While it is impossible to definitely exclude a viral etiology for this case, negative viral serologies and absence of symptoms prior to vaccination make it less likely. While early post-vaccination prodrome favors a hypersensitivity reaction, hypersensitivity myocarditis is usually a retrospective, circumstantial diagnosis. The diagnostic accuracy of endomyocardial biopsy remains poor and was not indicated. Coronary angiography may be performed if there is significant uncertainty as to whether the clinical picture reflects acute coronary syndrome versus myopericarditis. Cardiac MRI has been shown to be a highly sensitive (76 %) and specific (96 %) alternative for myocarditis detection and differentiation from infarction. However, it is not available in many resource-limited settings, including the county hospital to which this patient presented.

ACUTE NECROTIZING PANCREATITIS: ATYPICAL MANIFESTATION AND MANAGEMENT Atena Lodhi; Sanghee Hong. Medical College of Wisconsin, Milwaukee, WI. (*Tracking ID #1916249*)

LEARNING OBJECTIVE 1: Identify presentations of severe acute pancreatitis without correlating high prognostic score.

LEARNING OBJECTIVE 2: Assess appropriate time and methods for nutritional support to minimize complications of acute pancreatitis.

CASE: A previously healthy 30-year-old male presented after a visit to outside hospital's ED for a 3-day history of persistent abdominal pain and nausea. It was a constant, colicky pain located in the epigastrum and radiated to the back. At outside ED, he had elevated lipase (>3,000 U/L), leukocytosis (19,400 cells/mm³), and elevated serum glucose (141 mg/dL) but otherwise patient was afebrile and had unremarkable lab results. CT from outside ED showed findings of acute pancreatitis with peripancreatic free fluid. When patient presented to our ED, his lipase and glucose decreased but leukocytosis (23,500 cells/mm³) had worsened. His abdomen was non-distended but diffusely tender, predominately in the epigastric area. Social history was negative for extensive smoking or drinking history and extensive work up ruled out autoimmune, obstructive, malignant, hyperlipidemia-induced, or trauma-induced pancreatitis. Four days after admission,

repeat CT was done when patient was tolerating a clear liquid diet and pain. It showed necrosis involving pancreatic head, neck, and proximal body. He was placed NPO and had two failed attempts of feeding through nasal-jejunal tube over 3 weeks. Four weeks after admission, patient had direct hyperbilirubinemia and subsequent CT showed an enlarging pseudocyst with dilated common bile duct, narrowing extrahepatic portal vein, and subhepatic inferior vena cava. Interventional gastroenterology was consulted for urgent drainage. Patient underwent endoscopic ultrasound guided cystogastrostomy with two double pigtail stents placement. The patient's condition has improved markedly over next several days with resolution of signs of biliary obstruction.

DISCUSSION: Even with low prognostic score (<3 Ranson's criteria and <8 APACHE II scale), acute pancreatitis may have high risk of developing complications. Although supportive medical management for all levels of pancreatitis shares a goal of maintaining adequate perfusion and prevention of infection, patients should be monitored closely for complications with CT severity index regarding extrapancreatic fluid collection and extent of pancreatic involvement. There is a controversy in management of sterile pancreatic necrosis. However, as complicating sepsis from necrosis accounts for more than 80 % of acute pancreatitis-related deaths, repeat imaging and frequent clinical exam, especially in the first 3 weeks to evaluate for endoscopic or surgical intervention was reasonable. Nutrition is another important component in management of patients with pancreatitis. Enteral feeding was shown to reduce mortality, infection, and hospital stay compared to parenteral feeding. About 20 % of pain relapse was reported with oral re-feeding and jejunal feeding was shown to reduce the risk. However, this case presented with worsening symptoms at jejunal feeding. It is likely from extent of enlarging pseudocyst already compressing on intra-abdominal cavities. This was a patient case with atypical presentation of severe acute pancreatitis and severe complications including necrosis and pseudocyst formation without spontaneous resolution. It is important to be familiar with this common condition with highly variable manifestation to ensure best clinical outcome.

ACUTE NEUROLOGICAL MANIFESTATIONS OF ATYPICAL TRAMADOL WITHDRAWAL Pranathi Sundaragiri¹; Saraschandra Vallabhajosyula¹; Sakshi Malhotra^{2,1}. ¹Alegent-Creighton University Medical Center, Omaha, NE; ²Vetsans Affairs Medical Center, Omaha, NE. (*Tracking ID #1928252*)

LEARNING OBJECTIVE 1: Recognizing lesser known contributors of altered mental status in substance abuse

LEARNING OBJECTIVE 2: Understanding addiction potential and neurological manifestations of tramadol withdrawal

CASE: Introduction: Tramadol is an analgesic medication that acts as a typical Mu-opioid receptor agonist with some non-analgesic activity mediated via serotonin and norepinephrine reuptake inhibition (SNRI) 1. With a low potency at Mu-receptors (1/10th affinity of Morphine) 2 it has been reported to have typical withdrawal symptoms on discontinuation due to its opioid-like action, despite being chemically unrelated to the opioids 1-3. Atypical withdrawal symptoms predominantly involving the central nervous system (CNS), as presented in this case, have been infrequently reported in literature 1. Case Report: A 71-year-old African-American female with past history of chronic kidney disease, osteoarthritis and hypertension presented with new onset altered mental status (AMS) and reduced verbal output of one-day duration. Review of systems was positive for diffuse myalgia, malaise and history of non-compliance with home medications since 1 week. Patient's family reported that she took about 30 tramadol tablets the day prior for arthralgia. Neurological examination was significant for miosis (pupillary diameter 2 mm) and lower extremity proximal weakness with normal reflexes. Laboratory parameters were significant for mild leukocytosis and negative urine toxicology screen. She was empirically started on broad-spectrum antimicrobial therapy for suspicion of meningoencephalitis. Cerebro-spinal fluid (CSF) revealed mildly elevated protein and no infective etiology. Patient continued to be disoriented, with visual and auditory hallucinations. In addition, paranoia with delusions of persecution was noted. Magnetic resonance imaging was unremarkable for any acute pathology and antimicrobial therapy was de-escalated. Patient's AMS gradually resolved with a short course of risperidol with subsequent normal mood and affect. The AMS was believed to be secondary to her acute tramadol ingestion with atypical withdrawal symptoms. Patient was cautioned against self-management of her medications and remained asymptomatic at six-month follow-up. **DISCUSSION:** Tramadol has been popular with clinicians for analgesic use due to its non-scheduled nature, lack of 'opiophobia' and relative lack of side-effects 4. It has, however, documented physical and psychological effects, with dose-dependent addiction potential and typical withdrawal symptoms similar to opiates 1-4. It has been linked extensively to seizure disorder and general disorganization on EEG 5,6. Atypical tramadol withdrawal noted in 1 of 8 cases of tramadol withdrawal, manifests as anxiety, panic attacks, delusions, confusion and paresthesia. Tramadol is hypothesized to exert its atypical features via the SNRI action, though this remains unproven. It does not have any age or gender predilection, but is however typically

associated with a dose range of 50–1300 mg/day¹. Acute high-dose tramadol use (as noted in our patient) or sudden decrease in tramadol use has been associated with atypical withdrawal^{3,7}. There are no established guidelines on management. Various regimens proposed include methadone, low-dose benzodiazepines and reinitiating low-dose tramadol^{1,3,7}. Gradual taper of tramadol has been recommended, but however further randomized controlled trials are required to establish standardized treatment protocols. References: 1. ACUTE ONSET MUSCLE WEAKNESS AFTER EATING FIVE BOWLS OF FROSTED CEREAL Christine N. Salvaggio; David I. Rotstein; Matthew T. Czaja; Sarang Kim. Rutgers-Robert Wood Johnson Medical School, New Brunswick, NJ. (*Tracking ID #1931474*)

LEARNING OBJECTIVE 1: Review the differential diagnosis and treatment of a patient presenting with acute muscle weakness and hypokalemia.

CASE: A 23-year-old man presents with acute onset appendicular muscle weakness after consuming five bowls of frosted cereal on the morning of admission. He had noted mild, progressive muscle weakness involving his lower and upper extremities for the past 6 weeks, as well as tremor, palpitations, diaphoresis, nausea, diarrhea and a 10-lb weight loss. The patient denies trauma, neck or back pain, numbness, bowel or bladder incontinence, dysphagia, or shortness of breath. He denies exposure to iodine or radiocontrast agents. He also denies family history of autoimmune diseases. On physical exam, his temperature is 97.4, blood pressure 134/52 mmHg, pulse 135, and respiratory rate 22 per minute. Cardiac exam reveals a tachycardic, irregularly irregular rhythm. Muscle strength is 3/5 in proximal muscle groups bilaterally, and 4/5 in the distal muscle groups bilaterally in both his upper and lower extremities. Deep tendon reflexes are 1+ and symmetric in the patella, Achilles and brachioradialis. Exam is negative for lid lag, proptosis, thyromegaly, nodules, or thyroid bruit. The remainder of the exam is unremarkable. Laboratory investigation demonstrates a potassium level of 1.4 mEq/L. High sensitivity TSH is <0.01 mIU/L (normal range 0.35–5.50), and free T4 is 3.39 ng/dL (normal range 0.9–1.8). EKG reveals atrial flutter and a prolonged QT interval. Treatment was initiated with IV potassium and oral propranolol. Overnight, the patient's weakness completely resolved. Thyroid ultrasound, TFTs and positive thyroid stimulating immunoglobulin confirmed the diagnosis of Thyrotoxic Hypokalemic Periodic Paralysis (HPP) in the setting of Graves' disease.

DISCUSSION: Thyrotoxic HPP is a rare neuromuscular disorder related to a defect in muscle ion channels that occurs in association with hyperthyroidism. This case illustrates the importance of considering thyrotoxic HPP in a patient with acute paralysis and hypokalemia. The differential diagnosis of sudden tetraparesis includes Guillain-Barré syndrome, multiple sclerosis, myasthenia gravis and spinal cord trauma, ischemia, inflammation or tumor. Distinguishing characteristics of thyrotoxic HPP are thyrotoxicosis and hypokalemia. Thyrotoxic HPP predominantly occurs in Asian males in the third decade of life. Patients present with acute muscle weakness, commonly in the shoulders and hips. Deep tendon reflexes may be decreased, but ocular, bulbar, and respiratory muscles are usually spared. In these patients, elevated levels of thyroid hormone, exercise, alcohol consumption or high carbohydrate meals can increase the Na⁺/K⁺ pump activity on skeletal muscle cell membranes, driving potassium into cells and leading to a hypokalemia. Recognition of this syndrome is critical to the institution of appropriate therapy. Acute treatment involves potassium administration, which can hasten recovery and prevent life-threatening hypokalemic-related arrhythmias. While evidence-based guidelines do not exist, experts recommend KCl 10–20 mEq every 2 h. Potassium levels should be monitored during replacement, as rebound hyperkalemia has been seen in at least 40 % of patients. Non-selective β-blockers such as propranolol can diminish hyperadrenergic activity and the Na⁺/K⁺ ATPase dependent K⁺ cellular influx, which have been implicated in the pathogenesis of the disease. Additionally, patients with thyrotoxic HPP merit a thorough evaluation to determine the etiology of their hyperthyroidism. Only

definitive treatment of thyrotoxicosis will prevent further occurrences of HPP. Our patient was diagnosed with Graves' disease and treated with methimazole with plan for radioactive iodine ablation in the future.

ACUTE PANCREATITIS AS INITIAL PRESENTATION OF COCAINE-INDUCED VASCULITIS Ayorinde Ogunbameru; Mohammed Badr Jandali; Amer Issa; Waleed Quwatli; Timothy Woodlock; Wajid M. Choudhry. Unity Health System, Rochester, NY. (*Tracking ID #1934655*)

LEARNING OBJECTIVE 1: Recognize Acute Pancreatitis as an atypical and rare systemic manifestation of Cocaine-induced ANCA negative necrotizing immune glomerulonephritis

CASE: A 22 years old male with no past medical history, presented with a 2 day history of mid abdominal pain radiating to the chest with Shortness of breath. Patient was sent to the Emergency room for a Chest CT after routine lab test at Urgent care showed elevated D-Dimer. Patient denied any fever, chills, recent travel or history of thromboembolic disease. Patient was adopted and does not know his family history. BP was 139/74, HR 67/min, RR 18, O₂ sat 98 % on room air. Clinical examination showed mild epigastric tenderness, otherwise unremarkable. Chest CT was negative for Pulmonary Embolism but showed some stranding at the tail of the pancreas suspicious for Acute Pancreatitis. Labs showed WBC 14.4/mm³, elevated Lipase (754), Cr(0.79), ESR(1), CRP(0.08), ALT(23), AST(71), ALP(139), GGTP(209). Patient was kept NPO, Intravenous normal saline and IV Dilaudid were commenced. Patient admitted to drinking ½ L of whiskey daily. Right Upper Quadrant Ultrasound did not show any evidence of gallstones but revealed fatty liver. Lipid panel and Triglycerides were normal. A urine toxicology screen was positive for cocaine and marijuana. Ethanol level was normal. On day #2/3 of admission, patient was noticed to have elevated Creatinine (3.71) with baseline (0.59) and thrombocytopenia (59) with baseline (159). SC Heparin was stopped. Patient subsequently became oliguric with a Urine output of (200 cm³ in 24 h) despite adequate fluid hydration (8 L). Renal Ultrasound did not show any hydronephrosis or stones. GI, Nephrology and Hematology were consulted. Follow up MRCP done showed heterogeneous pancreas suggesting inflammation. Patient was thought to have an atypical form of pancreatitis. IGG-4 test done to rule out auto-immune pancreatitis was negative. Patient's labs showed thrombocytopenia, severe anemia, negative Platelet Factor-4, elevated direct bilirubin, low Haptoglobin, high LDH, elevated D-Dimer and positive FDPs. Schistocytes were seen on blood microscopy. Differentials of HUS/TTP or DIC were entertained but the definite diagnosis was still inconclusive. ADAMS-13 level was negative. Patient eventually became anuric and developed azotemia. A diagnosis of Acute Renal Failure with a likely vasculitic process was made. Urinalysis showed muddy brown casts, proteinuria and WBCs. FENA was 3.57. Work up for glomerulonephritis showed HIV, Hepatitis, ANCA, ANA, Anti-glomerular, Anti-cardiolipin, Scleroderma, Complement C3/C4 tests were negative. Hemodialysis was initiated. Kidney biopsy was done and revealed pauci-immune necrotizing glomerulonephritis with features of glomerular thrombotic microangiopathy. Patient was commenced on High dose IV Solumedrol and Rituximab. He was transfused with a total 9 units of Packed Red Blood Cells and he had 9 sessions of Plasmapheresis. Patient's renal function and hematological indices improved and he was discharged in stable clinical condition.

DISCUSSION: My patient had an ANCA negative pauci-immune necrotizing glomerulonephritis (thought to be induced by cocaine) which initially presented as acute pancreatitis which is atypical and rare, making the diagnostic process challenging. Pauci-immune necrotizing glomerulonephritis is the most frequent cause of rapidly progressive glomerulonephritis and in 60 % of cases; it is associated with positive anti-neutrophil cytoplasmic antibodies (ANCA). It is either the renal manifestation of Wegener's Granulomatosis, microscopic polyangiitis, Churg-Strauss syndrome, or a renal-limited vasculitis. Few case reports cite Wegener's Granulomatosis affecting the gastrointestinal system with an initial presentation of pancreatitis which may be rapidly progressive and fatal. Vasculitic disease of the pancreas, even though rare, should be considered when other causes of pancreatitis have been excluded. References: 1. Mohammed Abu-Hilal et al., Acute Pancreatitis as First Presentation of Wegener's Granulomatosis. Case Report, *JOP. J Pancreas* 2008; 9(3):300–304. 2. Saurabh Chawla et al., Acute Pancreatitis as a rare initial manifestation of Wegener's Granulomatosis. A case based literature review, *JOP. J Pancreas* 2011 Mar 9; 12(2):167–169.

ACUTE RENAL FAILURE ASSOCIATED WITH MASSIVE HEMATURIA IN IGA NEPHROPATHY Asad Jehangir; Leena Jalota; Manoj Singla. Reading Health System, West Reading, PA. (*Tracking ID #1928679*)

LEARNING OBJECTIVE 1: Recognize IgA Nephropathy (IGAN) as a potential cause of acute kidney injury (AKI); either by crescentic IgA nephropathy or massive hematuria leading to tubular obstruction by red cell casts.

CASE: A 45 year old male with multiple co-morbidities recently discharged after being treated for stroke and urethral stricture with normal renal functions (BUN 25 mg/dL, creatinine 1.5 mg/dL) presented within few weeks with gross hematuria and decreased urine output. Initial labs revealed a creatinine of 10.96 mg/dL and a BUN of 76 mg/dL. Bladder scan showed no evidence of urinary retention. Additional work up including ANA, anti-streptolysin O, blood and urine cultures, anti IGM antibodies, urinary eosinophils were negative. Renal ultrasound showed normal sized kidneys. Renal artery duplex suggested less than 60 % stenosis of right renal artery. Cystoscopy showed no evidence of obstruction. Subsequent renal biopsy showed ATN and IgA nephropathy. ACE inhibitor was discontinued and patient improved with initiation of temporary dialysis. Creatinine prior to discharge was 2 mg/dL.

DISCUSSION: IgA nephropathy is a relatively common but underdiagnosed disease as most cases have transient gross hematuria following upper respiratory infection. Others have persistent microhematuria and mild proteinuria associated with a benign course and uncommonly patients can have marked proteinuria. Rarely patients may present with AKI that requires dialysis, prolonged glucocorticoid and ACE inhibitor therapy. This report emphasizes the importance of recognizing that IgAN as a cause of AKI that may require dialysis. Furthermore, severe acute tubular necrosis may occur in IgAN and may be related to heavy glomerular bleeding.

ACUTE THORACIC CORD COMPRESSION DUE TO HIV-ASSOCIATED BURKITT'S LYMPHOMA Kristen Lee; Ameeta Kalokhe; Schuyler D. Livingston. Emory University School of Medicine, Atlanta, GA. (*Tracking ID #1939108*)

LEARNING OBJECTIVE 1: Recognize the high risk of non-Hodgkin's lymphoma in a patient with HIV/AIDS.

LEARNING OBJECTIVE 2: Describe potential serious causes of back pain in a patient with HIV/AIDS.

CASE: A 46 year-old African-American man with HIV, a CD4 count of 274/mcL and a viral load of 200 copies/mL, on combination antiretroviral therapy (cART), presented with 1 month of progressive mid-to-low back pain without fevers or night sweats. He had no neurological deficits and was discharged with a diagnosis of musculoskeletal back pain. One week later, he developed lower extremity weakness and numbness. Physical exam demonstrated decreased lower extremity strength, loss of sensation to light touch, proprioception, and pain below the umbilicus, patellar tendon hyperreflexia, bilateral ankle clonus, and decreased rectal sensation. Spine MRI showed extradural soft tissue masses at the T3-T4 and T10-T11 levels with neural foraminal and paraspinal spread with severe canal stenosis at the T3-T4 level suggestive of lymphoma. Intravenous dexamethasone was initiated, followed by emergent laminectomy and epidural mass resection. Pathological exam of the mass showed dense lymphocytic infiltrate. Flow cytometry revealed a monoclonal B-cell population, and FISH studies demonstrated expression of the c-myc oncogene with chromosomal translocation 8q24 consistent with Burkitt's lymphoma (BL). Epstein-Barr virus (EBV) was detected in serum by PCR. CT of the chest, abdomen, and pelvis were negative for lymphadenopathy. Brain MRI showed no parenchymal lesions. Bone marrow biopsy was negative for malignant cells. PET scan showed increased FDG activity within the right trochanter. Systemic and intrathecal chemotherapy were initiated.

DISCUSSION: Non-Hodgkin's lymphoma (NHL) is an AIDS defining malignancy that is 200–600 times more common in HIV-infected patients compared to the general population. High grade diffuse large B-cell or Burkitt-like lymphomas are more common in people living with HIV and are associated with EBV coinfection. The incidence of NHL has decreased in the cART era. A recent review of 61 cases of NHL in AIDS patients in France showed that the major risks for NHL included both longer and current exposures to a viral load above 500, and a CD4 below 200. Patients commonly present with "B" symptoms, and usual sites of involvement include bone marrow, lungs, abdomen, and CNS. Epidural spinal cord compression occurs in 0.1 to 6.5 % of NHL patients, either at the time of relapse or as the initial manifestation of NHL. Burkitt's lymphoma (BL) is a highly aggressive, mature B-cell NHL. Endemic variant BL occurs in African children, usually presenting with a mass at the jaw or neck, and is associated with EBV infection. Sporadic BL usually presents with an abdominal mass. Immunodeficiency-related BL is seen in AIDS patients and often involves the lymph nodes, bone marrow, and CNS. Few cases of spinal involvement in adults with BL have been reported in the literature. BL is associated with unique cytogenetic translocations involving the c-myc oncogene. This case demonstrates the potential seriousness of back pain in patients with HIV/AIDS. The differential diagnosis includes cancers that metastasize to bone, compression fracture from

osteoporosis, spinal epidural abscess, and NHL including BL. Clinicians should have a lower threshold for imaging HIV-infected patients with back pain when compared to the general population.

ACUTE URINARY RETENTION DUE TO SACRAL HERPES ZOSTER Maryam Mahmood; Anthony A. Donato. Reading Health System, Reading, PA. (*Tracking ID #1900837*)

LEARNING OBJECTIVE 1: Recognize uncommon causes of urinary retention

CASE: A 76-year-old woman with history of myasthenia gravis on chronic mycophenolate mofetil presented to the emergency department with a 2 day history of incomplete voiding, increasing urgency, and abdominal discomfort. Three days prior she had noted a painful unilateral vesicular rash over her right buttock diagnosed as zoster and treated with oral valacyclovir. On examination she was afebrile with stable vital signs. Abdominal examination revealed a tender bladder palpable at the level of the umbilicus, as well as was a unilateral erythematous, vesicular rash on the right buttock in the distribution of S1-S2 dermatomes. Polymerase chain reaction culture of an affected vesicle confirmed herpes zoster virus. Urinalysis was remarkable for pyuria and microscopic hematuria with negative urine culture. Renal ultrasound revealed no structural abnormalities. Postvoid bladder scanning confirmed significant unvoided urine. Foley catheterization was performed and 700 mL of urine was obtained. The patient was diagnosed with acute urinary retention secondary to zoster and discharged home with a Foley catheter with re-evaluation by Urology in 1 week.

DISCUSSION: Varicella zoster is a neurotropic virus that recurs in nearly a third of all adults, presenting as a painful unilateral vesicular rash that may result in post-herpetic pain syndromes. Less commonly the autonomic nervous system or viscera can be involved with associated morbidity. Herpes zoster associated voiding dysfunction is rare and typically occurs with lumbosacral involvement. The main clinical manifestations include cystitis, neuritis-associated retention and myelitis related overflow incontinence. Acute urinary retention associated with zoster is related to sacral reactivation causing Detrusor muscle atony. It is often accompanied by severe constipation and may persist for 2 to 6 weeks. It should be considered as a cause of acute urinary retention in patients with unilateral sacral dermatomal pain syndromes, with or without vesicular rash, as neurologic dysfunction can precede skin outbreaks.

ADDRESSING DRESSLER'S SYNDROME Ewa M. Rakowski. Montefiore Hospital, Bronx, NY. (*Tracking ID #1937679*)

LEARNING OBJECTIVE 1: Identify the etiologies of post myocardial infarction pericardial effusions

LEARNING OBJECTIVE 2: Recognize the diagnosis, pathophysiology and management of post myocardial infarction syndrome (Dressler's syndrome)

CASE: A 71 year old man with history of uncontrolled diabetes and hypertension presented with 1 week of intermittent severe chest pain. Physical exam was unremarkable. Electrocardiogram revealed ST elevations in the inferior leads and concomitant Q waves. Cardiac catheterization revealed extensive three vessel disease including 100 % occluded right coronary artery with collateral vessels. Initial troponins were elevated. Overall presentation was consistent with delayed presentation of ST elevation myocardial infarction (STEMI) with multi-vessel disease not amenable to stenting. Echocardiogram showed normal ejection fraction, wall motion, right ventricular dilation and small pericardial effusion. Patient had a complicated medical course requiring intensive care. Two weeks later when acute issues were resolved work up for coronary artery bypass graft surgery was initiated. Repeat echocardiogram revealed a new large pericardial effusion with early tamponade physiology and an area of the ascending aorta concerning for hematoma. MRA chest confirmed pericardial effusion and revealed bilateral pleural effusions but excluded aneurysm and hematoma. CT surgery performed pericardial window with 300 cm³ of serosanguinous fluid drained. Pericardial fluid cytology was positive for extensive inflammation. In combination with clinical history and time course this was consistent with diagnosis of post myocardial infarction syndrome (PMIS). The patient was started on colchicine and recovered well.

DISCUSSION: With the advent of fibrinolytic therapy and cardiac catheterization the 30 day mortality of STEMI's has decreased from 15 % to those medically managed to 3–5 % for those receiving optimal reperfusion therapy. Likewise there has been a significant decrease in post-myocardial infarction complications including pericardial complications such as early infarct-associated pericarditis and post myocardial infarction syndrome. Pericardial effusion is a common early complication of transmural myocardial infarction and is detected by echocardiography in one third of patients by day three post infarct. Half of these patients do not have a pericardial

friction rub. These pericardial effusions are often irritative or due to hydropericardium or hemopericardium. Irritative effusions are usually small and result from increased vascular permeability. Hydropericardium should be considered in large Q wave infarcts that present with clinical heart failure. Hemopericardium can occur from spontaneous hemorrhage or secondary to thrombolytic and antithrombotic therapy or most fatally from myocardial wall rupture. The latter should be considered for any post myocardial infarct patient with persistent pericardial rub and drop in hematocrit. Finally, PMIS should be considered in patients who present with delayed pericardial effusion post acute or subacute infarct whether or not they have symptoms and especially if there are pleural effusions and infiltrates in absence of heart failure. PMIS, also known as Dressler's syndrome occurs 1 week to several months post myocardial infarction. Clinically it presents with pericardial friction rub, malaise fever and leukocytosis. Half of patients will have a pericardial effusion which can be serous or hemorrhagic. Chest x-ray often shows pleural effusions and infiltrates. Historically PMIS had an incidence of up to 5 % post-STEMI and occurred more often in larger infarctions, specifically those anterior or inferior infarctions and in those with complicated hospital courses. With the advent of early re-perfusion therapy leading to decreased size of infarction this diagnosis has become less common. The pathogenesis behind PMIS is that myocardial necrosis releases cardiac antigens which stimulate antibody formation. An inflammatory response occurs from immune complex deposition in the pericardium, pleura and lungs. Therefore, a latent period of minimum 1 week is necessary for diagnosis and distinguishes PMIS from infarct-associated pericarditis which occurs immediately post-infarct. It is an important clinical distinction because PMIS is more likely to lead to larger effusions, life threatening tamponade, constrictive pericarditis and hemorrhage. With a diagnosis of PCIS the patient should be hospitalized and observed for cardiac tamponade. Non-steroidal anti-inflammatory drugs or colchicine are recommended however data is lacking. Given the increased propensity for bleeding, if anticoagulation therapy is strongly indicated the patient must be monitored closely. The presence of cardiac tamponade confers an increased 30 day mortality and requires urgent drainage. Symptoms of PCIS may recur but overall the prognosis is favorable.

ADULT ONSET STILL'S DISEASE Karen Y. Cheng¹; Baran Ho²; Victoria T. Liu¹; Helen Wang²; Pearl Yu²; Gregory Middleton³; Christina Le². IUCSD, San Diego, CA; ²University of California, San Diego, La Jolla, CA; ³University of California, San Diego, La Jolla, CA. (*Tracking ID #1923776*)

LEARNING OBJECTIVE 1: Recognize the clinical features of Adult Onset Still's Disease

LEARNING OBJECTIVE 2: Diagnose Adult Onset Still's disease

CASE: A 39 year-old woman presented with 2-months of throat discomfort and migratory joint pain of the hands, knees, and shoulders. Physical exam revealed a new onset holosystolic murmur and a mildly erythematous oropharynx. She had traveled to Hong Kong 8 months prior, but denied any unusual food exposures, arthropod bites, or sick contacts. One week later, the patient developed intermittent nocturnal fevers up to 39 °C and a transient urticarial rash over the trunk and extremities with dermatographism. Rheumatic fever was suspected due to the murmur and recent travel to Hong Kong during a known strep throat outbreak. Erythrocyte sedimentation rate (ESR) was elevated at 35 mm/h, but there was no evidence of infection on multiple blood cultures or serological examination for group A strep. The patient's symptoms resolved and remitted over the next 2 months. During this period, comprehensive infectious and rheumatologic workup was pursued and all tests came back negative. However, CT imaging of the chest showed mid-axillary lymphadenopathy. The patient was admitted for further workup, with an emphasis on evaluation for occult malignancy and endocarditis. During this hospitalization, she developed a new nonpruritic, light-colored erythematous maculopapular rash, and experienced inflammatory polyarthritis with quotidian fevers. Echocardiogram showed no valvular vegetations. CT showed interval enlargement of axillary lymph nodes, prompting biopsy, which showed reactive follicular hyperplasia without evidence of lymphoma. A diagnosis of adult onset Still's disease was made following the negative infectious and neoplastic workup and the patient was started on prednisone 40 mg daily with significant improvement.

DISCUSSION: Adult onset still's disease (AOSD) is a rare condition that often presents as fever of unknown origin (FUO). Classic AOSD is characterized by high spiking fevers, arthralgias, and nonpruritic salmon colored rash. This case illustrates an atypical, indolent course of AOSD punctuated by periods of improvement. Diagnosis is clinical and requires exclusion of infectious, neoplastic, and other rheumatologic disorders. A hallmark diagnostic feature of AOSD is a nonpruritic, maculopapular, salmon-colored rash. Atypical rashes have been described, but are rare. Diagnosis can be made using the Yamaguchi criteria, which has a 92.1 % specificity for AOSD if five criteria are satisfied. After admission, this patient satisfied three major criteria (fever, arthralgia, typical rash), as well as four minor criteria (sore throat, lymphadenopathy, liver dysfunction, and absence

of rheumatoid factor and antinuclear antibody). A comprehensive workup was performed to rule out neoplastic and infectious etiologies of FUO.

ADULT ONSET UREA CYCLE DISORDER IN THE SETTING OF GASTRIC BYPASS SURGERY Michelle Kromas; Omar Mousa. SUNY Upstate Medical University, Syracuse, NY. (*Tracking ID #1939278*)

LEARNING OBJECTIVE 1: Recognize a rare and potentially fatal complication of bariatric surgery

LEARNING OBJECTIVE 2: Diagnose and manage adult onset urea cycle disorders

CASE: We present a case of a 56-year-old male who developed altered mental status soon after Roux-en-y gastric bypass surgery (GBS). He presented initially to his PCP with intermittent neurological manifestations including confusion, tremors, inappropriate emotional responses, and ataxia. Multiple referrals left him with a diagnosis of Parkinson's disease, for which he was prescribed Sinemet, with no improvement. He presented to our emergency department with symptom progression. Physical exam was significant for tremors, inability to concentrate, and memory impairment. He denied history of substance use or toxin exposure. Laboratory investigations including BMP, CBC, iron panel, hepatic function panel, carnitine level, zinc, manganese, Vitamin B12, Vitamin A, and Vitamin D levels which were unremarkable. Abdominal ultrasound and well as brain MRI were also non-revealing. Of significance was an ammonia level of 155mcg/dL. This finding spurred further workup significant for elevated urine orotic acid, consistent with a urea cycle disorder. Conservative management with low protein diet, lactulose and supportive care were initiated with improvement in the patient's symptoms.

DISCUSSION: In the United States, 40 % of adults aged 20 years and over are obese prompting 200,000 bariatric surgeries annually. Hyperammonemia encephalopathy as a complication of gastric bypass surgery is very uncommon, especially when the etiology is adult onset urea cycle disorder. This rare non-specific neurologic presentation, in the absence of overt liver disease, presents a true diagnostic challenge. This may delay diagnosis and treatment, causing increased morbidity and mortality. Urea cycle disorders result from a deficiency in hepatic enzymes involved in the conversion of ammonia to urea thus impeding nitrogen disposal. Classically, these deficiencies become apparent in the neonatal period with failure to thrive and neurologic manifestations. However, a continuously growing body of literature has identified cases of disease manifesting in adulthood, likely secondary to a partial enzyme deficiency or a mutated enzyme that becomes apparent in the presence of an inciting stressor. Diagnostic tools include blood ammonia, plasma amino acids and urine organic acids as well as DNA or enzymatic testing. We indicate the importance of raising awareness among internists of this possible complication of gastric bypass surgery. Very few reports have described Post-GBS encephalopathy as a result of secondary nutrient deficiencies or unmasked urea cycle disorders. An early diagnosis may prevent associated complications by incorporating a simple and inexpensive intervention, dietary modification with protein restriction. Patient education about such potential complications can also reduce post-operative dissatisfaction. A high index of suspicion for unmasked urea cycle disorders post GBS can prevent the debilitating consequences of unrecognized and untreated disease and improve outcomes.

AGGRESSIVE ARTHRALGIA: A CASE OF GRANULOMATOSIS WITH POLYANGIITIS Claiborne Childs. NYH-WCMC, New York, NY. (*Tracking ID #1939157*)

LEARNING OBJECTIVE 1: Describe an accelerated clinical presentation of an uncommon clinical condition and highlight its musculoskeletal manifestations.

LEARNING OBJECTIVE 2: Review the latest diagnostic criteria for Granulomatosis with Polyangiitis (GPA, formerly known as Wegener's Granulomatosis)

CASE: A previously healthy 63-year-old woman presents to her PMD with a chief complaint of diffuse joint pain (knees, feet, shoulders) and swelling in her legs and ankles, with associated weight gain over the course of the proceeding week. Her PMD prescribes a short course of NSAID for presumed joint inflammation due to overuse. She returns to clinic 4 days later with no improvement in symptoms. Basic labs (CMP, CBC) as well as ESR, ANA, RF, ASO, and Lyme titers, all resulted as normal. Physical exam at the time revealed 1+ bilateral pitting edema in her lower extremities and pain with palpation of affected joints. (bilateral ankles, wrists, knees) No erythema or swelling was noted. Remainder of exam including, HEENT, cardiovascular, pulmonary, and abdominal exam were normal. The patient was instructed to continue oral NSAIDs and given a prescription for oral furosemide. Her lower extremity edema and arthralgia briefly improved. Three weeks following initial presentation, the patient develops worsening dyspnea, new cough, worsening lower

extremity edema, and was noted by a family member to have decreased urinary frequency. The following day, she presents to the ED following an acute episode of cough and worsening dyspnea at rest. The patient was hypoxic to 80 % on room air. Labs in the ED were notable for: BUN (=128) and creatinine (=18.1, previous Cr=0.75), anemia (Hgb=6.7), and leukocytosis (WBC=14). Chest radiograph showed diffuse alveolar opacities. While in the ED, the patient developed worsening hypoxia and hemoptysis. She was emergently intubated and transferred to the medical intensive care unit. Labs subsequently revealed elevated ESR (=129), CRP (=19) and a positive serum cANCA/PR3. A renal biopsy revealed Pauci-immune, severe diffuse crescentic/necrotizing glomerulonephritis with significant tubular dysfunction consistent with an ANCA positive vasculitis. The patient was given high dose steroids, cyclophosphamide and underwent plasmapheresis. She was extubated and clinically improved prior to discharge from the hospital. She remains on hemodialysis due to lack of recovery of renal function.

DISCUSSION: The clinical presentation of GPA includes: ENT manifestations (sinusitis, nasal crusting, bloody or purulent discharge) which present in 90 % of patients, lung involvement is present in 87 % of patients, signs of glomerulonephritis present in 77–85 % of patients and musculoskeletal symptoms present in 65–75 % of patients. Multiple diagnostic criteria exist for GPA: American College of Rheumatology (ACR, 1990) criteria include: (1) nasal/oral inflammation (oral ulcers, bloody discharge, etc.), (2) abnormal CXR (infiltrates, cavities, nodules), (3) UA abnormalities (hematuria, casts) and (4) biopsy proven granulomatosis. The presence of two or more criteria is 88 % sensitive and 92 % specific for GPA. Chapel Hill Consensus Conference Criteria (CHCC, 1994) includes: (1) granulomatous inflammation of the respiratory tract, (2) necrotizing vasculitis, and (3) positive c-ANCA with proteinase 3 (PR3) specificity. The more recent European Medicine Agency Algorithm (2007) includes: (1) abnormal chest radiograph (infiltrates, nodules, etc.), (2) upper airway/nasal or oral inflammation (bloody discharge, ulceration, etc.), (3) glomerulonephritis (hematuria or casts) and (4) positive c-ANCA. The more recent European Medicine Agency's algorithm combines criteria of earlier ACR and CHCC criteria. Even though not in the diagnostic criteria, musculoskeletal symptoms are very common and may be the patient's presenting symptom. GPA may uncommonly be rapid and progressive, therefore early diagnosis and treatment may be both life saving and organ sparing.

AIDS SUGAR RUSH: DIABETIC KETOACIDOSIS IN A NEWLY DIAGNOSED AIDS PATIENT Felix H. Luu¹; Sara L. Swenson¹; Diana Antoniucci². ¹California Pacific Medical Center, San Francisco, CA; ²California Pacific Medical Center, San Francisco, CA. (*Tracking ID #1939735*)

LEARNING OBJECTIVE 1: Review the differential diagnosis and work up of hyperglycemia in an AIDS patient

LEARNING OBJECTIVE 2: Highlight a rare treatment complication of AIDS/HIV CASE: A 30 year-old Asian male recently diagnosed with AIDS and hepatitis C presents with generalized weakness for the past 2 weeks. Four weeks prior to admission, he was hospitalized for septic shock secondary to pneumocystis jirovecii pneumonia. He was discharged to a skilled nursing facility (SNF) to complete a 21-day course of IV pentamidine. In the hospital, his blood sugars were elevated (100 s), which were thought secondary to steroids received for his PJP infection. His steroids were stopped prior to SNF transfer. However, his blood sugars elevated to the 300 s during his SNF course and a hemoglobin A1C was 6.7 %. Approximately 2 weeks prior to admission, the patient noted a 10-pound weight loss, polyuria, polydipsia, and blurry vision. He denied fevers, chills, or recurrence of cough. Medications included prophylactic dapsone and HAART therapy with norvir, atazanavir, and epzicom, which had been started 2 months prior to his hospitalization. On exam, he was afebrile with dry mucous membranes. His blood glucose was 1584 mg/dL with a bicarbonate of 22 mmol/L, anion gap of 23, pH of 7.28 and pCO₂ of 46 mmHg. His urinalysis showed 3+ glucose and 1+ ketones, and a serum lipase was 512 U/L. A work-up for infection was unrevealing. A repeat hemoglobin A1C was 11.3 %. The patient was admitted to the ICU for aggressive hydration and insulin drip. Within 2 days, his blood glucose normalized, and subcutaneous insulin was started. We initially attributed his ketoacidosis and hyperglycemia to DKA from either new-onset type 1 diabetes mellitus (DM1) or diabetes secondary to HAART medications, so his HAART medications were held. However, his C-peptide level was low, and antibodies for GAD 65, IA2, and Insulin were negative. Given that his development of hyperglycemia coincided most closely with the initiation of pentamidine, we ultimately attributed his DKA and new-onset diabetes to pentamidine therapy. He was discharged with basal (glargine)

and bolus (lispro) insulin, and restarted on his HAART therapy. At 6 month follow up, he had no recurrence of his ketoacidosis.

DISCUSSION: We report a case of pentamidine-induced diabetic ketoacidosis in an AIDS patient. Although we initially considered a diagnosis of autoimmune type 1 diabetes, his low C-peptide level and lack of autoantibodies did not support this. Given his lack of prior documented insulin resistance or type 2 diabetes, we turned to medication-related causes of hyperglycemia. Initially, the patient's elevated blood glucose was thought to be secondary to steroids or HAART medications. Ritonavir and atazanavir have both been associated with the development of insulin resistance, hyperglycemia, and new-onset diabetes. However, his initiation of HAART therapy predated his hyperglycemia by 2 months. Moreover, he developed severe hyperglycemia only after starting pentamidine for PJP. Pancreatic dysfunction leading to hyperglycemia has been a rare side effect of pentamidine. Usually associated with hypoglycemia (6 %) and renal impairment (24 %), pentamidine has been linked less commonly to severe pancreatic toxicity and hyperglycemia, which would explain a low c-peptide level. Pentamidine, an aromatic diamidine, has been used in the treatment of PJP pneumonia in those allergic to sulfa medications and severe disease. Pentamidine may induce a direct cytolytic effect on pancreatic beta cells that initially leads to insulin release and hypoglycemia and, less commonly, eventual insulin deficiency and diabetes. Hyperglycemia during pentamidine therapy may be a predictor for the development of diabetes mellitus. This case emphasizes the potential for severe pancreatic toxicity leading to DKA in patients receiving IV pentamidine, especially in conjunction with other medications, such as protease inhibitors, that can affect glucose metabolism. As the AIDS population lives longer, we remain alert to the possibility that we may identify additional cases similar to this one.

ALL THAT GLITTERS ISN'T WISN Naomi Karlen; Melody Oncale. Tulane University Health Sciences Center, New Orleans, LA. (*Tracking ID #1925932*)

LEARNING OBJECTIVE 1: Recognize the presentation and treatment of Warfarin induced skin necrosis in the acute inpatient setting.

LEARNING OBJECTIVE 2: Discover an algorithm to diagnose purpura.

CASE: A 61 year-old woman presented with chief complaint of 6 days of bilateral gluteal pain. The pain was described as burning, tingling, and associated with a feeling of puffiness. It progressively worsened until she felt the need to seek emergent care. She has a medical history of coronary artery disease and recently was hospitalized due to acute myocardial infarction. Physical exam revealed stellate purpuric skin lesions without necrosis over bilateral hips and sacrum. Each was tender to palpation and associated with involuntary guarding. There was no associated warmth, erythema, or swelling. Laboratory studies revealed no thrombocytopenia, PT 27.5, PTT of 38.4 and INR of 2.6. During her recent hospitalization for myocardial infarction, she experienced sudden onset of left foot numbness and pain. This was thought to be secondary to atherosclerotic plaque embolization. She was enrolled in a double-blinded warfarin study with an unknown dosage, which was started 21 days prior to presentation. Warfarin was immediately stopped and punch biopsy of the purpuric lesion was performed. The painful lesions improved without active treatment following cessation of warfarin. The biopsy revealed purpura without thrombi or vasculitis.

DISCUSSION: Skin lesions are one of the most common complaints an internist will encounter. When approaching new purpuric skin lesions of unclear etiology, having an algorithmic approach is helpful. Laboratory evaluation should include platelet count and a coagulation panel and a thorough history with medication reconciliation is imperative in assisting the differential. In a patient with normal platelets and prolonged PT/PTT, the differential includes coagulation factor deficiency, von Willebrand's Disease, pharmacologic anticoagulation, and liver disease. The patient in this case was recently started on warfarin, and thus the initial differential should immediately include WISN. Although a rare complication, with 0.01–0.1 % prevalence, it can be life threatening if it goes unrecognized and untreated. WISN usually presents 3–6 days after starting warfarin therapy, but cases have been reported up to 3 years after starting therapy. WISN is more commonly associated with patients who are obese, middle-aged, female, and whose purpuric lesions appeared akin to early presentation of potentially necrotic lesions. Treatment is mainly supportive, with the goal to stop warfarin and reverse its effects with vitamin K and fresh frozen plasma. Consequences of lack of treatment include predisposition to sepsis and expansion of skin involvement. Despite not having biopsy-proven WISN, this patient experienced symptomatic relief and abatement of the lesions after withdrawal of the medication in addition to her laboratory studies being suggestive of WISN. In cases with an unclear diagnosis, the history may yield important clues. Internists must be thorough data gatherers and remember to consider medications as potential culprits.

In the case of WISN, timely withdrawal of the offending agent may prevent the progression to life-threatening necrosis.

ALL THAT LOOKS LIKE “BRUGADA” IS NOT “BRUGADA” - CASE SERIES OF BRUGADA PHENOCOPY CAUSED BY HYponATREMIA
Sourabh Aggarwal; Vishal Gupta, Western Michigan University School of Medicine, Kalamazoo, MI. (Tracking ID #1940315)

LEARNING OBJECTIVE 1: To understand Brugada phenocopy

LEARNING OBJECTIVE 2: To understand patho-physiology of Brugada phenocopy associated with hyponatremia

CASE: Brugada syndrome (BS), a life-threatening channelopathy associated with reduced inward sodium current due to dysfunctional sodium channels, is characterized by ST-segment elevation with downsloping “coved type” (type 1) or “saddle back” (type 2) pattern in V1-V3 precordial chest leads. Brugada phenocopy, a term describing conditions inducing Brugada-like pattern of electrocardiogram (EKG) manifestations in patients without true BS, is an emerging condition. We describe a case series of Brugada phenocopy with hyponatremia. A 63 year old lady, with history of diabetes mellitus, hypertension and schizoaffective disorder, on haloperidol, presented to ER with confusion and altered mental status. She was drinking up to 12 l water and 4-5 beer cans every day. Physical examination, including vitals, was unremarkable except for confusion and disorganized thought process. Initial labs were significant for hyponatremia (Na 112 mEq/L). EKG showed prolonged QTc (547 ms) and “coved type” ST elevations in leads V1-V3. Cardiac markers were within normal limits. Electrophysiological studies and left heart catheterization were unremarkable. Her haloperidol was held and water restriction initiated. Her sodium level improved gradually with serial EKGs showing resolution of ST elevations and QTc interval returning to normal. A 54 year old male, with history of hypertension, presented to ER complaining of lethargy, vomiting, anorexia and decreased fluid intake for 7 days. He denied any cardiovascular symptoms. Physical examination was unremarkable except for signs of dehydration. Initial labs revealed significant hyponatremia (Na 106 mEq/L) with EKG showing prolonged QTc (526 ms) and a “saddle back” type ST elevation in leads V2-V3. Telemetry did not show any evidence of arrhythmia. He was fluid resuscitated with gradual return of sodium level towards normal, and serial EKGs showing resolution of EKG findings with improving sodium level.

DISCUSSION: Brugada phenocopy associated with hyponatremia has been very rarely described. There have been very few isolated case reports. This, to the best of our knowledge, is first case series of Brugada phenocopy with hyponatremia. Sodium channel blockers are used to unmask and/or induce EKG-manifestations of BS in susceptible patients. Electro-physiologically, hyponatremia works similarly by decreasing electrochemical gradient and causing decreased inward current, leading to Brugada phenocopy. We believe that reduced trans-membrane gradient was responsible for Brugada phenocopy in our patient which was reversible and resolved with improvement in sodium levels and potentially trans-membrane gradient. Prognostic implications of these changes are unknown, however both our patients are doing fine till date. Management of these patients is supportive with intensive observation. Clinicians should be aware of the association of Brugada phenocopy with hyponatremia and be vigilant for diagnosis of true BS in case EKG findings fail to resolve with supportive management.

AMIODARONE INDUCED THYROTOXICOSIS: A DELAYED EFFECT
Suzanne J. Supplee; Shobhit Gupta; Shannon Schamel; Richard Alweis. Reading Health System, West Reading, PA. (Tracking ID #1939145)

LEARNING OBJECTIVE 1: Diagnose amiodarone induced thyrotoxicosis (AIT).

LEARNING OBJECTIVE 2: Recognize symptoms of amiodarone toxicity may manifest long after discontinuation of drug due to its long half life.

CASE: An 88-year-old male presented to clinic with a 1 month history of progressive dyspnea, lower extremity swelling, and weight loss. His past medical history included paroxysmal atrial fibrillation previously treated with amiodarone, which had been discontinued 7 months prior secondary to hepatotoxicity. Thyroid studies at the time of discontinuation were normal. Physical exam demonstrated weight loss, muscle wasting, intermittent tachycardia, and significant pedal edema. Laboratory studies revealed a suppressed TSH at 0.013 IU/ml, and an elevated free T4 at 3.4 ng/dL. A new goiter was noted on ultrasound and echocardiogram showed normal left ventricular function. Based on his constellation of symptoms and laboratory abnormalities, he was diagnosed with type 1, amiodarone induced thyrotoxicosis (AIT) and started on methimazole.

DISCUSSION: Amiodarone is a widely used anti-arrhythmic drug with a high iodine content that causes direct toxicity to the thyroid gland. Amiodarone induced thyrotoxicosis is associated with a three-fold increase in the rate of major adverse

cardiovascular events. Three to five percent of patients treated with amiodarone in the US develop AIT 3 months to 4 years after starting therapy. Its long half-life of 100 days causes continued effect on thyroid hormone production even months after the drug is discontinued making the diagnosis a challenge. Clinical manifestations of AIT include development of arrhythmias, heart failure, weight loss, restlessness and low grade fever. Treatment is aimed at restoring a euthyroid state by using thionamide drugs, radioiodine, surgery, or steroids. This case highlights the importance of recognizing AIT, even in cases where amiodarone is not on an active medication list. It is critical, as AIT is associated with life threatening ventricular arrhythmias if not treated appropriately.

AMYLOIDOSIS PRESENTING ALONG WITH PERIPANCREATIC CASEATING GRANULOMATOUS LYMPHADENITIS
Paulina Alcalan; Valentine M. Ebuh; Michael Sheffield; Carlos Taboada. Dallas Methodist Hospital, Dallas, TX. (Tracking ID #1939187)

LEARNING OBJECTIVE 1: Recognize the clinical features of amyloidosis.

LEARNING OBJECTIVE 2: Diagnosis of Amyloidosis when other diagnoses do not fit.

CASE: A 44 y.o. HF with depression presented with 5 to 6 months of intermittent abdominal pain, nausea, vomiting, and diarrhea. She had recently been evaluated at another facility and had an exploratory laparotomy which revealed peripancreatic lymphadenopathy. Biopsy then revealed peripancreatic caseating granulomatous lymphadenitis. Patient presented to our facility with weakness and syncopal episodes. Review of symptoms was positive for weakness, 60 lb. weight loss over 3 months, dizziness, dyspnea, cough with clear phlegm, nausea, vomiting, abdominal pain, diarrhea and syncopal episodes. She denied smoking, alcohol and drug use. Her home medicines included meclizine and Celexa. On physical exam her blood pressure was 76/45, pulse 82, temperature 98.8, oxygen saturation was 97 % on room air. Exam was essentially unremarkable except for a macular rash on the sole of her right foot. Pertinent labs on admission revealed WBC 7.7 and hemoglobin 9.4. Basic metabolic panel, liver function tests and urinalysis were normal. Abdominal CT scan with contrast revealed small bilateral pleural effusions, patchy atelectasis, 5 mm right middle lobe pulmonary nodule, mild ascites, hepatomegaly, splenomegaly and nodular densities along the parietal peritoneum on the right posterolaterally. She was hospitalized with refractory abdominal pain and weakness. With biopsy report showing peripancreatic caseating granulomatous lymphadenitis and pulmonary symptoms, there was originally a concern that patient had either a fungal or mycobacterial infection as the cause of her complaints. She was started on 4 drug therapy for presumed tuberculosis. Serologic tests including a Quantiferon gold test for TB, AFB smear and culture, HIV test, Urine histoplasma antigen, blastomyces antibody, brucella IgG and IgM, coccidioides antibody, and aspergillus antibody were all negative. Antinuclear antibody was normal and rapid plasma regain and treponema palladium were non-reactive. Lung biopsy and stomach/duodenum biopsies were done and revealed AL amyloidosis. Anti-mycobacterial therapy was discontinued and she was started on Velcade and dexamethasone.

DISCUSSION: Amyloidosis refers to extracellular tissue deposition of fibrils, which demonstrates characteristic apple-green birefringence when stained with Congo red and viewed under polarized light. In immunoglobulin light chain (AL) amyloidosis the fibrils are composed of fragments of monoclonal light chains. The incidence of AL amyloidosis is 6 to 10 cases per million, median age at diagnosis is 64 and it affects predominantly males. AL amyloidosis is a systemic disorder and can present with heart failure, nephrotic syndrome, peripheral neuropathy, and hepatomegaly. Presenting symptoms usually depend on the organs affected. Amyloidosis can involve virtually every organ in the body and should be considered in the differential diagnosis of obscure cases such as this one.

AN A (MASS) ING CASE OF LEUKOCYTOSIS
Jessica R. Howard-Anderson; Edward Ha. University of California, Los Angeles, Los Angeles, CA. (Tracking ID #1929441)

LEARNING OBJECTIVE 1: Distinguish and assess various causes of leukocytosis.

LEARNING OBJECTIVE 2: Recognize squamous cell carcinoma as a potential cause of extreme leukocytosis.

CASE: A 67-year-old female with a history of type 1 diabetes mellitus and a combined kidney and pancreas transplant 15 years ago (on immunosuppressive medications) presented to the hospital with 1 week of vomiting, diarrhea, fevers, and altered mental status. Further history revealed that she had a chronic wound in her right upper extremity that she had been debriding with scissors at home. On admission she had a temperature of 38.7 °C and was mildly tachycardic, but

normotensive with a normal respiratory rate and oxygenation saturation. A complete physical exam was remarkable for an open ulceration in her right upper extremity that was approximately 6 cm long × 4 cm wide × 2 cm deep without any drainage or evidence of active infection. Her white blood cell (WBC) count was $27 \times 10^3/\mu\text{L}$ with a neutrophilic predominance. A full infectious work up including cultures of cerebrospinal fluid, blood, urine, sputum and stool yielded a diagnosis of *Clostridium difficile* colitis. Cultures from her upper extremity wound initially grew coagulase negative staphylococcus, presumed to be a contaminant as there were no signs of infection on exam. A peripheral blood smear showed reactive granulocytosis. She was treated with oral vancomycin and intravenous metronidazole. Despite this treatment and an overall clinical improvement with normalization of her vital signs and resolution of her fevers, her leukocytosis continued to rapidly increase. Within 2 weeks her WBC count had increased to $78 \times 10^3/\mu\text{L}$. Concomitantly, her upper extremity wound had also rapidly grown in size. In 1 week it had progressed from an ulcer to a large exophytic mass, elevated approximately 3 cm above the skin. A biopsy of this mass revealed squamous cell carcinoma. A whole body PET-CT scan revealed no evidence of metastasis. A second culture of the mass 2 weeks after admission revealed vancomycin resistant enterococcus; treatment with daptomycin was initiated. Two days later there was still no significant change in her WBC count. At that time, approximately 16 days after admission, she was taken to the operating room for excision of the mass. Immediately after excision of the mass, her WBC count decreased from $69 \times 10^3/\mu\text{L}$ to $36 \times 10^3/\mu\text{L}$, without other intervention. Over the next 6 days her WBC count continued to decrease to $8 \times 10^3/\mu\text{L}$ and stayed in this range until discharge 1 week later.

DISCUSSION: This is an interesting case of extreme leukocytosis that persisted despite antibiotics. Leukemoid reactions are likely to be identified initially by general internists and so it is imperative to understand the common causes of extreme leukocytosis and initiate an appropriate diagnostic work-up. A complete WBC count and differential should be obtained along with a peripheral blood smear to identify the predominant cell type and any immature cells, blasts or atypical cells. Our patient had a neutrophilic leukocytosis, which is commonly associated with infections, states of stress (including emotional stimuli, exercise, pain, surgery or extreme temperatures), trauma, cigarette smoking, medications and reactions to non-hematologic malignancies. Myeloproliferative disorders such as polycythemia vera, chronic myelogenous leukemia, and chronic neutrophilic leukemia should be considered if there is no clear cause of neutrophilia. If myeloproliferative disorders are suspected, a specialist in hematology/oncology should be consulted to identify potential clonal cells and cytogenetic abnormalities. In this case our patient's extreme and persistent elevation in WBC count despite appropriate antibiotics or inciting stressor suggested that her leukocytosis was most likely due to her squamous cell carcinoma. Her leukocytosis rapidly improved after surgical excision of the mass, further supporting this hypothesis. There have been other case reports in the literature documenting similar leukemoid reactions in patients with head and neck, lung, esophageal, gastric, bladder, gynecological, and cutaneous squamous cell carcinomas that improve with treatment of the malignancy. It has been hypothesized that this leukocytosis in squamous cell carcinomas is due to tumor production of granulocyte colony stimulating factor (G-CSF). Most reports of leukocytosis from squamous cell carcinoma have been described in cases of very aggressive tumors, frequently leading to death. Prompt diagnosis, staging and treatment for the malignancy is therefore essential.

AN ASYMPTOMATIC, PRO-ARRHYTHMIC INTRA-ATRIAL MASS Amara Hussain; Ilya Karagodin; Appesh Mohandas. Medical College of Wisconsin, Milwaukee, WI. (*Tracking ID #1934787*)

LEARNING OBJECTIVE 1: To recognize the various types of extramedullary manifestations of acute myeloid leukemia.

LEARNING OBJECTIVE 2: To distinguish the pathophysiology and clinical presentation of cardiac myeloid sarcoma, a rare extramedullary manifestation of acute myeloid leukemia.

CASE: Extramedullary manifestations of acute myeloid leukemia (AML) are quite rare (<10 % of all cases). These extramedullary solid collections of leukemic cells, also referred to as myeloid sarcomas or chloromas, typically involve the skin, spine, orbits, digestive tract, and lymph nodes. Even more unusual is the presence of immature myeloid cells in the heart, also known as cardiac myeloid sarcoma (<1 % of cases). Cardiac myeloid sarcoma can occur as the initial presentation of AML, alongside marrow disease, or at the time of disease relapse. The small number of cases described in the literature have shown a marked predilection for the right atrium, and a striking male predominance. We present a case of an asymptomatic right intra-atrial mass in a 64-year-old male with a history of Monosomy 7 AML, allogeneic bone marrow transplant, graft-versus-host-disease, and chloroma of the

right eye and tongue. At a routine visit to his oncologist, the patient was found to be in atrial flutter with 2:1 block at a rate of 146 bpm. A CT PE protocol highlighted a filling defect within the right atrium consistent with intra-atrial thrombus or mass. A cardiac MRI showed a large right atrial mass that extended from the superior vena cava to the inferior vena cava with several small adherent clots. To obtain tissue samples and facilitate a diagnosis, a right heart catheterization was performed with the aid of intracardiac ultrasound. Biopsy of the mass demonstrated cardiac muscle fibers with extensive fibrosis and an atypical infiltrate of small round blue cells consistent with myeloid sarcoma. Given the location of the chloroma, the patient was started on CLAG chemotherapy rather than adjuvant radiation therapy. Over the course of his hospitalization, the patient transitioned from a junctional escape rhythm with intermittent, non-sustained runs of ventricular tachycardia and atrial fibrillation to normal sinus rhythm. He was loaded with amiodarone and slowly tapered to a maintenance dose. Interestingly, the patient remained symptom-free throughout his entire treatment course. Follow-up cardiac MRI after CLAG chemotherapy demonstrated significant interval regression in the size of the mass (3 mm thick vs. 5.5 mm previously). There was also interval improvement of superior vena cava patency. The luminal diameter of the SVC was 4 mm prior to the initiation of chemotherapy, and 10 mm following the conclusion of chemotherapy.

DISCUSSION: The right atrial mass was the third extramedullary manifestation of this patient's AML, whose marrow remained disease-free at presentation. The patient's arrhythmias were likely caused by irritation of the SA node by the right atrial mass, causing sino-atrial exit block and intermittent failure of atrial depolarization. This fascinating case suggests that one or more episodes of myeloid sarcoma places an individual at higher risk for additional extramedullary manifestations in different anatomic locations.

AN ATYPICAL CAUSE OF ACUTE LOW BACK PAIN Rebecca Liu; Crystal Ritsema. Yale School of Medicine, New Haven, CT. (*Tracking ID #1935200*)

LEARNING OBJECTIVE 1: Recognize the atypical neurological manifestations of vitamin B12 deficiency

LEARNING OBJECTIVE 2: Diagnose and treat functional vitamin B12 deficiency in the setting of borderline low B12 levels

CASE: A 42 year-old female without significant past medical history presented with debilitating low back pain radiating down her legs, along with weakness, numbness and tingling of her upper extremities. Eleven months prior to this visit, she presented with acute low back pain radiating down her right leg and was diagnosed with sciatica. Ibuprofen, cyclobenzaprine, tramadol and prednisone were sequentially trialed but did not alleviate her symptoms. A lumbar spine MRI was unremarkable. She was lost to follow-up and re-presented with bilateral lower extremity pain and weakness in addition to weakness, numbness and tingling of her upper extremities. She also reported left facial droop, blurry vision and decline in memory and attention. Physical exam revealed a distressed woman, in pain and ambulating with a cane. Neurologic examination revealed normal cranial nerves, reflexes, strength and sensation in all extremities. MRI of the brain showed no evidence of demyelinating disease. Her hemoglobin, hematocrit, and mean corpuscular volume were 15.3 g/dL, 44.4 %, and 91 fL, respectively. Hemoglobin A1C was 5.1 %. TSH was 1.55 $\mu\text{U}/\text{mL}$. HIV and chronic viral hepatitis panel were negative. Antibodies to Borrelia burgdorferi were negative. Vitamin B12 level was 205 pg/mL, and on repeat was 189 pg/mL. Homocysteine (8.9 $\mu\text{mol}/\text{L}$) and methylmalonic acid (MMA) (0.24 $\mu\text{mol}/\text{L}$) were not elevated. On the basis of her clinical symptoms and these laboratory values, the diagnosis of functional vitamin B12 deficiency was made and parenteral B12 therapy was initiated. One month later, she reported dramatic improvement in the weakness, numbness and tingling in her arms as well as improvement in her lower back pain and weakness of left leg. Her B12 level at this visit had improved to 546 pg/mL. She was transitioned to daily oral B12 supplement, and on further follow-up continued to improve with complete resolution of her left leg and bilateral arm symptoms and only mild residual pain in her right leg.

DISCUSSION: The most common neurological manifestations of vitamin B12 deficiency are paresthesias, peripheral neuropathy, and subacute combined degeneration. This patient, with borderline-low vitamin B12 despite normal homocysteine and MMA, demonstrates atypical neurological manifestations of vitamin B12 deficiency that rapidly responded to B12 therapy. It is unusual for patients to exhibit B12 deficiency-associated symptoms with normal homocysteine and MMA. Savage et al. reported that only 1 out of 406 'clear-cut' B12-deficient patients showed normal levels for both homocysteine and MMA. Nevertheless, there is evidence in the literature of patients with normal B12, homocysteine, and MMA levels who quickly respond to parenteral B12 with resolution of symptoms. In summary, this case details an atypical presentation of B12-deficiency associated polyneuropathy that proved

highly responsive to B12 therapy. This case also highlights the importance for clinicians to develop comprehensive differential diagnoses prior to obtaining labs, and despite borderline normal lab results, to use overall clinical judgment to properly diagnose and treat patients with commonly encountered conditions in General Internal Medicine.

AN ATYPICAL ULCERATIVE COLITIS FLARE: TAKING A DEEPER LOOK Allison R. Bond²; Artur Viana¹; Boston Medical Center, Boston, MA; ²Boston University School of Medicine, Boston, MA. (*Tracking ID #1937106*)

LEARNING OBJECTIVE 1: To recognize the signs and symptoms that may indicate an ulcerative colitis (UC) flare has been complicated by a secondary cause
LEARNING OBJECTIVE 2: To understand the risk of opportunistic infections that chronic immunosuppressive treatments can pose among patients with ulcerative colitis.

CASE: A 53-year-old man with ulcerative colitis presented with bloody diarrhea and abdominal pain. The patient had two prior ulcerative colitis flares in the 16 years since diagnosis, which were treated with a brief steroid course and did not require hospitalization or long-term immunosuppression. Five weeks prior to admission, the patient developed bloody diarrhea and intense abdominal pain, and was started on mesalamine without effect. He was subsequently admitted and received IV methylprednisolone and one dose of infliximab. His symptoms improved and he was discharged. However, when bloody bowel movements and abdominal pain recurred, he was readmitted. The patient had no fever or leukocytosis and was again placed on IV methylprednisolone, with oral and rectal mesalamine. He continued to have 10–15 bloody bowel movements a day, and a flexible sigmoidoscopy revealed transmural ulcerations with anal involvement deemed uncharacteristic of ulcerative colitis. Biopsy showed inflamed mucosa consistent with moderate ulcerative colitis, along with cytomegalovirus (CMV) in the mucosal cells. The patient was started on ganciclovir IV and continued on mesalamine; the dose of methylprednisolone was also reduced. Despite appropriate therapy, his symptoms progressed and a repeat sigmoidoscopy showed marginally improved deep ulcerations. He subsequently underwent a total colectomy with end ileostomy and a surgical specimen revealed nearly transmural ulcerations. He recovered from the colectomy without major issues and was discharged a week later.

DISCUSSION: This is a case of CMV colitis in the setting of acute immunosuppression and local mucosal inflammation. Gastrointestinal CMV can occur anywhere in the gastrointestinal tract, presenting as diarrhea, bloody stools, abdominal pain, fever, and weight loss. As these symptoms mimic ulcerative colitis, it is impossible to pinpoint when the patient developed CMV colitis. However, the infection likely exacerbated a pre-existing UC flare and prevented recovery. Immunodeficiency is the most common setting in which GI CMV is found, including patients with HIV/AIDS or immunosuppression (organ transplant, malignancy chemotherapy or steroid therapy). This case underscores the importance of considering CMV as a causative agent of diarrhea in systemically immunosuppressed patients. Once diagnosed, the patient's CMV presented a treatment conundrum, as the immunosuppressants intended to alleviate the flare could possibly hinder the body's ability to clear the CMV infection. It has been noted in previous studies that CMV, while commonly reactivated in patients with ulcerative colitis, may resolve without treatment. Furthermore, mortality rates among patients with concurrent UC and colonic CMV infection were formerly reported to be 33 %, with a need for surgical treatment in 80 % of patients. With the use of ganciclovir, however, a minority of patients have required surgery, and death from CMV superinfection is rare. Antiviral treatment was favored in this patient as his symptoms were thought to be due in large part to a CMV infection. Unfortunately, his symptoms worsened and he ultimately required intervention.

AN CASE OF SOLITARY OCULAR LANGHERHANS CELL HISTIOCYTOSIS PRESENTING AS PROPTOSIS Ragisha Gopalakrishnan; Harris Naina. University of Texas Southwestern Medical Center, Dallas, TX. (*Tracking ID #1938796*)

LEARNING OBJECTIVE 1: To recognize solitary orbital manifestations of langherhans cell histiocytosis (LCH) as part of the differential for unilateral proptosis and orbital tumors.

CASE: A 28-year-old Hispanic female with a history of hypothyroidism presented to her ophthalmologist after having unilateral blurry vision, proptosis, right upper eyelid swelling, and intermittent headaches for 1 year. She denied any fevers, chills, night sweats, changes in vision, denied using contacts. She did not smoke, and did not use recreational drugs, or smoke tobacco. On exam, she was noted to have significant

proptosis in her right eye, but her exam showed was no evidence of conjunctival injection, focal neurologic deficits, skin lesions, or lymphadenopathy. Labs showed that her BMP was within normal limits, and TSH was 3.2 (normal). Subsequent workup including a MR of the orbits performed showed an ill-defined superior right 4 mm anterior posteriorly ×10 mm transverse orbital mass with adjacent right frontal bone erosion. Biopsy of the mass showed a large infiltrate was strongly positive for CD1a and S100, which was diagnostic of Langerhans cell histiocytosis (LCH). A PET scan, A MRI spine, and CT chest and CT abdomen and pelvis showed no evidence of systemic disease. Local radiation and/or surgical excision have been previously used in the past to treat children who presented with solitary orbital manifestations of LCH. However, local surgery and/or local radiation could not be performed because the tissue obtained was too friable and thin. She was referred to malignant hematology clinic, and systemic therapy with cytarabine was recommended. However, the patient decided to undergo herbal treatment.

DISCUSSION: Langerhans cell histiocytosis (LCH) is a rare disease with clonal proliferation of dendritic histiocytes forming a pseudotumoral growth. Orbital manifestation of LCH is a rare form of LCH and are best studied in children. Local surgery and radiation therapy are used as first line therapies, and systemic chemotherapy is often used as an adjunctive therapy if local surgery or radiation therapy is not possible. There have been only 2 cases of solitary orbital manifestations of LCH documented in adults till date. Both patients survived with local surgery and radiation therapy. Hence, this case demonstrates that orbital LCH should be considered as part of the differential for proptosis and orbital tumors. It also underscores the need for further investigation into treatment protocols for solitary ocular manifestations of LCH in adults.

AN EMOTIONAL CASE OF A NEUROLOGIC DISEASE Katie Tipton; Kobina Wilmot. Emory, Decatur, GA. (*Tracking ID #1940210*)

LEARNING OBJECTIVE 1: Altered mental status can have an exhaustive differential which requires thorough work up to ensure correct diagnosis.

LEARNING OBJECTIVE 2: Psychologic derangements are present in at least half of all patients with multiple sclerosis.

CASE: A 25 year old female with no past medical history presented for evaluation of bizarre behavior. She was in her normal state of health until 5 months prior to presentation. At that time she developed significant paranoia, quit her stable job, had decreasing interaction with her family and fiancée, and developed full body tremors. Family also witnessed her walking the streets in the middle of the night, undressing in public and urinary incontinence. She was minimally interactive with staff, and physical exam was only positive for hyper-reflexia in lower extremities. During initial work up, she underwent lumbar puncture which showed mild pleocytosis but glucose and protein levels were within normal limits. Infectious work up was negative, including HIV, HSV, CMV, VDRL, and blood, viral, and fungal cultures. Metabolic work up was grossly within normal limits except mildly suppressed vitamin D level of 16. Rheumatologic work up was negative, including ANA. Cat scan of her head was also within normal limits. During hospitalization her behavior remained altered including minimal interactions with all staff, inappropriate laughter, crying spells, and overall behavioral regression. Psychiatry was consulted, and she was started on Zyprexa with mild improvement in her symptoms. Prior to inpatient psychiatric hospitalization, an MRI brain was performed. This imaging revealed numerous (greater than twenty) white matter lesions of varying ages consistent with multiple sclerosis. Neurology was consulted but steroids were held in the setting of her acute psychosis.

DISCUSSION: Multiple sclerosis (MS) is an autoimmune inflammatory demyelinating disease of the central nervous system. This disease affects more women than men primarily between the ages of 23 and 30. Though symptoms vary greatly among all patients with MS, most patients have a primarily neurologic complaint such as vision, sensory, and/or gait changes at time of diagnosis. Though physical complaints are the most common, approximately half of all MS patients also have some emotional disturbance as well. The most common of these is depression, but patients also suffer from pathologic laughing and crying, euphoria, anxiety, and rarely psychosis. Our patient was a bit more unique as her entire presentation was psychological abnormalities. She experienced the pathological laughing and crying which is common with pseudobulbar palsy as well as anxiety and paranoia. Psychosis is more atypical with MS as it is considered to involve more gray matter rather than white matter. However, a subset of patients do experience psychosis particularly with frontal lobe and cognitive dysfunction. This case demonstrates the importance of a complete work up whenever a patient presents with altered mental status and behavioral changes. Since this patient was within the common age of presentation of a variety of psychiatric illnesses, her underlying demyelinating disease was almost

misdiagnosed. Every patient with altered mental status should undergo a complete infectious, rheumatologic, metabolic, and neurologic work up to ensure potential underlying organic causes are found.

AN EXTREMELY RED EXTREMITY Julia Fleming; Darlene LeFrancois. Montefiore Medical Center, Bronx, NY. (*Tracking ID #1939692*)

LEARNING OBJECTIVE 1: Identify the differential diagnosis for erythema in an extremity

LEARNING OBJECTIVE 2: Recognize the clinical presentation of pyomyositis

CASE: A 53 year-old man with uncontrolled diabetes mellitus type two on high dose steroids presented with redness that had progressed from his right hand to upper arm over the course of 3 days. He also noted pain and warmth of the arm. He reported no fevers or changes in strength or sensation in the hand. He noted no trauma or recent insect bites, and recalled no peripheral IVs in the arm despite having a recent hospitalization where he was diagnosed with hemophagocytic lymphohistiocytosis and initiated on steroids. Vitals were T 97.8 F, BP 153/65, HR 72, and RR 16. He was found to have erythema, warmth, tenderness, and accompanying 2+ pitting edema extending from the volar aspect of the right wrist to the mid-humerus. Induration and more severe tenderness but no overt fluctuance of the right forearm was appreciated. Passive wrist extension that stretched the flexor compartment of the forearm was particularly painful for the patient. Labs revealed a WBC 15.8 k/uL, and CPK 17 U/L. Blood cultures showed no growth. There was no deep venous thrombosis by ultrasound. Non-contrast CT of the forearm revealed extensive edema throughout the subcutaneous tissues and muscles with a discrete fluid collection that interdigitated the edematous flexor muscles. Several days of intravenous vancomycin, clindamycin, and ampicillin/sulbactam did not yield clinical improvement. He underwent surgical debridement of the forearm revealing purulent material infiltrating all fascial planes of the anterior compartment and fibrinous material covering the muscle surfaces, consistent with pyomyositis involving superficial and deep flexor muscle groups. Wound cultures grew methicillin-sensitive staphylococcus aureus.

DISCUSSION: Erythema of an extremity is a commonly encountered problem. It is often difficult to distinguish cellulitis from deep tissue infections but a systematic approach can assist in diagnosing less common sources of erythema. Starting from the skin and moving towards deeper structures allows for thorough identification of both infectious and non-infectious conditions, including: skin—cellulitis, skin abscesses, and contact dermatitis; fascia—necrotizing fasciitis; muscle—pyomyositis, diabetic myonecrosis, and necrotizing myositis; vasculature—deep venous thrombosis; joints—septic arthritis, and gout; and lastly bone—osteomyelitis. Particular exam findings that are concerning for pyomyositis include edema and increasing pain classically localized to a single muscle group but not infrequently involving multiple muscles whereas necrotizing fasciitis often presents with progressive fever and/or systemic toxicity, crepitus, and pain out of proportion to skin findings. Pyomyositis is an acute bacterial infection of the muscle due to hematogenous spread. Pyomyositis is commonly seen in tropical climates, but less commonly in temperate climates. Most cases in temperate climates are seen in patients with underlying immunodeficiency, such as HIV, diabetes or malignancy, as was the case with this patient. Staphylococcus aureus is the most common cause of infection, resulting in more than 75 % of cases seen in temperate climates. Bacteremia is seen in ~25 % of cases. Most common sites of involvement are the thigh, followed by the calf, buttock, upper extremity, and iliopsoas. Pyomyositis can be divided into three clinical stages. In the invasive stage (days 1–10), patients develop local, crampy muscle pain, swelling, and “woody” texture to the muscle. In the suppurative stage (weeks 2–3), patients are noted to have worsening fever, extreme muscle tenderness, and edema with presence of pus and often frank abscess in the muscle. Fluctuance is frequently not present. In the third stage, patients develop sepsis and systemic toxicity. Early diagnosis of pyomyositis may be difficult since findings are often nonspecific - pain and cramping of the muscle. A high index of clinical suspicion is necessary. Laboratory findings vary, although CPK is usually normal. Imaging studies - CT, MRI - are most helpful to make the diagnosis. MRI is more sensitive than CT for showing the full extent of tissue involvement. While early stage infections may be treated with antibiotics alone, later stage infections also require drainage.

AN EYE OPENING DIAGNOSIS Gurkaran Garcha; Neeti Reddy; Priti Dangayach; Himabindu Kadiyala. Baylor College of Medicine, Houston, TX. (*Tracking ID #1939605*)

LEARNING OBJECTIVE 1: Recognize malignant melanoma as a cause of ocular pathology via distant metastases

LEARNING OBJECTIVE 2: Review screening rationale and strategies for early detection of malignant melanoma by the General Internist

CASE: A 53 year old male presented to the Emergency Room with an inability to spontaneously open his right eyelid for 1 day. Three weeks prior to presentation, he noted drooping of his right eyelid which then progressed gradually to complete closure 1 day prior to presentation. He was able to open his eyelid fully with his hand. There was no loss of vision, diplopia, or headache. The degree of ptosis did not vary during the course of the day or with fatigue. No history of ocular surgery or trauma. Past medical history was significant for resection of a “skin cancer” from the first digit of his right foot 12 months prior to presentation, and the patient was lost to follow up afterwards due to loss of health insurance. The physical exam was significant for ptosis of the right eye leading to complete closure of the eye lid. Levator function was decreased but constant throughout the examination. Pupils were equal, round, and reactive to light. Extraocular movements were intact along with visual acuity and visual fields. A MRI of the orbits showed a 1.8 cm×1.6 cm×1.3 cm well defined intracanal mass in the superior aspect of the orbit, inseparable from the levator palpebrae and superior rectus muscles. A right orbitotomy revealed a grey colored irregular appearing mass, and pathology showed tumor cells positive for S100, Mart1 and HMB45, consistent with malignant melanoma. Further staging also revealed two small frontal lobe metastases which were surgically resected. Our patient is currently undergoing whole brain radiation therapy.

DISCUSSION: Melanoma of the skin is the most commonly fatal type of skin cancer. The American Cancer Society estimates 76000 new cases of invasive melanoma in 2013. Malignant melanoma can present with distant metastases leading to unusual presentations as in our patient. Patients with metastatic disease have a poor prognosis, with a 5-year survival rate of less than 20 %. Limited therapeutic options are available for these patients. Cytotoxic chemotherapy has not been shown to induce remission or prolong life. The therapeutic considerations include surgical metastasectomy, immunotherapy (IL 2 or ipilimumab), targeted inhibition of the MAP kinase pathway (dabrafenib), and radiation therapy to symptomatic sites of metastases. For the vast majority of patients, these approaches only prolong life by 1–6 months. Screening and early detection of melanoma by the primary care physician may offer a cost effective way to decrease melanoma mortality. Multiple studies report that clinicians are able to detect melanomas thinner than those self reported by patients. Although data from randomized controlled trials is lacking, large population based screening programs such as the SCREEN project have demonstrated up to a 50 % decrease in melanoma mortality. The American Cancer Society guidelines recommend routine skin examinations for early detection of melanoma, particularly in high risk individuals: atypical or high nevus counts (>25), ultraviolet exposures, and phenotypic traits (light skin, high density freckling, and green or blue eyes). The A, B, C, D, Es of melanoma recognition are a valuable tool for clinicians providing initial screening. Additionally, examination of the total skin surface can lead to a six fold increase in the likelihood of detecting a melanoma. Malignant melanoma may present with widely metastatic lesions leading to unusual presentations. Periodic screening for cutaneous melanoma may play a role in decreasing melanoma mortality.

AN HISTORICAL CLINICOPATHOLOGICAL ANALYSIS. HOW FLAVIUS JOSEPHUS, GUSTAV MOREAU, OSCAR WILDE, AND RICHARD STRAUSS OFFER INSIGHTS INTO THE MYSTERIOUS ILLNESS OF KING HEROD Cianna Leatherwood; Richard Panush. University of Southern California, Dept of Internal Medicine, Los Angeles, CA. (*Tracking ID #1938067*)

LEARNING OBJECTIVE 1: Recognition of Chronic Lead Intoxication as a possible diagnosis of the deleterious illness of King Herod the Great.

CASE: Herod the Great was “King of Jews”, appointed by the Roman Emperor and Senate to govern Judea; he lived from 73/74 BCE - 1 CE. He died from a mysterious illness that was depicted by Richard Strauss in his classic opera, Salome, considered by critics among the best of this genre. That opera was derived from a play of the same name by Oscar Wilde which was based on an 1876 painting, “Salome Dancing Before Herod”, by Gustav Moreau. Josephus authored the definitive history of the Herodian epoch. We suggest a novel diagnosis of Herod’s illness and speculate about its historical impact. The operatic Herod was afflicted with an illness characterized by dementia, hallucinations, paranoia, alcoholism (from drinking the Emperor’s wine), violence, twitches, and sterility; different depictions showed him also with falls, chills, shaking, thirst, forgetfulness, and sleepiness. The historical Herod was described with severe abdominal pain, extremity swelling, and likely renal failure, in addition to his psychotic behavior.

DISCUSSION: We considered a differential diagnosis including vasculitis/systemic rheumatic disease, Behcet syndrome, sarcoidosis, thyroid disease, brain tumor, renal

disease, amyloidosis, infections, malignancies, and paraneoplastic syndrome, among certain other possibilities, as unifying diagnoses. We suggest that he had chronic lead intoxication. He had compatible symptoms (encephalopathy and neuromuscular symptoms) and consumed excessive quantities of imperial wine, known to be highly contaminated with lead and likely associated with similar symptoms among Roman aristocracy. We are not aware that Wilde or Strauss had similar maladies and therefore do not believe their depiction of Herod to be based upon personal experiences. We therefore offer a novel diagnosis for the illness of the historic and operatic King Herod. Herod's demented cruelties—an oppressive reign including the beheading of John The Baptist—exacerbated the political climate and may have contributed to the subsequent violent 7-year revolt culminating in the destruction of the second temple. How different might history have been if Herod the Great had been abstemious?

AN INTERESTING CASE OF CELLCPECT TOXICITY Mona Hassan; Hiba Hadid; David Paje. Henry Ford Health System, Detroit, MI. (*Tracking ID #1938952*)

LEARNING OBJECTIVE 1: To shed the light on one of the less common but devastating side effects of Mycophenolate mofetil, bowel necrosis.

CASE: We present a case of a 62 year old female with autoimmune hepatitis, on prednisone and Cellcept for 8 months, who presented with diarrhea for 1 month. The diarrhea was non-bloody in the form of 5 to 6 bowel movements per day. The patient also noted increasing fatigue and a 10 lb weight loss over a 6 month period. Stool work up, urine and blood cultures were all negative. There was no history of recent travel or exposure to sick contacts. Her symptoms began approximately 2 months after initiating it. The decision was made to hold Cellcept. A colonoscopy was performed and biopsies were obtained. Pathology revealed Bowel necrosis that was pathognomonic of that found in Cellcept toxicity. Upon 2 week follow up the patient's diarrhea had completely resolved.

DISCUSSION: Gastrointestinal injury can occur with short-term exposure to Cellcept. Cellcept induced gastrointestinal toxicity is thought to occur from injury to enterocytes and formation of immunotoxicologic reactions. Endoscopy reveals gross inflammatory changes in addition to mucosal injury. Our case emphasizes the importance of having a high index of suspicion in patients taking Cellcept presenting with diarrhea.

AN INTERESTING CASE OF CRYOFIBRINOGENEMIA Aswini Kumar1; Aswanth Reddy2; Aditya Kalakonda1; Kiran Pokhrel1; Amit S. Dhamoon1. ISUNY Upstate Medical University, Syracuse, NY; 2Saint Vincent Hospital, Worcester, MA. (*Tracking ID #1933290*)

LEARNING OBJECTIVE 1: Recognize cryofibrinogenemia in appropriate clinical settings.

LEARNING OBJECTIVE 2: Understand the importance of prompt diagnosis.

CASE: 25 year old male with H/O IV drug abuse presented to the emergency department with abdominal pain, diarrhea, arthralgia and purpuric lesions in the extremities. Labs showed leukocytosis and abdominal imaging revealed possible colitis. Treatment was initiated with IV antibiotics. Infective endocarditis was excluded by negative blood cultures and transesophageal echocardiogram. Vasculitis and rheumatological panel were unremarkable except for elevated ESR and low complements. Hepatitis B and C were negative and coagulation profile was normal. Subsequently he developed acute renal failure with hematuria and proteinuria. At that point, diagnosis was unclear and the patient was deteriorating. Skin biopsy of the lesions showed leukocytoclastic vasculitis with thrombosis of the dermis and renal biopsy revealed hypereosinophilic deposits suggestive of cryofibrinogenemia. There was significant improvement in renal parameters after treatment with corticosteroids.

DISCUSSION: Cryofibrinogenemia (CF), first described by Korst and Kratochvil in 1955 refers to the presence of plasma cryoproteins comprising fibrinogen, fibrin and fibrin split products. It can be primary, of unknown etiology or secondary to malignancy, autoimmune, infectious or thrombotic disorders. It is a potentially serious disease which commonly affects skin but can involve any organ causing thrombosis. There is paucity in medical literature about renal involvement of Cryofibrinogenemia (CF). CF is a disease often underrecognized in routine practice. High clinical suspicion is necessary and prompt diagnosis with assay is life saving. Clinicians should be aware of renal involvement in CF as it can be reversed with early treatment.

AN INTERESTING CASE OF FALSELY ELEVATED TSH LEVEL DUE TO HUMAN ANTI-MOUSE ANTIBODIES (HAMA) INTERFERENCE WITH THYROTROPIN ASSAY Samaneh Dowlatshahi; seyedAmirHossein AfsharImani; Erica Sinsheimer; Harvey Friedman. St Francis Hospital, Evanston, IL. (*Tracking ID #1923838*)

LEARNING OBJECTIVE 1: Heterophile antibodies that interfere with the TSH assay have been described in the past. Human antimouse antibody (HAMA), which is the most commonly encountered heterophile antibody, may be present in the serum of up to 10 % of patients. The incidence increases in people who have received or have been treated with radiolabeled mouse monoclonal antibodies.

LEARNING OBJECTIVE 2: It has been suggested that these heterophile antibodies are natural antibodies in normal people, although they could represent autoantibodies. We present a patient with falsely elevated TSH levels secondary to presence of HAMA.

CASE: A 45 year old male presents with an incidentally found abnormal thyroid panel which showed elevated TSH levels along with normal free T3 and free T4. Patient complaints of prolonged constipation. He was started on increasing doses of levothyroxine. At 6 weeks follow up TSH did not show any significant changes. TSH was repeated at another laboratory with the addition of mouse serum to the patient's sample, and it was normalized.

DISCUSSION: A common and the first test to diagnose thyroid dysfunction is TSH measurement. HAMA is one of the multiple factors that can interfere with this test result and can result in costly diagnostic evaluation and unnecessary treatment. It is crucial to evaluate for the interfering factors prior to initiating unnecessary and potentially harmful clinical interventions. In this case we report the presence of HAMA as the interfering substance in the TSH assay.

AN INTERESTING CASE OF PITUITARY MACRO-ADENOMA PRESENTING AS SYMPTOMATIC INTERNAL CAROTID ARTERY COMPRESSION Samaneh Dowlatshahi; seyedAmirHossein AfsharImani; Harvey Friedman. St. Francis Hospital, Evanston, IL. (*Tracking ID #1923825*)

LEARNING OBJECTIVE 1: Non-functioning pituitary macroadenoma are usually benign in origin, however mass effects may lead to serious clinical symptoms such as visual impairments, chronic headache, and pituitary insufficiency.

LEARNING OBJECTIVE 2: Obstruction of the internal carotid artery by a pituitary tumor is a rare occurrence, particularly in the absence of pituitary apoplexy. Pituitary macroadenomas can invade the cavernous sinus and rarely cause occlusion of the internal carotid artery (ICA). Most patients with symptomatic obstruction of the ICA by a pituitary tumor have been reported as a result of apoplexy. In this case report we present a patient with symptomatic carotid compression by a pituitary adenoma without evidence of apoplexy.

CASE: A 67 y.o. male patient presented with a right sided weakness, and 3 months history of progressive loss of vision on both eyes. Physical exam showed a bitemporal hemianopsia. The MRI revealed a 2.7 cm pituitary mass likely a macroadenoma, which was extending into the suprasellar cistern and was displacing the optic chiasm, and laterally the mass was pressing on cavernous portions of both internal carotid arteries. Also there was evidence of an acute stroke in the left pons. There was no radiologic evidence of apoplexy. Hormone studies at that time was consistent with panhypopituitarism, his prolactin level was initially 29 ng/ml (elevated but not at the extend of prolactinoma,) and a dilutional test showed even lower prolactin level of 21 ng/ml, so patient was diagnosed with a non-functioning macroadenoma. Surgical resection of the tumor and ICA decompression via the transsphenoidal route resulted in prevention of further symptoms. Histopathologic analysis confirmed a nonfunctioning pituitary adenoma without evidence of hemorrhage or intra-tumoral infarction. Patient was started on 20 mg prednisone twice daily which was reduced to 5 mg twice daily at 1 month follow up. TSH at 1 month follow up remained low and he was continued on 125 mcg levothyroxine daily.

DISCUSSION: There is a clinical impression that when tumors invade the cavernous sinus, compression of the internal carotid artery and cerebral ischemia is rare with pituitary adenomas and more common with other types of lesions but there are no actual data to support this impression. In this case report, we present a patient with symptomatic carotid compression by a pituitary adenoma without evidence of apoplexy.

AN INTERESTING CASE OF TRICHINELLOSIS Jason Sayanlar; John Meriwether. Georgetown University Hospital, Washington, DC. (*Tracking ID #1942081*)

LEARNING OBJECTIVE 1: To understand the clinical importance of Trichinellosis as a rare but serious cause of systemic infection.

LEARNING OBJECTIVE 2: To understand the clinical importance of Trichinellosis as a rare but serious cause of systemic infection.

CASE: A 38 year-old Caucasian male with no past medical history presented to the hospital with a one-day history of hematuria. Approximately 2 weeks prior, he reported consuming pork purchased from a local grocery chain. The next day he began experiencing fevers and diarrhea, which persisted for several days. As his diarrhea resolved, he noticed “puffiness” around his eyes, leg swelling, and general weakness. One week later, his diarrhea resumed, along with muscle pain in his arms, legs, and lower back. On the day of admission, he noticed bright red urine, which prompted him to present to the emergency department. Elevated transaminases gave concern for viral infection, including hepatitis and Ebstein-Barr, along with Legionella. However, significant serum eosinophilia was noted, suggesting a parasitic infection. His urinalysis indicated muscle injury (gross hematuria with few erythrocytes) and creatine phosphokinase (CPK) was markedly elevated- both suggesting a muscle-infiltrating disease. Markedly elevated IgE levels returned, and trichinellosis became the unifying diagnosis. An enzyme-linked immunosorbent assay (ELISA) was positive, and was later confirmed with western blot. Invasive diagnosis with muscle biopsy was not pursued. After initiating therapy with albendazole and prednisone, the patient's abnormal lab values began to improve- eosinophilia peaked at 31 %, aspartate aminotransferase at 215, alanine aminotransferase at 370 and CPK at 3541. Within days, he noticed a significant improvement in peripheral edema and resolution of myalgia. He was discharged home on a two-week course of albendazole and a prednisone taper.

DISCUSSION: Trichinellosis is a rare parasitic infection caused by a nematode from the genus *Trichinella*. Ingestion of undercooked pork is the most common source of infection. However, wild boar, horse, walrus, moose, and bear have all been identified as potential sources. Infection is characterized by the enteral and the parenteral phases. Ingested larvae penetrate the host's intestinal mucosa, traveling through vessels to ultimately reside in skeletal muscle fibers. Larval migration triggers an inflammatory response, releasing mediators such as histamine and bradykinin, which augment the permeability of host capillaries, resulting in widespread edema. Initial complaints may include gastrointestinal disturbances, fevers/chills, myalgias, or edema. Rarely, myocarditis and encephalitis are also seen. Diagnosis is made clinically, but clinicians should check a complete-blood-count, to assess for eosinophilia, and a metabolic panel with CPK, to assess for muscle damage. Anti-*Trichinella* antibodies are detectable on ELISA after 3 weeks of infection, and are confirmed with western blot. Definitive diagnosis can be made with muscle biopsy (to look for larval infiltration), however, biopsy is reserved only for cases of uncertain diagnosis. Most cases are uncomplicated and self-limited. However, signs of systemic involvement such as hematuria, encephalopathy, pulmonary or cardiac inflammation should be treated with anti-helminthic therapy and corticosteroids.

AN INTERNIST'S WORST NIGHTMARE- MANAGING A RIVAROXABAN BLEED Naveen Nannapaneni; Marwan Al-Hajjeli. Wayne State University/Detroit Medical Center, Detroit, MI. (*Tracking ID #1923321*)

LEARNING OBJECTIVE 1: Manage an acute bleed while on rivaroxaban.

LEARNING OBJECTIVE 2: Recognize the utility of using prothrombin complex concentrate for reversal of rivaroxaban.

CASE: For decades the mainstay of outpatient anticoagulation has been warfarin, a problematic drug requiring close monitoring and which has several medication interactions. With the arrival of a new generation of oral anticoagulants, significant burdens on both the patient and the healthcare system have been alleviated. Nevertheless, shortfalls exist in regards to agents or protocols for reversal of these anticoagulants in the setting of an acute bleed, as exhibited in our case. A 39-year-old woman with a history of bilateral pulmonary emboli and schizoaffective disorder presented to the ER with a 2 week history of vaginal bleeding. She associates abdominal cramping and low back pain with the bleeding and endorses fatigue, dyspnea and lightheadedness. At her baseline she reports normal cyclical bleeding lasting less than 1 week. She reports being transitioned from warfarin to rivaroxaban 6 weeks ago. Physical exam revealed stable vitals, fresh blood and clots in the vaginal vault, and after they were cleared, bleeding from a closed external cervical os was identified. Her hemoglobin on presentation was 2 g/dL below her baseline. In the ER she was given intravenous fluids along with a dose of intravenous FEIBA (prothrombin complex concentrate, PCC) per ER protocol. Hematology was consulted and recommended transfusing packed red blood cells, decreasing the dose of, and ultimately holding, rivaroxaban and discontinuing the PCC due to concern of an increased risk of thrombosis. Additional attempts to stop the bleeding via intravenous conjugated estrogen and balloon tamponade recommended by gynecology were unsuccessful. After discussing the implication to her fertility, the patient was agreeable to a dilation and curettage with endometrial ablation which resulted in cessation of her bleeding. She was discharged on fondaparinux with hematology follow-up.

DISCUSSION: The acute management of a bleed while on rivaroxaban is a challenge for any physician. In our case, the patient was given PCC based on an ER algorithm derived

from an individual study that suggests its efficacy for reversal. This protocol, however, was not continued after consultation with hematology as it was noted that the study was conducted in healthy subjects and followed thrombin and activated prothrombin times to gauge reversal, both of which are suboptimal methods of monitoring rivaroxaban. Moreover, the use of PCC is associated with an increased risk of further thrombosis, a significant concern given our patient's history of unprovoked pulmonary emboli. At present there is no guideline regimen to induce reversal of rivaroxaban. As a result, supportive management including transfusions and compression or tamponade are performed, but cessation of bleeding ultimately requires metabolism and clearance of the drug. Our case reiterates the uncommon, and difficult, management of patients bleeding while on rivaroxaban.

AN OCULAR PLASMACYTOMA PRESENTING AS ASYMPOTOMATIC, RED EYE Ragisha Gopalakrishnan; Harris Naina. UT southwestern, Dallas, TX. (*Tracking ID #1939389*)

LEARNING OBJECTIVE 1: To recognize that solitary ocular plasmacytomas can present as asymptomatic red eye.

LEARNING OBJECTIVE 2: To recognize that solitary ocular plasmacytoma behave clinically and biologically different from systemic multiple myeloma with ocular manifestations.

CASE: A 73-year-old gentleman with a medical history of hypertension was referred to an ophthalmologist by his friend after his friend noticed that his right eye was turning red for 3 months. He denied any recent vision changes, fever, chills, weight loss, night sweats, dry mouth, or dry eyes. There was no family history of autoimmune disease, glaucoma, leukemia, or lymphoma. He did not smoke or wear glasses. On exam, a small nodularity was noted the lateral aspect of the patient's right iris. There was mild erythema noted in the right eye, but there was no evidence of pallor, scleral icterus. Visual acuity was 20/20 on exam, and there was no evidence of the lymphadenopathy on exam. Slit lamp examination showed a nodularity on his right conjunctiva. Subsequent biopsy showed a dense subepithelial infiltrate composed of CD19+, CD20+ plasma cells expressing lambda light chains, consistent with ocular plasmacytoma. He was subsequently referred to malignant hematlogy clinic for further management. A serum protein electrophoresis (SPEP), serum free light chain assay, skeletal survey were done and showed no evidence of systemic manifestation of multiple myeloma. The patient underwent surgical resection, and has remained symptom free till date.

DISCUSSION: Primary ocular plasmacytomas represent less than 5 % of ocular neoplasms. In the literature thus far, most cases of ocular plasmacytomas have been in context of patients presenting with systemic manifestations of multiple myeloma. However, primary ocular plasmacytomas are a separate entity that behave clinically and biologically different from multiple myeloma. These tumors are often localized. They respond well to local radiation or surgery, and the complete response rate is greater than 80 %. Systemic chemotherapy is rarely required as their no evidence of systemic end organ damage such as hypercalcemia, renal failure, etc. On the other hand, in patients presenting with ocular manifestations of multiple myeloma, patient have evidence of systemic disease including disease involving disease. To distinguish these two entities, systemic evaluation including an SPEP, UPEP, serum free light chain assay, and histologic examination of bone marrow may be required. There have been 20 cases of ocular plasmacytomas reported in the literature, and most of these cases have been reported in the context of multiple myeloma. Till date, there are seven cases of solitary plasmacytomas. In all of these cases, patients report symptoms of vision loss, eye swelling, or blurry vision. On the other hand, our patient did not report such as symptoms. This suggests that primary ocular plasmacytoma should be considered as part of the differential of a chronic, asymptomatic red eye. In addition, this case also underscores that primary ocular plasmacytomas are a separate clinical entity, but close follow up is required to ensure that patients do not develop signs of systemic myeloma.

AN OPPORTUNE OBSTRUCTION Nicolas Cortes-Penfield; Anna Kolpakchi,1,2; Lee Lu1. 1Baylor College of Medicine, Houston, TX; 2Michael E DeBakey VA Medical Center, Houston, TX. (*Tracking ID #1938865*)

LEARNING OBJECTIVE 1: Recognize gastrointestinal histoplasmosis as a serious cause of non-specific gastrointestinal symptoms in patients with AIDS

LEARNING OBJECTIVE 2: Recognize that gastrointestinal histoplasmosis may mimic other gastrointestinal disorders, including inflammatory bowel disease, on radiographic imaging.

CASE: A 40-year-old woman with AIDS and a CD4 count of 72 on HAART presented with several months of intermittent abdominal pain. She had had many visits to emergency room for this complaint. Abdominal CT 1 month prior to presentation showed small bowel dilatation without obstruction, which was not evaluated further. Three weeks prior, she was hospitalized at another facility with a partial small bowel obstruction (SBO), and

small bowel thickening was observed on CT at that time. She was treated with steroids for presumed inflammatory bowel disease based on radiographic findings, but still had pain at discharge. She described the pain as severe, sharp, and cramping in the epigastric area. She denied nausea, vomiting, fever, chills, or change in bowel habits. On exam, her abdomen was distended and diffusely tender to palpation. An abdominal CT showed small bowel obstruction with numerous mesenteric lymph nodes. Due to the worsening of symptoms of SBO, she underwent exploratory laparotomy and was found to have extensive small bowel disease with multiple areas of obstruction and stricture. Pathology demonstrated granulomatous inflammation with budding yeasts characteristic of Histoplasma capsulatum, which also grew from surgical cultures. Treatment with liposomal Amphotericin B resulted in rapid improvement and resolution of her abdominal pain.

DISCUSSION: Disseminated histoplasmosis is common in patients with AIDS, and the gastrointestinal tract is involved in 70–90 % of cases, though isolated gastrointestinal histoplasmosis occurs in only 3–12 % of patients. Gastrointestinal histoplasmosis is not readily recognized because the symptoms are non-specific, the clinical presentations can mimic other AIDS-related enteropathies, and the radiographic appearance can be mistaken for other diseases such as colon cancer or inflammatory bowel disease. The most common presenting symptoms include abdominal pain, weight loss, fever, and diarrhea. Bowel obstruction, GI bleeding, and perforation are major complications. Tissue diagnosis is definitive. Treatment involves a 2-week induction phase with 3 mg/kg liposomal amphotericin B, followed by 12 months of oral itraconazole. Gastrointestinal histoplasmosis is a rare but treatable disease that should be included in the differential diagnosis in the immunocompromised patient with gastrointestinal complaints. Because antifungal therapy improves outcomes for >80 % of patients and early initiation of therapy decreases morbidity and mortality, it is important to be aware of different presentations of gastrointestinal histoplasmosis in order to treat this potentially life threatening infection in a timely manner.

AN UNCOMMON CAUSE OF ACUTE POST-OPERATIVE HYPOXIA: NEGATIVE PRESSURE PULMONARY EDEMA Samantha L. Klebe; Kumar Vipul. Wellspan York Hospital, York, PA. (Tracking ID #1933859)

LEARNING OBJECTIVE 1: Recognize negative pressure pulmonary edema (NPPE) as an immediate post-operative complication of elective surgery.

LEARNING OBJECTIVE 2: Distinguish NPPE from other post-operative causes of hypoxia.

CASE: A 36 year-old African-American female with mild intermittent asthma was transferred with respiratory distress post-extubation from a scheduled knee arthroscopy under conscious sedation. On post-procedure withdrawal of laryngeal mask airway (LMA), her oxygen saturation was around 70 %. After a failed LMA re-insertion attempt, she tolerated rapid induction and intubation. Arterial blood gas confirmed hypoxemia with pO_2 114 mmHg on FiO_2 100 %. Chest x-ray (CXR) showed moderate pulmonary edema and proper endotracheal tube (ETT) placement. Electrocardiogram (ECG) confirmed sinus arrhythmias without acute changes. BNP was normal (20 pg/mL). Pink, frothy secretions were found in the ETT. On physical examination, there were coarse breath sounds with bilateral crackles. Pertinent negative findings included wheezing, rhonchi, cyanosis, murmurs, peripheral edema, or jugular venous distention. Vitals were stable, and the patient was supported on volume control mode of ventilation. Furosemide was administered with the goal of negative fluid balance. There was complete resolution of pulmonary edema on subsequent day's CXR. The patient passed spontaneous breathing trial, and after confirmation of negative cuff-leak test, she was extubated successfully.

DISCUSSION: Recognition of NPPE is crucial as it is an uncommon but potentially life-threatening complication of elective surgery with reported mortality of 40 % (1). NPPE has two subtypes. Type 1 occurs acutely after inspiration against an upper airway obstruction including ETT or LMA, laryngospasm, or strangulation. Type 2 occurs after resolution of a chronic upper airway obstruction (1, 2). In type 1 NPPE, forced inspiration against an occluded airway causes negative intra-thoracic pressure, increased venous return, and increased left ventricular end-diastolic pressure leading to fluid extravasation from pulmonary capillaries into the alveolar spaces (2). Use of LMA is strongly associated with NPPE (1). NPPE usually affects young, healthy patients, as they can generate large negative intra-thoracic pressures (3). Clues from the anesthesiologist include difficult intubation or extubation, biting on tubing, or “bucking” the ventilator (3). Clinical presentation differentiates NPPE from other post-operative causes of hypoxia. Aspiration leads to chemical pneumonitis with abrupt dyspnea, tachycardia, fever, sputum, and infiltrates in selective tracheobronchial segments. Cardiogenic edema can be surmised by cardiac history, ECG or echocardiogram findings, or abnormal heart sounds (4). Acute bronchospasm presents with wheezing, small tidal volumes, prolonged expiration, and hypercapnia. Obstructive sleep apnea is exacerbated by narcotics, with prolonged and increased

frequency of apneas or desaturation. With laryngeal edema, CXR is normal, and wheeze is absent. Finally, recovery from NPPE is faster compared to acute respiratory distress syndrome. Therapy is supportive with correction of hypoxemia and establishment of a safe airway. Diuretics may be used judiciously to decrease intravascular volume and hydrostatic pulmonary edema. It is important to recognize NPPE as a complication of elective surgery because treatment is highly effective, and misdiagnosis could lead to hazardous therapeutic choices.

AN UNCOMMON CAUSE OF VERTEBRAL OSTEOMYELITIS AND PARASPINAL ABSCESS LEADING TO QUADRIPARESIS IN A HEALTHY YOUNG MAN Afaq Motiwala; Jenny C. Lee; Divyanshu Dubey; Oanh K. Nguyen. 1University of Texas Southwestern Medical Center, Dallas, TX; 2University of Texas Southwestern Medical Center, Dallas, TX; 3University of Texas Southwestern Medical Center, Dallas, TX. (Tracking ID #1938755)

LEARNING OBJECTIVE 1: Recognize coccidioidomycosis can present as disseminated disease in at-risk immunocompetent persons.

LEARNING OBJECTIVE 2: Recognize disseminated coccidioidomycosis as a potential cause of vertebral osteomyelitis and paraspinal abscess leading to quadriplegia in endemic areas.

CASE: A previously healthy 39 year old African American man presented to the emergency department with progressively worsening descending weakness of his bilateral upper and lower extremities. Three weeks prior to admission, he noted the onset of neck and shoulder pain, followed by hand clumsiness, decreased grip strength, increased stumbling and falls, and ultimate progression to an inability to lift his arms or walk. On the day of admission, he was bed-bound. Review of systems was notable for 15 lb weight loss over 4 months, night sweats, fatigue, and a ‘pustule’ over the sternum of 4 months’ duration, and negative for fever, cough, shortness of breath and altered mental status. He had no prior history of illness, did not take any medications and had no known sick contacts or high-risk health behaviors. Of note, he was a missionary in a small rural town on the northeast Mexican border and had also recently worked as an air conditioning repairman. Exam revealed a thin man in no apparent distress who was alert, oriented and appropriately responsive. Chest exam was notable for a 1×1 cm non-draining ulceration over the sternum; heart and lung exams were unremarkable. Neurologic exam was notable for 2/5 strength, decreased vibratory sensation, increased tone, and hyperreflexia in the bilateral upper and lower extremities; bilateral sustained ankle clonus; and decreased sensation to pinprick in the trunk (T4-L4 distribution). Cranial nerves 2–12 were intact and symmetric. Labs were notable for C-reactive protein of 2.9 mg/dL and erythrocyte sedimentation rate of 65 mm/h. Human immunodeficiency virus antibody was negative. Magnetic resonance imaging of the spine showed vertebral osteomyelitis and paraspinal abscesses at multiple spinal levels (C4-T1, T3-T4, L1-L2, S3-S4) with cord compression from C4-T1. Empiric broad-spectrum antibiotic coverage for methicillin-resistant *Staphylococcus aureus*, tuberculosis and brucellosis was initiated. Patient underwent cervical disectomy and incision and drainage to relieve cord compression. Surgical wound cultures, chest skin scraping and serum antibody tests were positive for *Coccidioides* spp. Dual antifungal therapy was initiated with amphotericin B for 6 weeks and fluconazole indefinitely.

DISCUSSION: Coccidioidomycosis is caused by inhalation of airborne spores of the fungus *Coccidioides*, endemic to the southwestern U.S. and parts of Central and South America. Approximately 60 % of individuals with primary coccidioidomycosis are asymptomatic. The remainder experience influenza-like symptoms, including cough, fever, arthralgias, myalgias, and fatigue. Progression from initial pulmonary infection to disseminated disease occurs in 5 % of symptomatic patients and 1 % of patients overall. Common sites of dissemination are skin and soft tissue, brain and spinal cord meninges, and bone. Risk factors for disseminated infection include cell-mediated immunodeficiency, pregnancy, male gender, and Filipino or African ancestry. Mainstays of therapy are oral azoles given for at least 6 months, or indefinitely in patients with immunosuppression or neuromeningeal involvement. Initial therapy with amphotericin B is recommended for disease that is rapidly progressive or involves a critical location (e.g., spinal column). Surgery is indicated with neurologic compromise, progression despite medical treatment, or refractory pain. In conclusion, disseminated coccidioidomycosis should be considered as a potential cause of vertebral osteomyelitis and paraspinal abscess in highly endemic areas, particularly among immunocompetent individuals with risk factors for disseminated illness.

AN UNCOMMON PRESENTATION OF A RARE PATHOGEN: CONSIDERING THE CAUSE OF PROLONGED HICCUPS Sarah Nickoloff; Anil Sharma; Jesse Martin. 1Medical College of Wisconsin, Milwaukee, WI; 2Zablocki VA Medical Center, Milwaukee, WI. (Tracking ID #1933243)

LEARNING OBJECTIVE 1: To recognize the differential diagnosis for prolonged hiccups.

LEARNING OBJECTIVE 2: To review the clinical manifestations and management of pulmonary actinomycosis.

CASE: A 67 year-old male with a 42 pack-year history of smoking presented to clinic with complaints of hiccups of 2 weeks duration and decreased appetite with nausea and vomiting over the past 4 days. He also had an 18-pound weight loss over the past 4 months. Past medical history was notable for a history of well-controlled hypertension and chronic low back pain. A chest X-ray demonstrated a $15.0 \times 8.3 \times 8.0$ cm soft tissue mass density in the posteromedial left lower chest that was felt to be consistent with primary lung cancer. Labs were remarkable for leukocytosis of 20.9 K/ μ L, new anemia, thrombocytosis, hyponatremia, hypokalemia, hypochloremia, hypobicarbonatemia, elevated BUN, and elevated creatinine. He was admitted, where he was afebrile with a physical exam significant for poor dentition, decreased breath sounds and dullness to percussion at the left lung base. A CT scan revealed a left posterior basilar pleural effusion with pleural thickening, thereby shifting the most likely diagnosis from lung cancer to empyema. The patient was started on intravenous piperacillin-tazobactam and vancomycin after becoming febrile to 101.6° F. A chest tube was placed and set to suction. Pleural fluid analysis was significant for white blood cell count of $95,920$ cells/ μ L (98 % neutrophils), pleural fluid to serum protein ratio of 0.3, pleural fluid to serum lactate dehydrogenase (LDH) ratio of 77, LDH greater than two-thirds the upper limit of normal, and pH of 7. The pleural fluid was determined to be exudative in nature with a pH of less than 7.2, therefore highly suggestive of an empyema. Pleural fluid Gram stain revealed branching, pleomorphic Gram positive rods, and culture grew *Actinomyces turicensis*. Antibiotic coverage was narrowed to oral amoxicillin/clavulanic acid. Over the course of his admission, the patient improved clinically with resolution of his symptoms. Leukocytosis resolved prior to discharge and regular chest X-rays during hospitalization demonstrated interval improvement in the empyema. Metabolic derangements improved with intravenous fluids and electrolyte replenishment.

DISCUSSION: Pulmonary actinomycosis is a rare, slowly progressing disease that can often present similarly to other infectious and inflammatory diseases, as well as mimic neoplastic processes. The responsible agent is the *Actinomyces* species, which enters the respiratory tract through aspiration of oral secretions. Risk factors include underlying pulmonary disease, alcoholism, and poor oral hygiene. Clinical manifestations are nonspecific and variable, though most common symptoms include cough, sputum production, hemoptysis, fever, chest pain, and weight loss. Radiologic manifestations can also vary and include consolidation, mediastinal and/or hilar lymphadenopathy, atelectasis, cavitation, or pleural effusion. Pulmonary actinomycosis is generally highly susceptible to penicillin; however, it typically requires a long course (6 to 12 months) of therapy. In addition to medical therapy, surgical or percutaneous drainage of abscesses or empyemas may be necessary, as was seen in this patient. This case underscores the importance of good oral hygiene and a high index of suspicion for this disease, particularly in patients with pulmonary symptoms and poor oral hygiene.

AN UNDERDIAGNOSED SYNDROME OF LOWER EXTREMITY PAIN AND WEAKNESS IN A PATIENT WITH DIABETES MELLITUS Daniele Massera; Darlene LeFrancois. Montefiore Medical Center, Bronx, NY. (Tracking ID #1936348)

LEARNING OBJECTIVE 1: Recognize the syndrome of diabetic lumbosacral radiculoplexus neuropathy as a cause of proximal muscle weakness and pain in patients with diabetes mellitus.

LEARNING OBJECTIVE 2: Manage diabetic lumbosacral radiculoplexus neuropathy with the use of steroids.

CASE: A 69 year-old man with a history of prior stroke and diabetes mellitus type 2 on insulin with a hemoglobin A1c level of 7.7 complicated by distal sensory neuropathy presented with 3 days of pain in his right thigh and inability to rise from a chair. He described the pain as constant at rest and worsening with standing and ambulation. He reported distal radiation of pain with a "shooting" quality and the sensation of leg swelling in the same distribution. Prior to the onset of his symptoms he could walk up to half a block with a cane, whereas now he was not able to stand without assistance. Motor exam did not reproduce pain but demonstrated moderately decreased strength of right hip flexors, quadriceps and hamstrings, and only mildly decreased strength of plantar flexion and extension. Tenderness to palpation of the right quadriceps without edema was noted. Reflexes were absent on both legs and sensation was decreased on both feet. Motor exam of the left leg was normal. The creatine kinase level was 154. Initial head CT showed prior infarction consistent with previous imaging, but no changes suggestive of recent ischemia. Nerve conduction

studies showed bilaterally reduced amplitudes of sensory and motor action potentials in both lower extremities suggesting axonal damage without demyelinating changes. Needle EMG demonstrated spontaneous activity of the right quadriceps with preservation of distal motor nerve integrity correlating with the neurologic exam. Magnetic resonance imaging of the lumbar spine and hips did not show structural causes of radiculopathy. A high level of clinical suspicion combined with characteristic EMG changes in absence of structural lumbosacral disease confirmed the diagnosis of diabetic lumbosacral radiculoplexus neuropathy (DLRPN). The patient's symptoms responded to a two-day course of methylprednisolone IV at a dose of 1000 mg/day. After treatment, his pain and weakness were markedly improved, and he was able to stand up and walk five steps without assistance.

DISCUSSION: Lower extremity pain and weakness are common presentations in primary care and hospital medicine settings. The differential diagnosis includes musculoskeletal, neurogenic and vascular etiologies, but also lesser known causes. In patients with diabetes mellitus associated with a multitude of neuropathies and pain syndromes, the differential is especially broad. The most important features of our case that prompted further investigation are objective proximal muscle weakness and pain irrespective of rest or action. DLRPN was first reported in a 1955 paper by Garland as "diabetic amyotrophy", and is prevalent in approximately 1 % of diabetics with a median age of 65 years. It was first described as unilateral syndrome of pain, weakness, wasting and areflexia with acute or subacute onset affecting buttock, thigh or the entire leg. It can progress distally or contralaterally, and is characterized by spontaneous recovery over months. Similarly to our patient, the syndrome can be, but is not necessarily associated with distal peripheral neuropathy. It usually affects diabetics with recent onset of disease and is unrelated to the degree of glycemic control. Weight loss and autonomic dysfunction are common features. Affected parts of the nervous system can include nerve roots, plexus or peripheral nerves. The etiology is largely unknown, but is thought to be due to ischemic injury of the affected axons by either microscopic vasculitis or metabolic derangements. Nerve conduction studies, electromyography and muscle biopsy are helpful diagnostic tools and typically reveal a multifocal process with primarily axonal degeneration. The natural course of this disease is characterized by debilitating pain and weakness for weeks to months causing considerable morbidity. Pain control with narcotic analgesics is often necessary in addition to non-steroidal anti-inflammatory agents. Several immunosuppressive therapies, e.g. steroids, intravenous immunoglobulin, cyclophosphamide and plasma exchange have been studied in small retrospective or non-randomized settings yielding conflicting results. One randomized double-blinded placebo-controlled trial of IV methylprednisolone in patients with DLRPN did not demonstrate a difference in improvement of the Neuropathy Impairment Score in the Lower Limbs (NIS-LL). However, improvement of pain and positive neuropathic symptoms was reported in the group receiving steroids. Our patient, who presented early in the course of the disease and was promptly diagnosed, responded to methylprednisolone with near eradication of pain and marked improvement of function.

AN UNEXPECTED CASE OF ACUTE HEPATITIS C Sophie Cai^{1,2}; Khendi T. White²; Brian Hoffman^{1,3}. ¹Harvard Medical School, Boston, MA; ²Brigham and Women's Hospital, Boston, MA; ³VVA Boston Healthcare System, Boston, MA. (Tracking ID #1940047)

LEARNING OBJECTIVE 1: Recognize challenges of acute Hepatitis C diagnosis and pursue appropriate work-up and treatment

LEARNING OBJECTIVE 2: Distinguish between hereditary hemochromatosis and secondary iron overload in patients with elevated iron studies

CASE: A 33-year-old otherwise healthy male veteran presented with 3 days of acute-onset scleral icterus, loose stools, and abnormal liver enzymes (AST 774, ALT 679, ALKPHOS 224, and T. Bili 7.8), with no other associated signs or symptoms by history or physical exam. He had been transferred from a four-month inpatient PTSD psychiatric hospitalization and denied history of alcohol abuse, IV drug use, blood transfusions, or needlestick injuries. He reported 2 years of no sexual activity. Family history was negative for liver or autoimmune conditions. Recent medication changes were notable for metformin initiation 10 days prior for an inappropriate diabetes diagnosis. Interestingly, he had been worked up 1 month prior for incidentally-found transient mild transaminitis (AST 75, ALT 80), at which time abdominal ultrasound had revealed fatty liver changes and viral hepatitis antibody panel had been negative. This transaminitis had been downrending at time of last follow-up 3 weeks prior to his admission. Our initial leading diagnostic hypothesis was metformin-induced hepatotoxicity based on case reports of metformin-induced liver injury and diarrhea and our patient's recent negative viral hepatitis workup. Four days after discontinuing metformin, however, his T. Bili and ALKPHOS began uptrending, later peaking at 12.7 and 244 respectively. To our surprise, comprehensive viral and autoimmune

antibody workup returned positive for HCV antibody, confirmed by RNA viral load. Serum iron studies were also elevated (transferrin saturation 72 %, ferritin 1957); HFE genotype was H63D/wt (unassociated with hereditary hemochromatosis). Liver ultrasound again showed fatty liver changes.

DISCUSSION: Acute Hepatitis C rarely presents symptomatically (15 % of cases). Encouragingly, symptomatic presentation predicts up to 67 % likelihood of spontaneous viral clearance, allowing a three-month watchful waiting period before therapy consideration. For those who do not spontaneously clear the virus, HCV genotyping and assessment of HIV status are important for guiding therapy. Just-FDA-approved sofosbuvir and other interferon-free direct-acting antivirals offer new hope to patients with historically poorly-interferon-responsive HCV genotypes such as our patient's HCV genotype 1b. In patients without known risk factors, diagnosis of acute Hepatitis C is often challenging. Proof of recent seroconversion, which allows definitive diagnosis, was possible in our case only due to the recent incidental transaminitis workup. Importantly, had we not ordered repeat hepatitis antibodies and relied on the previous month's negative results, we would have missed this critical diagnosis. Also of note, our patient's infection source remains uncertain—a not-uncommon problem in hepatitis patients. Thus, even in cases of low clinical suspicion, recent negative HCV antibody results should not preclude repeat evaluation. As HCV RNA and anti-HCV antibodies typically appear within 2 weeks and 6 months respectively of infection, healthcare-associated exposure in our long-hospitalized patient is one concerning possibility. In-depth repeat questioning also revealed possible history of a recently shared razor. Our patient's markedly abnormal iron studies, which returned before we had confirmation of our patient's acute Hepatitis C diagnosis, initially led us to suspect hereditary hemochromatosis. As hereditary hemochromatosis is known to be associated with HFE C282Y homozygosity (85–90 % of cases) and C282Y/H63D heterozygosity but not C282Y/wt heterozygosity, H63D homozygosity, or H63D/wt heterozygosity (our patient's genotype), we later recognized that our patient's underlying fatty liver disease was a possible cause of secondary hemochromatosis. In a recent retrospective review, Cherfane et al. report that failure to order and correctly interpret HFE genotyping among patients with elevated iron studies (transferrin saturation >45 % or increased ferritin) caused 38 % of patients with nonhereditary hemochromatosis genotypes to be inappropriately phlebotomized. Thorough workup and correct distinction between hereditary hemochromatosis and iron overload secondary to hematologic or chronic liver disease are critical to avoid such misdiagnosis. We look forward to following our patient's progress in the coming months. Given limited existing literature on acute Hepatitis C, we in particular plan to track whether fatty liver changes on ultrasound and elevated serum iron studies can occur secondary to acute Hepatitis C, as such associations with chronic hepatitis have been previously reported.

AN UNEXPECTED CASE OF BIGEMINY AND NON-SUSTAINED VENTRICULAR TACHYCARDIA Camille Clarke^{1,2}; Danny McCormick^{1,2}; Pieter Cohen^{1,2}; Deepak Thatai^{1,2}. ¹Cambridge Health Alliance, Cambridge, MA; ²Harvard Medical School, Boston, MA. (*Tracking ID #1939677*)

LEARNING OBJECTIVE 1: Recognize ventricular arrhythmias as an atypical presentation of pericardial effusion and cardiac tamponade.

LEARNING OBJECTIVE 2: Appreciate the utility of echocardiogram in elucidating etiologies of non-sustained ventricular tachycardia

CASE: A 68 year old Latino male with coronary artery disease and coronary artery bypass graft surgery 8 years prior presented with symptoms of progressive exertional shortness of breath for the past 3 months with acute worsening in the preceding 3 days. He endorsed mild palpitations during these episodes but denied any accompanying chest pain, orthopnea, dizziness, syncope or abnormal constitutional symptoms. On arrival, he was noted to have persistent bigeminy with a 5 beat run of ventricular tachycardia. Vital signs were within normal and electrocardiogram revealed sinus rhythm with persistent bigeminy but no ST-T segment changes. His basic metabolic panel was unremarkable, troponin negative and hematocrit 38. Chest x-ray showed minimal enlarged heart with no lung pathology. Physical exam revealed jugular venous distention to the angle of his mandible, lungs were clear and cardiac exam normal. On the night of admission patient had persistent bigeminy with significant couplets and a 40 beat run of ventricular tachycardia. He remained hemodynamically stable throughout. Echocardiogram was performed and showed inferoapical wall akinesia and two pockets of pericardial effusion behind the left atrium as well as a compressed right ventricle. He was transferred for cardiac catheterization, which revealed a patent cardiac graft but transudative pericardial fluid causing tamponade, which resolved after drainage.

DISCUSSION: Although ventricular arrhythmias have been reported as a presenting manifestation of metastatic or infectious cardiac arrhythmias it is an uncommon

presenting symptom of transudative pericardial effusion. Cardiac tamponade, a life-threatening condition, is caused by a slow or rapid compression of the heart due to pericardial accumulation and intrapericardial pressure. Classic findings such as distant heart sounds, pulsus paradoxus, elevated jugular venous pressure are helpful in diagnosis and chest imaging revealing cardiomegaly or electrocardiographic changes can help direct clinicians towards this diagnosis. These signs and symptoms are not always present, however, and their absence could be misleading thus a high index of suspicion should be maintained in certain clinical contexts. Our patient had a history of pericarditis and a pocket of pericardial fluid that accumulated and compressed his right ventricle, leading to cardiac tamponade with resultant ventricular arrhythmias. It is very likely that, in addition to the effusion, the stiffness of his pericardium from prior disease contributed to this large relative compression. Though ischemia was an appropriate initial suspicion given his history of coronary artery bypass graft surgery and cardiac risk factors, timely echocardiogram was imperative. Subcostal four-chamber view revealed both the size and location of the effusion, which was causing significant chamber compression that resolved once the effusion was drained. In summary, for patients with history of pericarditis, the appearance of ventricular arrhythmias should raise the suspicion for cardiac tamponade. Cases may go undiagnosed because typical associated clinical findings are absent or unapparent thus timely identification through emergent echocardiography plays a key role in confirming the diagnosis.

AN UNLIKELY SUSPECT: GROUP B STREPTOCOCCUS ENDOCARDITIS AND ASSOCIATED COMPLICATIONS Brianna S. Siegel; Wan L. Lam. Beth Israel Medicine Center, Mount Sinai Health System, New York, NY. (*Tracking ID #1925944*)

LEARNING OBJECTIVE 1: Diagnose atypical presentations of infective endocarditis.

LEARNING OBJECTIVE 2: Recognize group B streptococcus as an invasive pathogen in nonpregnant adults.

CASE: An 80 year old man presented to his primary care physician with severe lower back pain for 2 months and was treated with epidural glucocorticoid injections. Several weeks later he went to the hospital with worsening back pain, accompanied by fever and chills. Pertinent history included rheumatic heart disease (RHD) and osteoarthritis. Physical examination revealed the patient was febrile 39C, tachycardic to 110 beats per minute, blood pressure 117/57 mmHg with a grade 3/6 systolic murmur at left sternal border. There was warmth over the lumbar spine accompanied by severe tenderness to palpation. MRI showed septic arthritis of the L4-L5 facet joints. Laboratory results included leukopenia 3.4 k/uL and an elevated C-reactive protein 27 mg/dL. Patient was admitted for septic arthritis, and was broadly covered with Vancomycin and Cefepime. All 4 blood cultures grew Streptococcus agalactiae, and antibiotics were narrowed to Penicillin G. Transthoracic echocardiogram was completed which revealed severe prolapse of the anterior mitral valve leaflet with a mitral valve mass. Soon after, the patient noted right hand weakness with numbness and gait instability. MRI revealed multiple punctate foci of ischemia within the cerebellar hemispheres, occipital lobes, and corona radiata compatible with septic emboli. The patient underwent transesophageal echocardiogram confirming a 1.8 × 1.7 cm mobile mitral valve vegetation. A mitral valve replacement was done using a bioprosthetic valve. Pathology of the vegetation revealed gram positive cocci, consistent with group B streptococcus (GBS). The patient was treated with Penicillin G for a total of 8 weeks.

DISCUSSION: GBS is an established pathogen in pregnant women and neonates, rarely causing infections in other populations (incidence of 4.4 per 100,000). Risk factors for GBS infections are age >60 years, diabetes, malignancy, alcoholism and human immunodeficiency virus. RHD is a risk factor for infective endocarditis, seen in 6 % of cases. This patient was at risk for GBS endocarditis because of his age and history of RHD. The case illustrates the invasive potential of GBS in non-pregnant adults who have risk factors for infection. The initial presentation suggested steroid injections were the etiology of the septic arthritis. However, positive blood cultures and a heart murmur uncovered endocarditis as the underlying cause. We believe the septic arthritis and embolic strokes were complications of GBS endocarditis. This case highlights both the potential virulence of GBS in the elderly with a history of RHD and the variability in clinical presentations of infective endocarditis.

AN UNRESPONSIVE PATIENT? IT MAY BE SERO-TONE-IN Victoria Gutgars^{1,2}; Jonathan T. Cheah^{1,2}; Athina Vassilakis^{1,2}. ¹Montefiore Medical Center, Bronx, NY; ²Albert Einstein College of Medicine, Bronx, NY. (*Tracking ID #1936837*)

LEARNING OBJECTIVE 1: Recognize and diagnose serotonin toxicity in an unresponsive patient

LEARNING OBJECTIVE 2: Outline the initial management of serotonin toxicity

CASE: A 59-year old man with atrial fibrillation and prior stroke presented with a 2 day history of decreased interaction and responsiveness. At baseline, the patient was alert and oriented to time, place and person and was able to ambulate with assistance. Due to concerns for depression, Sertraline had been commenced 1 week prior to presentation with a subsequent episode of tachycardia to 120 bpm attributed to his atrial fibrillation. Initial vitals were significant for temperature 37.8 °C, blood pressure 173/118 mmHg and heart rate 95 bpm. Examination revealed a diaphoretic and unresponsive individual with no vocalization and localization to painful stimuli only. There was a resting tremor evident with increased tone, inducible ankle clonus and hyperreflexia bilaterally. White blood cell count was 7.9 K/UL, creatine phosphokinase 49U/L and basic metabolic panel unremarkable. Urine and serum toxicology were negative while blood and urine cultures were without growth. Imaging of the head (both CT and MRI) did not reveal any evidence of acute pathology. Sertraline was discontinued for possible serotonin toxicity with subsequent recovery to baseline level of functioning.

DISCUSSION: Admissions for acute changes in mental status are common. The initial differential is broad, encompassing infective, vascular, toxic and metabolic causes amongst others. The narrowing of this differential relies on obtaining a comprehensive collateral history, physical examination and initial investigations. Serotonin toxicity is characterized by a triad of changes in mental status, neuromuscular abnormalities and autonomic instability. History reveals the recent initiation, addition or change in dose of a serotonergic agent, generally within 24 h of presentation. Aids to the diagnosis of serotonin toxicity include the Hunter Toxicity Decision Criteria, reported to have a specificity of 97 %. Criteria include at least one therapeutic dose of a serotonergic agent within the past 5 weeks in addition to one of the following: spontaneous clonus, inducible clonus with agitation or diaphoresis, ocular clonus with agitation or diaphoresis, tremor with hyperreflexia, or hypertonia with temperature greater than 38 °C and ocular or inducible clonus. Furthermore, careful consideration should be given to other etiologies which can present in a similar fashion. For example, neuroleptic malignant syndrome may also manifest with the same triad of changes and an unresponsive individual. However, there will be prior use of dopamine antagonists and laboratory investigation often reveals elevated creatine phosphokinase, lactate dehydrogenase and transaminases. The spectrum of serotonin toxicity spans from mild to severe depending on the mechanism by which intrasynaptic serotonin is increased. The use of serotonin reuptake inhibitors may result in milder episodes, where patients present with a more indolent course. In contrast, in combination with monoamine oxidase inhibitors, moderately severe toxicity has been shown in 50 % of cases as the degradation of synaptic serotonin is additionally prevented. Severe toxicity can be seen with agents that cause the direct release of serotonin, such as Amphetamine. Regardless of severity, initial management comprises discontinuation of the serotonergic agent. Mental state changes such as agitation are often controlled with benzodiazepines, whereas physical restraints are not recommended as they can increase isometric muscle contractions resulting in lactic acidosis. Neuromuscular instability is addressed by halting excessive muscle activity through the use of benzodiazepines or non-depolarizing agents such as Vecuronium. Control of autonomic instability involves stabilization of pulse and blood pressure, with hyperthermia managed by external cooling and hydration, often requiring admission to the intensive care unit in severe cases. When initial management has failed, serotonin antagonists such as Cyproheptadine can be considered. In conclusion, the unresponsive patient can often prove a diagnostic challenge, but careful history taking and physical examination may help in providing clues towards the eventual diagnosis.

AN UNSOLVED MYSTERY CASE OF CENTRAL DIABETES INSIPIDUS

Ricardo Cruz; Jennifer Russo; Ryan Chippendale. Boston University School of Medicine/Boston Medical Center, Boston, MA. (Tracking ID #1935100)

LEARNING OBJECTIVE 1: Understand the differential diagnosis for central diabetes insipidus

LEARNING OBJECTIVE 2: Recognize the clinical features and diagnostic criteria of POEMS syndrome

CASE: A 26 year old male presented with complaints of dry mouth, polyuria, polydipsia, polyphagia, and a burning sensation in his lower extremities for 1 month. His physical exam was notable for a morbidly obese gentleman with decreased sensation of his lower extremities bilaterally. Labs demonstrated a markedly elevated serum sodium level (168), a low Antidiuretic Hormone (ADH) level (less than 0.1), and a serum and urine osmolality of 345 and 185 respectively, consistent with central

Diabetes Insipidus (DI). Pituitary function testing was notable for low total testosterone and leutinizing hormone consistent with hypogonadotropic hypogonadism. A brain MRI revealed a normal pituitary gland, hyperintensities within the cerebellum and corpus callosum, enlargement of the adenoids, and lymphadenopathy within the retropharyngeal and parotid nodes. Due to this an infiltrative cause of DI was suspected. Later that year, he developed acute respiratory failure secondary to diastolic heart failure, requiring placement of a tracheostomy and gastrostomy tube. At this time he was found to be anemic and have significant splenomegaly at 18 cm. Given the constellation of laboratory and physical findings, a unifying diagnosis of POEMS syndrome was considered. Further work-up resulted in T cell predominance on flow cytometry, a normal lactate dehydrogenase and haptoglobin level, and a monoclonal lambda gammopathy on serum and urine immunofixation. The vascular endothelial growth factor (VEGF) level was normal, and bone marrow was without evidence of plasma cell neoplasm, nonhodgkin lymphoma, or acute leukemia.

DISCUSSION: Central DI is a condition which there is lack of production of vasopressin by the pituitary. It is characterized by excessive urination and volume depletion leading to hyponatremia. Causes of acquired central DI include intracranial mass lesions, brain trauma, and infiltrative disorders including sarcoid or Langerhans Cell histiocytosis. POEMS syndrome is a rare paraneoplastic syndrome arising from an underlying plasma disorder. The acronym POEMS refers to some of the distinguishing features of the disorder including polyradiculoneuropathy, organomegaly, endocrinopathy, monoclonal plasma cell disorder, and skin changes (hyperpigmentation, hypertrichosis, flushing). Other potential features include sclerotic bone lesions, Castleman's disease (lymph node hyperplasia), pleural effusion, edema, ascites, and thrombocytosis. The pathogenesis of this syndrome is not well understood but thought to be due to elevated VEGF production that enables angiogenesis. Diagnosing POEMS is based on a composite of clinical and laboratory features. The diagnosis is made when both mandatory major criteria (polyneuropathy and monoclonal plasma disorder) are met, along with 1 out of 3 other major criteria (Castleman's disease, sclerotic bone lesions, and VEGF elevation), and 1 out of 6 other minor criteria are present (organomegaly, extravascular volume overload, endocrinopathy, skin changes, papilledema, thrombocytosis/polycythemia). Although suspicious for POEMS syndrome, after extensive work-up, this patient did not meet the major and minor criteria to solidify the diagnosis. Therefore, the primary etiology of this patient's central DI remains an unsolved mystery.

AN UNUSUAL CASE OF ACUTE BACK PAIN Gaurav Rao¹; Andrea Card². ¹Montefiore Medical Center of the Albert Einstein College of Medicine, Bronx, NY; ²Montefiore Medical Center, Bronx, NY. (Tracking ID #1939550)

LEARNING OBJECTIVE 1: Identify the clinical features of serious back pain

LEARNING OBJECTIVE 2: Recognize the significance of hypercalcemia in the setting of concerning back pain

CASE: A 56-year old male with past medical history significant for a MVA trauma 15 years prior with subsequent right below knee amputation and right upper extremity paresis as well as mild mental retardation presented with a 3 week history of back pain. After presenting to his internist 2 weeks prior and an urgent care a week prior with less severe symptoms, the patient presented to the emergency department with excruciating lower back pain that persisted at rest, nocturnally, and was refractory to the acetaminophen, NSAIDs, muscle relaxants and hot packs he had been prescribed recently. The patient denied a history of similar symptoms, recent trauma, weight loss, or intravenous drug abuse. He had an electrocardiogram notable for sinus tachycardia at 116 beats per minute, distant heart sounds, severe thoracic vertebral tenderness, and no other neurological changes from baseline. Laboratory results were significant for a white blood cell count of 26.9 k/µL, corrected calcium of 15.6 mg/dl (12.3 mg/ml 2 weeks prior and 11.3 mg/dl 3 months prior at his internist's office), ionized calcium of 6.3 mg/dl, and parathyroid hormone level of 18.9 pg/ml. Computed tomography of the abdomen revealed a hepatic and pancreatic mass, bilateral adrenal masses, lymphadenopathy and bony metastatic disease most prominent in the thoracic spine. A moderate size pericardial effusion was also visualized and confirmed with a transthoracic echocardiogram to be early cardiac tamponade and intrapericardial masses. Patient underwent a pericardial window the following morning and the pathology sent intraoperatively revealed adenocarcinoma of lung or hepatobiliary origin. The patient expired 2 weeks later on the floor secondary to pulseless electrical activity arrest unresponsive to resuscitation attempts.

DISCUSSION: Back pain is one of the most common presentations in the primary care setting, most commonly due to benign etiologies such as lumbar strain or sprain, degenerative disease or disc herniation. Most patients recover with minimal treatment, however proper evaluation is important to identify any serious underlying pathology especially if any key warning signs are present. Unremitting night pain or pain at rest,

unexplained weight loss and failure to improve with conservative therapy should raise concern for insidious etiologies. Laboratory testing such as a cell blood count, inflammatory markers may be beneficial when infection, neoplasm, or an inflammatory condition is suspected. Alkaline phosphatase and calcium levels can identify conditions that affect bone metabolism, such as Paget's disease or neoplasm, but are not needed in all patients with back pain. In our patient, the relentless, severe nature of the back pain were the warning signs and impetus for further work up. The subsequent hypercalcemia discovered was secondary to an increase in osteoclastic bone resorption in areas surrounding the metastatic malignant cells within the marrow space. This mechanism is responsible for 20 % of cancer related hypercalcemia with the rest predominantly PTHrP-induced. Cancers most commonly associated with direct metastasis to bone are cancers of breast, prostate, lung, lymphoma, thyroid, kidney and multiple myeloma. Hypercalcemia has been reported in 20–30 % of patients with cancer during the course of their disease and signifies a poor prognosis with approximately 50 % of such patients expiring within 30 days. Our patient had chronic gradual elevations of calcium for months explaining the lack of a clinical sequela suggestive of hypercalcemia such as neurological dysfunction or gastrointestinal symptoms, which is more common in acute elevations of calcium levels. Elevations above the body's tightly controlled range of calcium should prompt early investigation and be treated to allow time to target the primary process responsible. This case underscores the diagnostic challenge of back pain, which is typically benign but internists should be vigilant of the clinical signs and laboratory findings which warrant concern for a more serious etiology.

AN UNUSUAL CASE OF HYPERAMMONEMIA - A CASE FOR CAUTION

Ravneet Bajwa; Mayur Mody; Maryam Sattari. University of Florida, Gainesville, FL.
(Tracking ID #1940329)

LEARNING OBJECTIVE 1: Be familiar with hyperammonemia as an important idiosyncratic side effect of Valproic acid (VPA).

LEARNING OBJECTIVE 2: Recognize that VPA-induced hyperammonemia can occur even with normal VPA levels.

CASE: A 41-year-old male with a history of bipolar affective disorder presented with progressive altered mental status (AMS), lethargy, diffuse weakness, slurred speech and inability to perform simple activities of daily living which he had previously been able to do without difficulty. Vital signs were within normal limits. He was alert and oriented, but responded to questions slowly. Physical exam was otherwise normal. Labs revealed normal liver function tests. Ammonia level was 209 mcmol/L (reference range <60 mcmol/L). Head CT and chest x-ray were unremarkable. On review of patient's medications, psychotropic medications included clonazepam, valproic acid (VPA), risperidone, venlafaxine, and Fluphenazine. Free VPA level was 5 mcg/mL (reference range 5–25 mcg/mL). Since he did not have any evidence of liver disease and inherited urea cycle disorders seemed less likely, his hyperammonemia was thought to be secondary to VPA. VPA was discontinued and lactulose was started. Ammonia level decreased to 84 mcmol/L and his mental status improved within 24 h. In 1 month follow-up, ammonia level was 43 mcmol/L. Lactulose was discontinued. Patient continues to remain asymptomatic and has normal ammonia levels to date off VPA and lactulose.

DISCUSSION: VPA has been associated with increased serum ammonia levels, even in the setting of normal renal and hepatic function. A possible mechanism for hyperammonemia includes VPA's inhibition of carbamoyl phosphate synthase I (CPS I), an enzyme involved in the urea cycle. CPS I is ultimately responsible for converting ammonia to urea to allow excretion through the urine. With CPS I inhibition, plasma ammonia levels rise. VPA's binding to carnitine and coenzyme A results in a reduction in fatty acid use for energy needs and dysregulation of the metabolism of nitrogenous waste, disrupting the urea cycle even further. Clinical presentation varies from asymptomatic hyperammonemia to symptoms resembling hepatic encephalopathy. Patients may present with AMS, somnolence, and asterixis, without other clinical stigmata of liver disease. Workup should include VPA levels (which may be supratherapeutic or therapeutic as in our case), as well as evaluation of liver structure and function to rule out concomitant liver disease. If symptomatic, VPA may be stopped for a few days. Use of levocarnitine and high-flux hemodialysis has also been reported for treatment. Lactulose and non-absorbable antibiotics, such as rifaximin, reduce ammonia levels in acute treatment and can be used, in addition to dietary modifications (i.e. low protein diet), to prevent recurrences. While most cases of hyperammonemia with or without encephalopathy are due to liver disease, clinicians should be aware of unusual etiologies of hyperammonemia to prevent delay in diagnosis and treatment in patients without liver disease presenting with hyperammonemia. With the increasing indications and off-label uses of VPA, physicians should be aware of this potential complication of VPA and check ammonia levels in patients taking VPA who present with AMS.

AN UNUSUAL CASE OF PROLONGED FEVER OF UNKNOWN ORIGIN

Duminda Suraweera¹; John Sy¹; Elizabeth Akiyama²; Emil Heinze³. ¹Olive View-UCLA Medical Center, Sylmar, CA; ²Olive View-UCLA Medical Center, Sylmar, CA; ³Olive View-UCLA Medical Center, Sylmar, CA. (Tracking ID #1939182)

LEARNING OBJECTIVE 1: Recognize the broad differential diagnosis in patients presenting with FUO including infectious, rheumatologic, and oncologic causes

LEARNING OBJECTIVE 2: Consider the implications of all the tests performed when considering a broad differential diagnosis to elicit the most likely etiology of the clinical presentation

CASE: The diagnostic workup for fever of unknown origin (FUO) remains challenging despite advances in medical technology and testing. Herein we present an unusual case of FUO with several confounding historical elements that detracted from the ultimate diagnosis of giant cell arteritis (GCA). A 50 year-old Guatemalan male with a history of sinusitis presented to our hospital approximately 4 months after the onset of daily fevers as well as upper and lower extremity myalgias. Approximately 5 months prior to his hospitalization, his travels included a hiking trip in Minnesota and a spelunking (caving) expedition in Kentucky. Three weeks after returning to Guatemala, he developed the aforementioned myalgias and fevers. Despite his myalgias resolving and an extensive infectious disease workup done in Guatemala (the patient received multiple antibiotics for treatment of Helicobacter pylori infection, a helminthic infection, prolonged sinusitis, and a typhoid infection), his fevers persisted. Due to his travel history, an infectious etiology was initially again pursued. Initial lab abnormalities included an elevated WBC to 14.2 and platelets to 744. ESR and CRP levels were elevated to 105 and 294, respectively. His infectious workup was negative including HIV, PPD, peripheral blood smear for malaria, and tests for brucella, Histoplasmosis, rickettsia, Strongyloides, Lyme disease, acute hepatitis, coccidioidomycosis, syphilis, and cryptococcus. A CT revealed rectal wall thickening and non-specific pulmonary nodules without evidence of malignancy. A flexible sigmoidoscopy and colonoscopy were unremarkable. Blood cultures revealed 1 out of 4 bottles positive for Streptococcus parasanguinis with sterile urine cultures. Repeat blood cultures remained negative and both TTE and TEE were unrevealing for vegetations. He was subsequently treated for his presumed Streptococcal bacteremia. During hospitalization, the patient developed vertical diplopia with decreased vision of the right eye. Ophthalmologic examination revealed boxcarrying and a rheumatological workup was then pursued with specific concern for vasculitis. Further questioning revealed 3 episodes of blurry vision and diplopia in the previous 3 months that spontaneously resolved within 30 min. No abnormalities to the temporal artery were felt on examination and the patient never complained of headache. Myeloperoxidase (MPO) antibodies returned positive as well as rheumatoid factor and SS-B. SS-A, ANA, Anti-citrullinated peptide (anti-CCP) antibodies were also unremarkable. Although an MRI/MRA of his head did not show evidence of vasculitis, the presumed diagnosis of GCA versus ANCA associated vasculitis was given and he was initiated on pulse dose steroids followed by transition to oral steroids. A subsequent biopsy of his temporal artery was consistent with GCA and he was appropriately treated.

DISCUSSION: Low grade bacteremia without septicemia has been documented in otherwise healthy patients following oral manipulation. Since the patient had no symptoms of septicemia or infective endocarditis, an infectious etiology to his FUO was excluded despite having *S. parasanguinis* in one of four bottles. Given that subsequent blood cultures were negative, contamination was suspected. Workup for malignancy with imaging was also unremarkable, leaving a rheumatologic diagnosis as the most likely cause of his FUO. Previous studies on FUO have suggested that up to 22 % of FUO cases end up with rheumatologic diagnoses compared to only 16 % attributed to infectious causes. This patient's FUO was ultimately associated with his diagnosis of GCA after meeting 3 of the 5 criteria for diagnosis (age > or = 50 years, ESR>50 mm/h, and biopsy consistent with the diagnosis). GCA accounts for approximately 2 % of all cases of FUO, although rarely do patients not present with headache or visual symptoms. Despite his rheumatological work up revealing a positive SS-B and RF, the patient did not meet criteria for Sjogren's syndrome or rheumatoid arthritis, two other known causes of FUO. This interesting case presenting with an otherwise unrelated travel history highlights the diagnostic dilemma when faced with multiple positive results and confounding factors. A detailed history to elicit specific details the patient might not associate with his present illness is appropriate in such cases. With the workup of FUO, the need for a systematic approach is also stressed. Elimination of each cause of FUO will usually lead to the correct diagnosis as in this case. Finally, all results should be considered in light of the clinical presentation as tests can be positive without clinical significance.

AN UNUSUAL CASE OF STATIN-INDUCED MYOPATHY Laura Nichols; Kurt J. Pfeifer; Chamindra Konersman. Medical College of Wisconsin, Milwaukee, WI. (Tracking ID #1928602)

LEARNING OBJECTIVE 1: Recognize statin-associated necrotizing autoimmune myopathy (NAM) as a cause of prolonged muscle weakness and creatine kinase elevation after cessation of statin therapy

LEARNING OBJECTIVE 2: Diagnose statin-associated NAM utilizing clinical history and characteristic EMG and muscle biopsy findings

CASE: A 63-year-old woman presented with continued elevation of creatine kinase (CK) after discontinuation of statin therapy as well as waxing and waning proximal muscle weakness. She had been taking simvastatin for approximately 10 years but was transitioned to atorvastatin 1 year prior to onset of her proximal muscle weakness after undergoing repeat cardiac stenting. CK at that time was noted to be elevated to 10,829 U/L. Atorvastatin was discontinued, but CK levels continued to be elevated, ranging from 4000 U/L to over 10,000 U/L in the 2 years preceding her diagnosis. Serology was negative for myositis or connective tissue disease-associated antibodies. She had irritable myopathy on EMG, and necrotizing autoimmune myopathy was confirmed on muscle biopsy. The patient was diagnosed with statin-associated necrotizing autoimmune myopathy. She subsequently tested positive for an experimental anti-HMGCoA reductase antibody that is often present in patients with statin-associated NAM. The patient was treated with immunosuppressive therapy including high-dose steroids, methotrexate and intravenous immunoglobulin (IVIG) with significant improvement in her symptoms. She continues on these therapies currently due to the aggressive nature of her disease.

DISCUSSION: Self-limited statin myopathy has been described for several decades; whereas, statin-associated autoimmune necrotizing myopathy is an entity that has been described only in recent years. Though it is rare, statin-associated NAM is an important consideration in any patient who has prolonged symptoms of muscle weakness and elevated CK levels after discontinuation of statin therapy. In addition to consideration of alternative causes of muscle weakness, workup should include EMG and muscle biopsy. Signs of irritable myopathy on EMG and prominent necrosis with minimal inflammation on muscle biopsy are indicative of necrotizing autoimmune myopathy. In the future, anti-HMGCoA reductase antibody testing will likely be routinely available to aid in confirmation of the diagnosis. Given our patient's ten-year history of simvastatin use and onset of symptoms only after initiation of atorvastatin therapy, there is reason to suspect relation to therapy with specific statins and possibly a dose-dependent toxicity. Though there are no controlled trials to aide in treatment selection, immunosuppressive therapy using high dose steroids is the mainstay of treatment. Methotrexate is commonly used as a steroid-sparing agent, and IVIG is utilized for particularly severe cases. Though response rates to standard therapies are generally good with most patients showing partial or complete response, approximately half of patients relapse after tapering immunosuppressive therapies. Given these challenges, continued research is necessary to better define statin-specific and dose-dependent risk as well as optimal treatment for this condition.

AN UNUSUAL CAUSE OF A "BROKEN HEART" Altaf Dawood. University of Nevada School of Medicine, Las Vegas, NV. (Tracking ID #1926357)

LEARNING OBJECTIVE 1: Pheochromocytomas are uncommon neuroendocrine tumors that typically present with paroxysmal headache, nausea, palpitations and hypertension. Rarely, Catecholamine secretion from pheochromocytoma induces a clinical syndrome mimicking acute coronary syndrome known as takotsubo cardiomyopathy or "broken heart syndrome". "Reverse takotsubo" is an atypical variant of takotsubo's cardiomyopathy causing left ventricular basal hypokinesis with apical hyperkinesia. We present a rare case of reverse Takotsubo syndrome with underlying pheochromocytoma.

CASE: A 53 year old Caucasian male with past history of hypertension and type II diabetes mellitus presented with anginal chest pain of 1 h duration. Electrocardiogram revealed diffuse T wave changes and troponin later came back elevated at 6.1, concerning for acute coronary syndrome. He was emergently started on antiplatelets and anticoagulants and underwent left heart catheterization. Angiographic evaluation revealed normal coronaries. Interestingly left ventriculogram revealed severe basal akinesis with apical hyperkinesia, consistent with "reverse Takotsubo" or stress induced cardiomyopathy. Transthoracic echocardiogram post procedure showed an ejection fraction of 35 % with features consistent with "reverse Takotsubo". Patient was started on ACE Inhibitor and beta blocker for non-ischemic cardiomyopathy. During the admission patient was also noted to have elevated blood pressure reading of 170/105, but did not undergo any workup for secondary hypertension as an

inpatient. Patient was subsequently discharged after optimization of therapy for cardiomyopathy. Several months later patient was re-admitted with markedly elevated blood pressure of 190/118 associated with dyspnea. Patient at this admission was worked up for secondary hypertension which revealed evidence of pheochromocytoma. He was found to have elevated plasma and urinary metanephrines and normetanephrines. CT abdomen done which was consistent with 11.8×11.6×11.2 cm left sided abdominal mass centered at the level of adrenal gland with solid and cystic component. After consultation with endocrinology and endocrine surgery, patient underwent left radical adrenalectomy. The tissue stained was positive for chromogranin, synaptophysin, S- 100 consistent with a diagnosis of pheochromocytoma. In the 2 months following tumor removal, Patient symptoms completely resolved and 6 months following tumor removal, 2D echo showed normal left ventricular systolic function.

DISCUSSION: Takotsubo cardiomyopathy is a unique form of transient non-ischemic cardiomyopathy. Reverse takotsubo cardiomyopathy is a rare variant with similar pathophysiological causes as classic takotsubo cardiomyopathy. Recognition and management of underlying cause is important in patients with takotsubo cardiomyopathy particularly with recurrent symptoms to improve morbidity and mortality.

AN UNUSUAL CAUSE OF CHRONIC COUGH David J. Epstein. UCLA, Los Angeles, CA. (Tracking ID #1927629)

LEARNING OBJECTIVE 1: Understand the diverse manifestations of sarcoidosis. **LEARNING OBJECTIVE 2:** Know the diagnostic approach for suspected sarcoidosis, including how to rule out similarly-presenting disorders.

CASE: A 71-year-old woman with no significant past medical history presented with a cough, hoarse voice, and rhinorrhea. Her initial physical exam was unremarkable, and labs showed only mild anemia. After symptoms persistent with conservative management, a CT of the sinuses, neck, and chest was performed. Imaging showed no essentially no abnormalities of the sinuses or chest. However, CT of the neck showed a soft tissue density on the right side encasing the common carotid and internal carotid arteries and causing mass effect on the right oropharynx and hypopharynx with occlusion of the right internal jugular vein. PET-CT showed hypermetabolic activity of these masses concerning for lymphoma; in addition hypermetabolic lymph nodes were found diffusely in the mediastinum, hilus, abdomen, and pelvis. A subsequent rigid laryngoscopy showed right vocal cord paralysis. An ultrasound-guided biopsy of the right neck soft tissue mass showed granulomatous inflammation, though was paucicellular. A subsequent excisional biopsy of the right neck lymph node showed nonnecrotizing granulomatous lymphadenitis. Gram stain, silver stain, and AFB stains showed no organisms. Bacterial, mycobacterial, and fungal cultures were sterile. Multiple other studies, including serologies for HIV, Brucella, Bartonella, syphilis, toxoplasmosis, coccidiomycosis, histoplasmosis, and HTLV were non-reactive. Cryptococcal antigen and MTB interferon gamma release assay were negative. ACE level was elevated at 72. The patient was diagnosed with sarcoidosis. She was started on methotrexate and prednisone.

DISCUSSION: Sarcoidosis is a multi-system disease with an unknown etiology. Since it most commonly effects blacks between the ages of 10 and 40, clinicians may be less likely to recognize this condition in older non-black patients. Furthermore, since over 90 % of patients have lung involvement, patients with exclusively extra-pulmonary sarcoidosis may pose a diagnostic challenge. Almost every organ and organ system can be affected by the disease, including the skin, eyes, brain, musculoskeletal system, kidneys, and heart. The reticuloendothelial system can be involved, as in the patient above. Patients with sarcoidosis can have peripheral lymphadenopathy, hepatomegaly, and splenomegaly, with granulomatous involvement of these structures. Though most patients have an elevated ACE level, this finding has poor predictive value, therefore tissue diagnosis is almost always required. Histopathology demonstrates non-caseating granulomas. In combination with compatible clinical and radiographic findings, this finding on histopathology can confirm the diagnosis of sarcoidosis, but only when other disorders with similar presentations are ruled out. These include occupational lung diseases and hypersensitivity pneumonitides (in the case of lung involvement), tuberculosis, and histoplasmosis, among others. Therapy consists of oral glucocorticoids.

AN UNUSUAL CAUSE OF IRON DEFICIENCY ANEMIA : A CASE OF PICA FOR ANTACIDS IN A PREGNANT WOMEN Venu M. Ganipiseti¹; Keeley M. Hack²; Mojtaba Akhtari²; Harvey Friedman¹. ¹Presence Saint Francis Hospital, Evanston, IL; ²University of Nebraska, Omaha, NE. (Tracking ID #1934951)

LEARNING OBJECTIVE 1: Recognize the importance of monitoring the dosage of over-the-counter medications in all patients, particularly pregnant women.

LEARNING OBJECTIVE 2: Recognize the importance of educating pregnant women about pica and its potential complications.

CASE: Introduction: Pica is defined as an unusual craving and purposeful consumption of non-food substances for a period longer than 1 month. Even though, it is a commonly noticed phenomenon in pregnant women, it is frequently underestimated. Case: A 39-year-old, G6P5A0 Caucasian woman in her third trimester of pregnancy was referred to our medical center for evaluation of severe iron deficiency anemia (IDA). Her past medical history is unremarkable. At 34 weeks gestation, she presented to her local ER with severe nausea, vomiting and dehydration. She was found to have severe anemia despite reported compliance with her prescribed prenatal vitamins and supplemental iron. Her lab values were as follows: Hb 5.9 g/dL (normal range 12–16), MCV 73 fL (80–100), HCT 19.9 % (36–48), MCH 21.8 pg (26–34), MCHC 29.6 g/dL (30–37), RDW 19.2 % (11.5–15.5), Serum iron 97 (37–170), TIBC 613 (250–450), and Ferritin 4 ng/mL (8–250). She was transfused with 2 units of packed RBCs, set up for an outpatient IV iron infusion and referred to our hematology clinic. Upon evaluation and getting a detailed history and ruling out other possible causes of her IDA, it was found that she was taking calcium-carbonate antacid in unusual doses. During her pregnancy, she developed heartburn and began taking this medication as needed. She then developed craving for it and was taking approximately 15 tablets every day, which she continued for several months. She was instructed to stop taking the tablet, educated about pica and management of heartburn in pregnancy, and was treated with parenteral iron therapy.

DISCUSSION: The physiologic demands of iron are high during pregnancy and maintenance of iron homeostasis depends on intact absorptive and digestive processes of the gut. Any dietary factors interfering with iron absorption can have significant impact and can lead to iron deficiency anemia, which is associated with increased maternal and neonatal mortality during pregnancy. Calcium-containing antacids are generally considered to be safe during pregnancy, and are very routinely used. Several radioisotope labeling studies and single meal studies have suggested that calcium can be a major inhibitor of iron absorption. Also, due to its antacid property, it can alter the pH of the gut, further interfering with iron absorption. In our case, the patient was taking the antacids in excessive amounts after she developed craving for this medication. She did not mention this habit to her obstetrician and ER physician probably due to the possible embarrassment involved in discussing this unusual behavior. This unchecked behavior has lead to severe iron deficiency and would have been detrimental to both the mother and fetus, if it was unrecognized. Therefore, we stress the importance of obtaining a thorough and accurate medication history, including over-the-counter medications in all patients, particularly pregnant women. Pregnant women should be educated about pica and encouraged to discuss their dietary habits.

AN UNUSUAL PRESENTATION OF BURKHOLDERIA CEPACIA IN A HOSPITALIZED PATIENT Derar Albashaireh1; Marcus Zervos2. 1Henry Ford Hospital, Detroit, MI; 2Henry Ford Hospital, Detroit, MI. (Tracking ID #1934402)

LEARNING OBJECTIVE 1: *Burkholderia cepacia* is an important pathogen implicated in nosocomial infection. Its diagnosis should prompt a thorough investigation to identify the source.

LEARNING OBJECTIVE 2: In intravenous drug abusers, *Burkholderia cepacia* is likely related to IV drug injection with contaminated materials.

CASE: A 19 year old male Caucasian patient, with past medical history significant of intravenous drug abuse (IVDU), presented with progressive productive cough, fatigue and fever of 2 weeks duration. On initial presentation, the patient was found to be hypotensive, tachycardic and febrile. He was admitted to the Intensive Care Unit for management of severe sepsis. A few hours later, his blood cultures were positive for methicillin resistant *Staphylococcus aureus* (MRSA). A two dimensional Echo confirmed the diagnosis of infective endocarditis involving the right tricuspid valve. The patient was started on Vancomycin for therapy of infective endocarditis. The patient clinically improved with serial repeated blood cultures which were negative. He was transferred to the general medical floor and the plan was to treat him for 6 weeks with IV antibiotics. However, he started to exhibit a drug seeking behavior in the hospital. After 2 weeks of IV antibiotics, he spiked a persistent fever. Blood cultures at that time were positive for *Burkholderia cepacia*. After further investigations, syringes and needles were found in the patient's belongings by security personnel. Apparently, he was crushing his oral narcotics, diluting it with tap water and then injecting himself using non-sterile needles and syringes. He was treated with Piperacillin/Tazobactam, and his central line was removed. His fever

resolved after 2 days. He was treated with IV antibiotics for 6 days that was switched to oral Bactrim after he decided to leave the hospital against medical advice.

DISCUSSION: *Burkholderia cepacia* is a gram negative bacilli that is widely distributed in the natural environment and has been isolated from water, soil, fruits and vegetables. It was discovered in 1949 by Walter Burkholder at Cornell University in rotting onions. *B. cepacia* is of particular concern for patients with cystic fibrosis (CF), in whom it can cause chronic endobronchial infection. It also is a well-known nosocomial pathogen among non-CF-patient populations. Numerous outbreaks of *Burkholderia cepacia* have been traced to contaminated products in a hospital setting, including tap, distilled, or deionized water; contaminated chlorhexidine; topical anesthetic agents; benzalkonium chloride; povidone-iodine solution; and quaternary ammonium solutions. Other outbreaks have been traced to mouthwash, albuterol nebulizer solution, infusion solutions, albumin infusion, blood gas analyzers and respiratory-therapy equipment. In our case, the contaminated syringes and needles were the most likely source of *B. cepacia* infection. *Burkholderia cepacia* infective endocarditis has been reported in injecting intravenous drug users. To our knowledge, it has never been reported in IVDU as a result of drug injection in the hospital. Surprisingly, it has been also reported in patients without predisposing factors. *Burkholderia cepacia* is an important pathogen implicated in nosocomial infection. Its diagnosis should prompt a thorough investigation to identify an environmental source and prevent further spread. In IVDU it should be suspected as likely related to IV drug injection with contaminated materials.

AN UNUSUAL PRESENTATION OF RESPIRATORY SYNCYTIAL VIRUS Tricia G. Charles -Cowan; Mahmoud Abdelghany; Christopher Begley. Conemaugh Health Systems, Johnstown, PA. (Tracking ID #1938623)

LEARNING OBJECTIVE 1: Human Respiratory Syncytial virus should be included in the differential diagnosis of acute respiratory failure in immunocompetent adults.

CASE: Respiratory Syncytial Virus (RSV) is a common and major respiratory pathogen that affects the lower respiratory tract in young children and infants. Adults at risk are the immunocompromised, institutionalized elderly patients with cardiopulmonary disease. It is estimated that RSV is responsible for 25 % of excess wintertime mortality, previously attributed solely to influenza. We report a case of a 42-year-old male with a past medical history of obstructive sleep apnea, morbid obesity and diabetes mellitus who presented to our hospital complaining of dyspnea, fever and cough for 1 week. Patient reported a maximum temperature at home of 40° Celsius with a nonproductive, persistent cough. He was recently diagnosed and treated for community acquired pneumonia with a course of ciprofloxacin. On admission the patient was found to be hypoxic with an oxygen saturation of 82 %, tachypnic with a respiratory rate of 24/ min and hypotensive with a blood pressure of 94/ 60 mmHg. Chest X-ray showed air space opacities in both mid to lower lung zones. Laboratory evaluation was significant for acute renal failure with a creatinine of 4.7 mg/dl, blood urea nitrogen 60 mg/dl, and bicarbonate of 15 meq/L. Blood cultures, respiratory culture and rapid influenza A and B were negative. The patient was admitted to the intensive care unit due to clinical deterioration with progressive hypoxia and tachypnea, which required mechanical ventilation. RSV was detected in the blood and sputum using ELISA technique. Treatment involved supportive care including ribavirin, bronchodilators, ventilator support and hemodialysis for acute renal failure. He later developed acute respiratory distress syndrome and died of end organ failure and complications associated with his illness.

DISCUSSION: Although RSV is common in children and immunocompromised adults, it is a rare cause of severe respiratory failure in adults. The CDC reports that people of any age can get RSV, but later infections are generally less severe. Elderly and adults with cardiopulmonary disease or the immunocompromised are at a higher risk of developing severe RSV. Transmission occurs primarily through close contact with contaminated fingers or fomites and self-inoculation. In addition, transmission via coarse aerosol produced by coughing or sneezing can occur. RSV typically starts 4 to 6 days after exposure and presents with respiratory tract involvement including cough, sore throat, wheezing, fever, rhinorrhea and decreased appetite. Diagnosis is made with history, immunofluorescence or ELISA of nasopharyngeal washes and aspirates. Treatment is supportive and involves hydration, suctioning of secretions, and anti-bronchospastic agents. RSV is usually self limiting in adults. In severe cases mechanical ventilation may be required. Currently there is no vaccination approved by the FDA for RSV and prevention involves proper sanitary techniques. RSV is typically under-diagnosed in adults. With the awareness of possible serious complications we should be more vigilant in diagnosis and aggressive in the treatment of the adult population.

ANAPHYLAXIS MIMICKING ISCHEMIC HEART DISEASE IN KOUNIS SYNDROME Naoki Takamatsu; Christine Kwan. Teine Keijinkai Hospital, Sapporo-shi, Japan. (*Tracking ID #1929516*)

LEARNING OBJECTIVE 1: Recognize that vasospasm causing typical acute coronary syndrome (ACS)-symptoms may occur during anaphylactic shock

LEARNING OBJECTIVE 2: Suggest a role of allergic insult behind the pathophysiology of cardiovascular (CV) disease

CASE: A 73 years old Asian woman comes with 1 h, worsening, dull, post-prandial epigastric pain. She is just discharged from the hospital 2 weeks ago for acute on chronic pancreatitis; she now describes a similar pain but denies all other review of systems. The patient's medical history includes chronic pancreatitis, pancreas divisum, pancreatic calculus with endoscopic stenting, diabetes mellitus, and dyslipidemia; she takes glimepiride and atorvastatin. She has prior tobacco (88 pack-years) and daily alcohol use (quit 8 years ago) but no recreational drugs. She is allergic to a cefoperazone/sulbactam which causes a rash and itchy throat. Family history is not significant. On exam, her vital signs include temperature 36C, heart rate (HR) 71, blood pressure (BP) 132/75, respirations 16, and O₂ saturation 100% room air. She appears calm and alert/oriented ×3. Abdominal exam shows a soft abdomen and epigastric tenderness with no rebound/guarding; otherwise, her exam shows no irregularities. Her labs show leukocytosis (12,900/µl), amylase 430 IU/L, and lipase 1300 IU/L, likely acute on chronic pancreatitis. Gabexate mesilate is given, which she has previously used without complications, but 8 min later, she complains of dyspnea, chest pain, and chest/extremities' rash. Systolic BP drops to 40's with bilateral wheezes; gabexate is withheld while epinephrine 0.1 mg IV is given. She becomes unresponsive 5 min later with diaphoresis, systolic BP 60's, HR 120's, and O₂ saturation 80 % on 10 L reservoir mask. Another dose of epinephrine is given, and she regains consciousness 7 min later. Electrocardiogram reveals ST elevations in leads II, III, and aVF while echocardiogram shows a hypokinetic inferior wall, but coronary angiography has no abnormalities. While the anaphylactic shock has been managed with hydrocortisone, famotidine, and chlorpheniramine, nitroglycerin is given for coronary artery spasm. Recovery is uneventful with stenting for pancreatitis.

DISCUSSION: Kounis syndrome, first coincidentally described, is a manifestation of cardiac symptoms responding to an allergic stimulus. Any drug can trigger it although most are beta-lactams and contrast media. Meanwhile, anaphylaxis caused by the protease inhibitor gabexate rarely occurs, and no reports of Kounis syndrome induced by this drug has been found. The patient's newly developed ACS-symptoms during anaphylactic shock suggest involvement of vasoactive mediators' contractions of the coronary arteries. In this case, even with prior use, the culprit appears to be gabexate, and though few in number, reports suggest its careful monitoring >30 min after, especially repeat, use. Furthermore, evidence shows inflammatory cells' infiltrating atheroma plaques even before actual plaque erosion occurs, not only as an acute inflammatory response during the coronary event. Perhaps an allergic reaction in the pathophysiology of CV disease exists as well. Highlighted is the translational impact of the linkage between physiological allergic responses to clinical cardiac involvement. Its significance not only lies in recognizing a rare complication of anaphylaxis but also gives insight into future implications for identifying patients at risk.

ANCA-ASSOCIATED VASCULITIS PRESENTING AS INTERSTITIAL LUNG DISEASE Stephen A. McCullough; Nneka Ufere; Albert Yeh; Badri Modi; Kristian Olson. Massachusetts General Hospital, Boston, MA. (*Tracking ID #1930631*)

LEARNING OBJECTIVE 1: Diagnose ANCA-associated vasculitis (AAV) presenting as interstitial lung disease (ILD).

LEARNING OBJECTIVE 2: Recognize the utility of rituximab for AAV.

CASE: Mrs. P is a 71-year-old woman with hypertension and hypothyroidism who presented with fatigue and dyspnea. Over the course of 1 month, she noted that her normal daily activities such as walking and grocery shopping became increasingly limited by fatigue and dyspnea. She presented to her PCP for evaluation and had laboratory studies that demonstrated normal general chemistries and CBC; elevated inflammatory markers with an ESR of 85 and a CRP of 134.3; and a UA notable for 2+ blood. A CT chest/abdomen/pelvis revealed diffuse basilar prominent subpleural ground-glass opacities and traction bronchiectasis consistent with ILD as well as a new 5 cm × 3 cm lobular para-aortic mass. There was a plan to further characterize her abdominal mass with an MRI, but she became severely dyspneic prior to this study and was admitted to our hospital. On admission she was hypoxicemic to 80 % on room air, had increased work of breathing, and coarse bibasilar crackles. The remainder of her examination was unremarkable. Her admission laboratory studies were notable only for a positive ANA at 1:160; her general chemistries, CBC, anti-dsDNA, anti-

Sm, anti-Jo-1, RF, anti-CCP, complement, SPEP, and UPEP were otherwise normal. A repeat CT chest confirmed an increase in subpleural ground glass opacities predominantly in the lower lung zones consistent with a Non-Specific Interstitial Pneumonia (NSIP)-type pattern. Shortly after her admission she was started on high dose prednisone and transferred to the Medical Intensive Care Unit for profound hypoxemia. Given her tenuous respiratory status, a bronchoscopy and open lung biopsy were deferred. Four days after her admission, she was found to be acutely confused with left sided weakness in the context of new paroxysmal atrial fibrillation (pAF). She underwent an MRI which revealed an acute infarction in the posterior circulation, and TPA was administered with resolution of her neurologic deficits. Her MPO-ANCA then returned positive and she was started on cyclophosphamide, high dose prednisone, and she was anticoagulated with warfarin for pAF. She was intubated for progressive hypoxemia, though after completing 7 days of cyclophosphamide she was uneventfully extubated. Though she had improved, she continued to require between 4 and 6 L of supplemental oxygen at rest. As such, she was given rituximab as an adjuvant agent to reverse her pulmonary process. Four days after extubation, she developed a recurrence of pAF, worsening hypoxemia, and was found to have bilateral pulmonary emboli despite having a therapeutic INR. At this point, she was transitioned to low molecular weight heparin and her respiratory status slowly improved. Over the following week, her ANCA titer decreased to undetectable and she was ambulating without supplemental oxygen. Prior to discharge, she underwent a CT-guided biopsy to elucidate the etiology of her para-aortic mass, which revealed a lymph node infiltrated with a poorly differentiated carcinoma of Mullerian origin. She underwent three cycles of neoadjuvant paclitaxel and carboplatin therapy followed by total abdominal hysterectomy, bilateral salpingo-oophorectomy, retroperitoneal lymph node dissection, and omentectomy. Her final pathology revealed a microscopic high-grade serous adenocarcinoma in the left fallopian tube wall without evidence of metastatic disease. She has continued on adjuvant paclitaxel with plans to continue low molecular weight heparin until the end of her chemotherapy course and then potentially transition to warfarin therapy. Though she feels weak with chemotherapy, she remains improved, off oxygen, with only a borderline detectable ANCA and without evidence of malignancy.

DISCUSSION: This case highlights the need to consider AAV as a rare, reversible etiology of new pulmonary disease in a patient presenting with imaging findings concerning for ILD. In one retrospective analysis of 511 patients with AAV, 14 patients had a coexistent diagnosis of ILD, all of which had MPO-ANCA. Additionally, rituximab has come to the forefront in the management of patients with AAV. Rituximab has shown noninferiority to cyclophosphamide and steroids in inducing remission in AAV, and rituximab had no differences in maintaining the duration of remission or the frequency or severity of relapses from AAV. The combination of both rituximab and cyclophosphamide, as used in our patient, has yet to be studied.

ANCHOR ON NSAID Francis Lam; Laura K. Snyderman. Tufts Medical Center, Boston, MA. (*Tracking ID #1923051*)

LEARNING OBJECTIVE 1: 1. Recognize the importance of checking HIV status regardless of patient risk factors. 2. Illustrate the value of a thorough differential diagnosis and appropriate work-up of someone with intra-renal AKI. 3. Recognize the significance of urinalysis and urine electrolyte studies in predicting the cause of nephropathy.

CASE: A 39-year-old obese black man with DM2 presented after routine labs from PCP's office revealed a creatinine of 6.3 (0.9 1 year prior). A month ago, he used 1800 mg of ibuprofen daily for headache. For past 6 months, he reported polyuria but denied fever, chills, dysuria, hematuria, back or abdominal pain, URI symptoms, or sick-contacts. Patient appeared well. Blood pressure was 151/99 and HR was 98. He had no CVA tenderness or peripheral edema. Laboratory data showed Na 136, K 5.7, Cl 113, HCO₃ 14, BUN 43, creatinine 6.3, albumin 2.1, and Hgb 11.2. Urinalysis revealed SG 1.025, 3+ blood, 3+ protein, and 13 RBC without casts or eosinops. Twenty-four hour urine collection revealed 18 g of protein. Ultrasound showed bilateral enlarged and diffusely hypoechoic kidneys suggestive of an infiltrative process. Other negative results included ANCA, anti-GBM, RPR, SPEP/UPEP, viral hepatitis, and complement levels. HIV test returned positive, and biopsy revealed focal segmental glomerulosclerosis (collapsing variant) consistent with HIV nephropathy. A more detailed history regarding HIV risk factors was then obtained. He had many sexual partners in the past and had gonorrhea as a teenager. HIV was, therefore, most likely from unprotected intercourse in setting of multiple sexual partners.

DISCUSSION: This case demonstrates the importance of consideration of HIV nephropathy in patients with unexplained acute kidney injury. HIV nephropathy was first reported in 1984, and was highly associated with African American. Most had CD4 count above 200. It is characterized by proteinuria, and most had moderate to severe renal insufficiency by diagnosis. This case was a diagnostic challenge due to

various risk factors that could explain his acute kidney injury. Because FSGS described a histologic diagnosis, clinical presentation and progression speed depended upon its etiology. Which diagnosis explains such a rapid and remarkable presentation of proteinuria? Focal segmental glomerulosclerosis (FSGS) from obesity, NSAID, or minimal change disease would not give such high proteinuria. Lack of casts in his urine made diabetic nephropathy unlikely. Other risk factors associated with FSGS included HIV, heroin usage, and vesiculoureteral reflux. In this case, biopsy confirmed the diagnosis. Our approach to the diagnosis demonstrates a high potential for confirmation bias; one could have easily anchored on the history NSAIDs usage and turned a blind eye to evidence not consistent with NSAID-induced nephropathy. This is a reminder to always confirm that the objective evidence fits the history.

ANCHORING HEURISTICS IN DIAGNOSIS Anene Ukaigwe; Christain Espana-Schmidt. The Reading Health System, West Reading, PA. (Tracking ID #1939233)

LEARNING OBJECTIVE 1: Recognize anchoring heuristics and its effect on patient safety

CASE: A 90-year-old right-handed male came to the Emergency Department (ED) complaining of left upper extremity numbness and weakness lasting 15 min, 5 h ago at dinner. His past medical history included atrial fibrillation, CHADS2 score of four (for hypertension, age and previous stroke), hyperlipidemia, bilateral carotid stenosis and poor adherence to treatment recommendations. He had no other neurologic complaints. He had multiple ED visits in the preceding 6 months for dizziness and hypertensive urgency, refusing workup each times. BP on admission was 205/90 mmHg. The remaining vital signs and physical examination was unremarkable. CT brain did not reveal any acute changes. He received intravenous hydralazine in the ED for Hypertensive emergency. BP dropped to 130/70 mmHg and left upper extremity numbness returned. Symptoms again improved when BP increased to 175/100 mmHg. He was diagnosed with TIA; ABCD2 score of three and admitted. Twelve hours later, the symptoms returned. This time, his left hand was slightly cooler than the right on examination. Duplex scan revealed an occlusive clot in the brachial, radial and ulnar arteries. He underwent thrombo-embolectomy. Intraoperative findings showed fresh thrombus superimposed on an organized portion of clot suggestive of a cardio-embolic source. Post-operative course was uneventful. He was discharged home on anticoagulation.

DISCUSSION: Heuristics are the cognitive processes we develop for daily medical decision-making. They are “educated guesses” or “rules of thumb”. Heuristics hasten the decision-making process in time-constrained, performance-driven work environments. However, the danger lies in the potential risk for diagnostic and medical error. Medical errors have a huge impact on patient care and physician wellbeing. Of the various heuristics, our case illustrates anchoring heuristic. Anchoring heuristics, (premature closure) refers to reliance on initial diagnostic impression, despite information suggesting otherwise. This is exemplified in our patient, who was diagnosed as having a cerebrovascular accident and hypertensive emergency based on risk factors, hypertension and previous stroke, without extensive consideration of other peripheral vascular disease or embolic phenomena sharing the exact same risk factors. Although subsequent evaluation alerted the managing team to critical limb ischemia and averted loss of limb, the outcome could easily have been worse. Recent strides to improve patient safety have tackled errors with medical administration and reconciliation, healthcare-associated infections, and peri-operative complications. Unfortunately, diagnostic errors have received less attention, despite studies indicating that they are common and often due to cognitive shortcuts rather than knowledge deficits. Recognizing heuristics in daily practice and training is the first step to avoiding its disastrous consequences in patient care. Other ways to mitigate the effects of heuristics include simulation training to increase knowledge and experience, reflection-based strategies to improve clinical decision-making skills and provision of cognitive assistance through clinical decision support tools.

ANTERIOR MEDIASTINAL MASS-LUCKILY IS NOT CANCER! Rami Hazzi; Anil Kumar Reddy Anumandla; Gaurav Kistangari. Cleveland Clinic, Cleveland, OH. (Tracking ID #1936593)

LEARNING OBJECTIVE 1: Recognize that Silicone implant rupture can migrate.

LEARNING OBJECTIVE 2: Recognize that Silicone induced lymphadenopathy can be confused for malignancy.

CASE: A 56 year-old nonsmoking women with a history of rheumatoid arthritis, breast augmentation surgery followed by explant and silicone exchange due to implant rupture many years prior, presented with complaints of exertional dyspnea and palpitations for 1 month. Prior outpatient evaluation including echocardiography,

exercise stress test and pulmonary function tests were unremarkable. During one of her outpatient visits she was found to be hypoxic and was sent to the emergency department (ED) for further evaluation. In ED, her vital signs and physical examination were unremarkable. Initial cardiac evaluation was negative for acute coronary syndrome. Computed tomography (CT) chest ruled out pulmonary embolism but revealed a 2.7 cm anterior mediastinal mass with mediastinal adenopathy along with a left supraclavicular adenopathy. The patient was known to have left supraclavicular adenopathy, for which she underwent FNA that was negative for malignancy, a month prior to admission. During the hospital course episodes of supraventricular tachycardia were seen on telemetry that were controlled with Metoprolol. No episode of hypoxia or exertional drop in oxygen saturation was noted during her hospital stay. CT guided core needle biopsy of the anterior mediastinal mass was inconclusive and revealed necrosis and debris. Subsequently, due to increased concern for malignancy, thoracic surgery was involved and complete excision of the mediastinal mass and supraclavicular lymph node was performed by video-assisted thoracoscopic surgery (VATS). Left upper lung wedge resection was also performed due to the adhesions between mediastinal area and lung. Review of the surgical specimens showed no malignancy but rather fibrosis and foreign body giant cell reaction to lipid like material compatible with silicone. The lung biopsy revealed the same reaction predominantly within the alveolar capillaries and perivascular regions consistent with silicone emboli.

DISCUSSION: Silicone implants are widely used either for breast reconstruction surgery or for breast augmentation. Direct silicone injections into the breast tissue for augmentation were discontinued in the United States because of the widespread occurrence of adverse events, including the migration of silicone to distant sites. Implants were considered technically superior as the envelope and the scar capsule were designed to retain the gel and to prevent migration. However, Implant rupture can still occur and is often a late complication that can be either: intra capsular, extra capsular or migrated gel. Most ruptures have no obvious traumatic cause. The frequency of asymptomatic rupture is around 0.2-4 %. The silicone gel that migrates beyond the breast tissue incites an inflammatory reaction and silicone granuloma formation regulated by cell mediated immune reactivity and T cell stimulation. Silicone gel entering the lymphatics, either through overt implant rupture or slow leakage across the intact outer shell can result in regional migration to the draining lymph node basins. Migration may not be limited to the corresponding axillary lymph nodes and can spread to more distant sites such as internal mammary, inguinal nodes, and abdominal wall. Silicone leak can also spread in a retrograde direction once it reaches the jugular-subclavian venous confluence. The development of lymphadenopathy may raise concerns regarding new or recurrent malignancy. In addition, positron emission topography (PET) scanning may demonstrate positive FDG uptake in silicone-induced lymphadenopathy and further heighten the suspicion of malignant disease. Magnetic resonance imaging (MRI) is the imaging study of choice in diagnosing implant rupture. Individual plastic surgeons have recommended prophylactic removal of implants within 8 years of implantation to avoid the increased risk of rupture as the implants ages. Few have advised that in the absence of definitive studies, the source of silicone should be removed from patients with symptoms of systemic disease. Breast implant rupture should always be treated aggressively to prevent extra capsular spread, distant migration and inflammatory reactions. However it is not recommended to routinely screen women for implant leak without symptoms. Our case adds to a growing awareness of this phenomenon and emphasizes the need for continued vigilance for signs and symptoms of migration and to recognize silicone migration as a cause of lymphadenopathy in patients with breast implants, not to be confused with metastatic cancer or other malignancy or infectious disease.

ANTERIOR T WAVE INVERSION: HEART OR LUNG? LEFT OR RIGHT VENTRICLE? Naoki Misumida; Elisheva Levine. Beth Israel Medical Center, New York, NY. (Tracking ID #1925559)

LEARNING OBJECTIVE 1: Recognize anterior T wave inversion as a sign of right ventricular dysfunction in patients with pulmonary embolism.

LEARNING OBJECTIVE 2: Review the diagnostic and prognostic values of anterior T wave inversion in patients with pulmonary embolism.

CASE: A 62 year-old man with chronic hepatitis C presented with a three-day history of pleuritic chest pain and shortness of breath. The patient had no recent travel or immobilization. His blood pressure was 132/82 mmHg, pulse rate was 87/min, respiratory rate was 18/min, and oxygen saturation was 91 % on 2 L of oxygen via nasal cannula. Physical examination showed bilateral clear breath sounds without jugular venous distention or lower extremity edema and the cardiac exam was without any murmurs, rubs or gallops. EKG revealed sinus rhythm and T wave inversions in leads V1 to V4 with marked QT prolongation (QTc 606 ms). Laboratory results were significant for a D-dimer of 7.04 UG/ML and a troponin I of 0.117 ng/ml. Chest X-

ray revealed an enlarged right pulmonary artery silhouette. These findings raised the suspicion of pulmonary embolism and empiric anticoagulation with enoxaparin was started pending further studies. Subsequent chest CT angiography showed bilateral extensive pulmonary emboli. The patient was successfully treated with enoxaparin, which was transitioned to warfarin. Echocardiography performed on the following day revealed right ventricular dilatation and right ventricular systolic dysfunction, whereas left ventricular size and systolic function were within normal limits. Coronary angiography was performed to exclude concomitant coronary lesions, and no obstructive lesions were found. The patient remained normotensive during his hospital stay and did not develop any ventricular arrhythmia. A repeat EKG obtained 1 month later showed normalized T-waves and a QTc of 424 ms.

DISCUSSION: Acute pulmonary embolism can produce several EKG abnormalities including right bundle branch block, S1Q3T3 pattern, and anterior T-wave inversion. These EKG changes are called right ventricular strain pattern and reflect the severity of pulmonary hypertension. One large observational study, which reviewed EKG's of 354 patients with pulmonary embolism, found that anterior T wave inversion was seen in 32.2 % of the patients and S1Q3T3 pattern was seen in 8.5 % of the patients. T-wave inversion in V1-V4 had a positive likelihood ratio of 3.7. In addition to the diagnostic value, right ventricular strain pattern also carries a prognostic value; another study of 386 patients with pulmonary embolism revealed that right ventricular strain pattern was associated with an increased risk of all-cause mortality and clinical deterioration with a hazard ratio of 2.58. In this case, anterior T wave inversion was accompanied by a prominent QT prolongation. However, the prognostic value of this unique EKG change is unknown due to the limited number of case reports. In conclusion, early recognition of right ventricular strain pattern should alter the estimated pretest probability of pulmonary embolism and prompt more aggressive treatment before hemodynamic instability ensues.

ANTIBIOTICS NON-RESPONSIVE FOOT ULCER, RETURNED TRAVELER FROM BOLIVIA Hirokazu Ban; Stanley R. Yancovitz; Joseph Petrosric. Beth Israel Medical Center, New York, NY. (*Tracking ID #1927748*)

LEARNING OBJECTIVE 1: Recognizing possible cutaneous leishmaniasis for returned travelers who present with soft tissue infection with ulcer who do not respond to antibiotics.

CASE: The patient was a 64-year-old man with no significant past medical history who presented to Emergency department with a progressively worsening right dorsal foot soft tissue infection with a painless ulcer formation over 6 weeks-old. He had recently visited Bolivia and joined river fishing trip where he was bitten by a sandfly about 4 months prior to admission. The patient started to notice an erythematous papule on his right dorsal foot about 6 weeks prior to admission which was gradually getting bigger in size and swollen and erythematous. And in the last 4 weeks, the lesion was spreading thin and started to have a painless ulcer formation with a raised rim. This prompted the patient to see a primary infectious disease doctor. He was treated with total 4 antibiotics courses with broad spectrum coverage (Doxycycline → Augmentin → Ciprofloxacin → Linezolid → Bactrim) and itraconazole for considered spider bite, tick related infection or fungal infection by a infectious disease specialist and a dermatologist without any improvement. Finally, patient was referred to another infectious specialist and advised to come to emergency department for tissue biopsy for possible nocardiosis, sporotrichosis or lymphocutaneous leishmaniasis. He did not have a fever, chills, weight loss, night sweat, appetite loss, chest pain, shortness of breath, nausea, vomiting, or diarrhea through the clinical course. On admission, a physical examination revealed normal vital signs and a significant 3–4 cm erythematous wound with a necrotic base and perilesional erythema with ulcer formation on right dorsal foot and sporotrichoid nodules ascending up the leg and lymphadenitis in the upper thigh. Admission lab findings were not significant. A vascular surgeon was called and did debridement and sent the sample to pathology and deep wound culture which came back positive for Leishmaniasis. Given complications with lymphangitis, patient started liposomal amphotericin B IV for 7 days and was discharged. The patient has been followed as an outpatient and we've observed sign of healing.

DISCUSSION: Cutaneous leishmaniasis is the 10th most common dermatologic diagnosis among returned travelers but still there is some difficulty making a correct diagnosis, sometimes even by specialists. In fact, his physicians were misled by long latent period and possible exposure to tick related infection. A definitive diagnosis is made by identifying amastigotes in tissue or promastigotes in culture, or by amplifying Leishmania-specific DNA or RNA in a PCR. Most cases of cutaneous leishmaniasis will be resolved by themselves without any specific treatment but in some specific situations, especially people who have a higher risk of developing mucosal leishmaniasis, systemic treatment is recommended. There are no licensed

drugs for treatment of cutaneous leishmaniasis in the U.S. Intramuscular SbV treatment is the most common with a overall 76 % cure rate but which is not familiar drug among general practitioner. Even though there are no controlled studies, a recent small case series suggests liposomal amphotericin B can be used as a first choice drug which is commonly used among physicians. To prevent more serious complications from cutaneous leishmaniasis, it is important to make a correct diagnosis and appropriately treat those who have a risk of developing mucosal leishmaniasis.

APPROPRIATE RISK STRATIFICATION OF PATIENTS WITH ACUTE PULMONARY EMBOLISM Zohair Ahmed; Nikhil R. Kalva. University of Illinois College of Medicine at Peoria, Peoria, IL. (*Tracking ID #1939635*)

LEARNING OBJECTIVE 1: Management in the setting of acute pulmonary embolism (PE) is dependent upon massive vs. sub-massive classification. For those patients that exhibit features from both of these classifications, there is no clear-cut algorithm to guide management. Clinical judgment, experience, and comfort level are crucial when there is no risk stratification tool. Here we report a case of successful thrombolysis in a patient with delayed cardiopulmonary arrest due to a saddle pulmonary embolism.

CASE: A 43 y.o. male with a past medical history significant for recently diagnosed unprovoked saddle PE presented with recurrent shortness of breath. He attested to compliance with Coumadin. He denied any chest pain, hemoptysis, fevers, chills, cough or flu-like symptoms. His initial vitals revealed a blood pressure was 130/85, heart rate of 86, respiratory rate of 16 and an oxygen saturation of 88 % on room air. He subsequently was placed on 3 L nasal cannula with improvement in his oxygen saturation to 95 %. His cardiac exam revealed normal heart sounds, no JVD, and lungs were clear to auscultation. His CBC, CMP, CXR, Troponin, and BNP were all within normal limits. His INR was in the therapeutic range at 2.3. Electrocardiogram revealed sinus tachycardia. CT angiogram of chest revealed stable saddle PE, with no increase in clot burden. The patient got up to use the bedside urinal, and complained of excruciating calf pain followed by severe shortness of breath. He was now placed on 15 l of oxygen delivered via non-rebreather facemask. He was tachycardic at 135 beats per minute with a BP of 110/80. He seemed very anxious and now had developed mild hemoptysis. Stat 2D TTE showed severe RV dilation and hypokinesis. Since BP was stable and the patient did not meet criteria for massive PE, the decision was made not to administer tPA at this time. Catheter directed tPA was also deferred for the aforementioned reasons. Four hours later a code blue was called for respiratory arrest. Pulseless electrical activity was noted on the bedside monitor. ACLS protocol was initiated and the patient was successfully intubated. A stat order for tPA was given. Approximately 24 min into the code, tPA arrived; and all 100 mg of it was given IV push. Shortly thereafter, return of spontaneous circulation was noted with evidence of a strong carotid pulse and rhythm consistent with sinus tachycardia. Maximum vasopressor support with Norepinephrine, Epinephrine and Vasopressin was initiated, and the patient was placed on therapeutic hypothermia for neuroprotection. Ten days later, the patient was transferred to a general floor with all neurological function intact, and was eventually discharged home in good condition.

DISCUSSION: This case illustrates the need for continued use of available risk stratification strategies in patients with acute pulmonary embolism. While systemic tPA remains a viable option in patients with pulmonary embolism with cardiopulmonary shock, its role in sub-massive forms remains controversial. While we eagerly await the results of the multicenter PEITHO study addressing this question, all patients should be assessed carefully upon presentation for indications and contraindications for thrombolytic therapy to potentially minimize immediate and long-term complications of acute pulmonary embolism.

ARIPIPRAZOLE INDUCED AGRANULOCYTOSIS: A RARE BUT IMPORTANT ASSOCIATION Gautam George1; Patrick R. Aquino2; Dalar Nazarian3; Susan Krikorian3. 1Mount Auburn Hospital- Harvard Medical School, Cambridge, MA; 2Mount Auburn Hospital- Harvard Medical School, Cambridge, MA; 3Massachusetts College of Pharmacy and Health Sciences, Boston, MA. (*Tracking ID #1940055*)

LEARNING OBJECTIVE 1: To identify a rare association between aripiprazole and agranulocytosis and understand the risk factors of drug-induced neutropenia.

CASE: A 57 year old woman with a past medical history of major depressive disorder and a documented history of topiramate induced neutropenia presented with complaints of a painful right thumb after a burn injury. She reported an attempt at incision and drainage that was made by another doctor 5 days ago, that yielded only blood. She was initiated on sulfamethoxazole/ trimethoprim at that point of time. Examination of her thumb revealed an area of erythema and tenderness, with an area

of central induration. Her medications for depression included aripiprazole that was started a month prior to admission and fluoxetine. Upon admission her white blood cell 1290 cells/mcL and absolute neutrophil count was 0, consistent with agranulocytosis. Sulfamethoxazole/trimethoprim and aripiprazole were discontinued and she was initiated on daptomycin for a potential secondary skin infection to her burn injury. Filgrastim was also started because of profound neutropenia. She demonstrated immediate recovery of leukocyte count and the offending agents were discontinued.

DISCUSSION: Drug induced neutropenia is an idiosyncratic reaction that commonly occurs within 4 weeks of drug administration. Agranulocytosis is more commonly seen in patients above the age of 50, women and in those with a past history of neutropenia. Anti-epileptics, anti-thyroid drugs and certain antibiotics are common culprits. In our case the absence of pus prior to the initiation of trimethoprim/sulfamethoxazole made aripiprazole the likely offending agent. Clozapine is an anti-psychotic drug that has a classical association with agranulocytosis, hence routine leukocyte count monitoring is advocated. Newer atypical antipsychotics such as aripiprazole are considered to be safer alternatives to clozapine and routine leukocyte count monitoring is not recommended. The exact pathophysiology of psychotropic-induced blood dyscrasias is unclear, but proposed mechanisms include a direct toxic effect to myeloid precursors, immune mediated destruction and peripheral destruction of neutrophils. As agranulocytosis can lead to life threatening infections, we recommend vigilance when initiating aripiprazole and other psychotropic drugs especially in the setting of pre-disposing factors.

ASCITES: AN UNCOMMON PRESENTATION OF LUPUS Christopher H. Blevins¹; Clement J. Michet². 1Mayo Clinic, Rochester, MN; 2Mayo Clinic, Rochester, MN. (*Tracking ID #1928897*)

LEARNING OBJECTIVE 1: Recognize the Prevalence of Peritoneal Involvement in Lupus

CASE: An 84 year old man was transferred to our hospital for further evaluation and management of nausea, vomiting, diarrhea, a 40 lb weight loss and drenching night sweats. His illness narrative began 2 years ago with constipation but recently worsened to include the aforementioned symptomatology which prompted hospitalization. He had an extensive workup prior to arrival that included a PET-CT showing hypermetabolic mediastinal and axillary lymph nodes, a node biopsy that was negative for malignancy, an unrevealing bone marrow biopsy, an exhaustive infectious workup that was negative, an abdominal CT that showed mild to moderate ascites, esophagogastroduodenoscopy showing chronic duodenitis with biopsies that were negative for infiltrative disease and infection, and a colonoscopy that showed non-specific colitis. Before arrival, he also had an anti-nuclear antibody study that was positive. Upon our interview with the patient, his rheumatologic review of systems was positive for 2 years of sicca symptoms, photosensitive rash on his face, history of unprovoked deep vein thrombosis, pulmonary embolism, and morning joint pain and stiffness. On physical exam, he was ill appearing, receiving total parenteral nutrition, and his abdomen was distended and diffusely tender with signs of ascites. His labs revealed: white blood cell count of $1.9 \times 10^9/L$ ($3.5\text{--}10.5 \times 10^9/L$), ANA of 5.1 U ($<1.0 \text{ U}$), anti-RNP of 1.0 U ($<1.0 \text{ U}$), total complement of 12 U/mL ($30\text{--}75 \text{ U/mL}$), C3 of 67 mg/dL ($75\text{--}175 \text{ mg/dL}$), C4 of $<3.0 \text{ mg/dL}$ ($14\text{--}40 \text{ mg/dL}$), IgG beta-2 glycoprotein of 35.8 U/mL ($<10 \text{ U/mL}$) and IgA beta-2 glycoprotein of 14.6 U/mL ($<10 \text{ U/mL}$). His ascites fluid showed a SAAG of 0.9 g/dL . He met diagnostic criteria for systemic lupus erythematosus and was treated with Solu-Medrol 500 mg IV for 3 days before transitioning to oral prednisone with resolution of nausea, vomiting and night sweats. He was able to stop the previously started total parenteral nutrition feedings and return home.

DISCUSSION: Lupus peritonitis is a rare form of the serositis that is associated with systemic lupus erythematosus (SLE). SLE is an autoimmune disorder that can affect any organ, with one of the hallmark clinical signs being serositis. Serositis refers to the inflammation of the serous lining of the lungs, heart, and abdomen. This usually presents as pericarditis, which is seen in 39 % of patients with SLE, and pleurisy or pleural effusions, seen in 30 % of patients. However, the GI tract can be involved in 40 % of patients with SLE. It is thought that most of the GI complaints surrounding SLE are a result of non-steroidal medications, corticosteroids, or cytotoxic medications used for SLE therapy with only a small proportion having abdominal pain as a direct consequence of the disease. It is thought that 8–11 % of patients with SLE present with ascites secondary to lupus. However, autopsy studies suggest that 60 to 70 % of patients with lupus have had an episode of peritonitis.

ASEPTIC MENINGITIS AFTER INTRATHECAL STEM CELL INFUSION Arthi Balu, UCSD Medical Center, San Diego, CA. (*Tracking ID #1940354*)

LEARNING OBJECTIVE 1: Review causes and treatment of aseptic meningitis.

LEARNING OBJECTIVE 2: Consider the safety and ethical consequences of experimental procedures.

CASE: A 27-year-old male with partial T6 paraparesis presented with 1 day of fever, headache, nausea, vomiting, and altered mental status. His history was remarkable for intrathecal infusion of fetal neuronal stem cells one-day prior. Per the patient, the cells were injected in the L4-L5 space at a clinic in Mexico. The therapy was undertaken in hopes of regenerating spinal tissue and reversing his paraparesis. On exam he was extremely sound and light sensitive, oriented only to self, and had worsening of his right lower extremity weakness. CT of the head was unremarkable and MRI of the lumbosacral spine was negative for epidural abscess. Analysis of the CSF revealed 170 RBC/mm^3 and 6500 WBC/mm^3 with 75 % neutrophils and 24 % macrophages. CSF chemistries were notable for glucose of 33, and protein of 900 mg/dL . Gram stain was negative. IV antibiotics and dexamethasone were initiated for bacterial meningitis. CSF cultures failed to grow any organisms, and testing for streptococcus pneumoniae antigen was negative. By hospital day 3 the patient had significant improvement—he was afebrile for 72 h, alert and oriented, and his peripheral WBC had fallen from 16 to 8. A repeat LP revealed WBC of 250, glucose of 49 and protein of 60 mg/dL . Gram stain and culture were again negative. The rapid improvement in the patient's symptoms and CSF profile suggested a biochemical inflammatory meningitis due to the stem cell injection rather than true bacterial meningitis. The patients IV antibiotics and steroids were stopped. He continued to do well clinically and was discharged without further treatment.

DISCUSSION: Aseptic meningitis develops in the absence of pyogenic bacteria in the cerebrospinal fluid (CSF). The underlying cause may be viral, a drug reaction, or an auto-immune/inflammatory process. Though rare, aseptic inflammatory meningitis can occur after spinal injections. A CSF profile with elevated WBC and protein may not indicate bacterial meningitis in such cases. However, given the mortality of bacterial meningitis, initial management should include IV antibiotics and steroids. This treatment course can then be modified if gram stain and cultures are persistently negative. Of note, 3 days of antibiotics, though sufficient to sterilize the CSF, should have minimal effect on CSF cell counts and chemistries. Therefore, the rapid improvement of CSF abnormalities in this case along with negative cultures argued against a bacterial etiology. This distinction is important, as unlike bacterial meningitis, aseptic meningitis can often be managed with close clinical observation and pain medications alone. In drug-induced cases of aseptic meningitis, the offending agent should be withdrawn. Anti-virals may also be indicated if suspicion for HSV is high. Spinal stem cell injection has shown promise in regenerating spinal tissue in rat models, but has not been demonstrated to be safe or effective in humans. The immunogenicity of stem cells is under question, and there are no standards for the collection or administration of these cells. Despite the risks, these therapies are being marketed as curative by for-profit clinics. Such clinics overwhelmingly target the most vulnerable patients, who undertake great personal and financial risk in the hopes of a cure for their illness. As in this case, aseptic meningitis is one potential adverse effect of such experimental procedures.

ASYMPTOMATIC LARGE PITUITARY INCIDENTALOMA IN A PATIENT WITH SARCOIDOSIS Leena Jalota; Ana Abaroa-Salvatierra; Richard Alweis. Reading Health System, Reading, PA. (*Tracking ID #1934741*)

LEARNING OBJECTIVE 1: Pituitary hormonal deficits should be addressed accordingly to identification of the cause as primary, secondary or tertiary.

LEARNING OBJECTIVE 2: Work up of pituitary incidentaloma includes MRI imaging, hormonal lab testing as well as visual field testing.

CASE: A 52 year old male with pulmonary sarcoidosis presented to his allergist for excessive tearing. CT scan of sinuses ordered for possible blocked nasolacrimal duct revealed abnormal expansion of the sella turcica. MRI suggested a homogeneously enhancing 4 cm soft tissue mass centered in the sella turcica extending into both the left and right cavernous sinuses as well as abutting the optic chiasm. TSH, free t4, t3, LH, FSH, testosterone, GH, IGF-1 and 24 h urine cortisol levels were normal with only abnormality a minimally elevated prolactin (24.4 ng/mL ($2.64\text{--}13.13$)). Visual field testing was normal. Patient underwent trans-sphenoidal excision of the mass.

DISCUSSION: Pituitary incidentalomas are unsuspected pituitary lesions discovered on an imaging study performed for unrelated reasons, and are classified on the basis of size and hormonal activity. The most frequent deficit (30 %) is hypogonadotropic hypogonadism without hyperprolactinemia. The differential diagnosis of sellar incidentalomas is broad; in this case, given the pulmonary sarcoidosis, the initial concern was for neurosarcoidosis. However, almost all cases (91 %) of neurosarcoidosis were diagnosed with neurologic symptoms or clinical hormonal deficits, neither of which was present in our patient. Given the size of the tumor and the absence of visual field deficits, despite the displacement of the optic chiasm, this tumor likely had a slow growth pattern that usually corresponds to nonfunctioning

macroadenomas. Surgical indications include resection of hormonally active tumors and those displacing the optic nerves on imaging studies or cause field deficits, but the future management would be directed based on pathology and immunocytochemical studies

ATRIAL FIBRILLATION CAUSED BY INDWELLING PERIPHERALLY INSERTED CENTRAL CATHETER (PICC) Anene Ukaigwe; Paras Karmacharya; Madan R. Aryal; Adetokunbo Oluwasanjo. The Reading Health System, West Reading, PA. (*Tracking ID #1936732*)

LEARNING OBJECTIVE 1: Identify indwelling Peripherally inserted Central Catheters (PICC) as a cause of new onset arrhythmias

LEARNING OBJECTIVE 2: Evaluate and successfully treat PICC associated arrhythmias

CASE: A 22-year-old female with no previous cardiac disease was admitted for treatment of meningitis. A right-sided PICC line was placed in arm for intravenous access and antibiotic administration. Chest radiographs had showed the PICC tip at the aorto-caval junction. A day later, she complained of palpitations. These started within an hour of PICC placement. Symptoms were worse with lying flat, arm movements and deep breaths. Electrocardiogram (EKG) showed atrial fibrillation (AF) with atrial and ventricular rate of 210/min and 78/min respectively. Previous EKGs at admission and dating back 6 months showed sinus rhythm. The PICC was thought to be the likely cause of AF given the positional variation of symptoms. The PICC withdrawn 1 cm from its prior location. Immediately after this, she returned to normal sinus rhythm. Placement at the distal third of the Superior Vena Cava (SVC) was confirmed on chest radiograph. Thyroid function tests, complete blood count, electrolytes and echocardiogram were all within normal limits. She was asymptomatic and maintained sinus rhythm until discharge.

DISCUSSION: Peripherally Inserted Central Catheters (PICC) are commonplace in patients requiring long-term intravenous therapy in both inpatient and ambulatory settings but arrhythmias are an infrequent complication of indwelling PICC lines. While transient arrhythmias during PICC placement may occur, these resolve within minutes of insertion. Arrhythmias associated with indwelling PICC may be of atrial or ventricular origin and are caused by irritation of the myocardial wall by the tip of the PICC. Blind PICC placement at the bedside is a cost effective alternative to placement with direct radiologic guidance. However blindly inserted PICCs are less successful than those placed under direct vision (84 % v 100 %). Blinely placed PICCs are also more likely to migrate irritating the myocardium. Even uneventful and well placed PICCs, may still be complicated by arrhythmias due to PICC migration. Additionally, changes in body posture for example arm abduction, deep respiration and lying supine may vary the position of the PICC resulting in intermittent positional arrhythmias. Repositioning the PICC is often all that is needed for treatment of these arrhythmias; in our patient, the PICC was withdrawn from the aorto-caval junction into the distal third of the SVC for relief. More proximal PICCs that is proximal SVC increase the risk of PICC associated thrombosis while more distal placement may lead to cardiac complications including arrhythmias, cardiac perforation and tamponade. Cardioversion is rarely needed. About 0.9 % of the patients with central catheter associated arrhythmias eventually require cardioversion. In conclusion, the evaluation of new arrhythmias in patients with a PICC line should include assessment of the effect of postural changes on the PICC and the arrhythmias.

ATTENTION!! HENOCH-SCHÖNLEIN PURPURA CAN OCCUR IN ADULTS WITH ACUTE ABDOMINAL PAIN AS AN INITIAL SYMPTOM Kaname Uno¹; Some Furukawa¹; Masato Yoshihara¹; Shinichi Mizuno²; Yoshinori Kobayashi³; Hiroshi Yamasita³; Mitsunori Iwase¹. ¹TOYOTA memorial hospital, Toyota, Aichi, Japan; ²TOYOTA memorial hospital, Toyota, Aichi, Japan; ³TOYOTA memorial hospital, Toyota, Aichi, Japan. (*Tracking ID #1929572*)

LEARNING OBJECTIVE 1: Note that abdominal pain can be the first symptom of Henoch-Schönlein purpura (HSP).

LEARNING OBJECTIVE 2: Recognize that the prognosis of the renal function is worse in adult HSP than in children.

CASE: A 67-year-old woman with a history of sigmoid colon cancer which was completely resected by laparoscopy 3 years before, complaining of acute abdominal pain. Five days before the admission, she developed acute abdominal pain, which was intermittent and sharp around epigastric area. Since her condition did not improve at all for 5 days, she was presented to our hospital. Vital signs were not remarkable but there was tenderness at the epigastric area and left lower area of the abdomen without rebound tenderness. Other physical examinations were not remarkable. On laboratory studies, WBC, CRP and D-dimer were elevated, 24300 /µL, 8.9 mg/dL, 14.8 µg/mL

respectively. Abdominal CT image showed the thickening of the duodenum, which made her diagnosed with either acute gastroenteritis or ischemia enteritis in the duodenum and fluid therapy was initiated. Four days after the admission, in addition to abdominal pain, arthralgia of both wrists and left ankle occurred. At the same time, the purpura suddenly appeared in the legs and urine protein became positive. From these findings, HSP was suspected. The renal biopsy revealed mesangial IgA deposition and additional blood test found coagulation factor 13 decreased, which led to the final diagnosis of HSP. After the diagnosis, steroid pulse therapy was initiated for 3 days followed by oral corticosteroid therapy. Additionally, we conducted steroid pulse therapy for three times and continued oral corticosteroid therapy. At present, her creatinine is 1.34 mg/dL and urine protein is 1.37 g/day, which suggests an irreversible renal failure has already progressed.

DISCUSSION: HSP is the most common acute vasculitis in children, but relatively rare in adults. Patients with HSP present with purpuric rash, which is the most common initial symptom in both adults and children. On the other hand, some patients have only abdominal pain in early phase of HSP like this patient. In these cases, it is very difficult to differentiate the diagnosis of HSP. Some reported that the severe inflammation of duodenum is the first sign of HSP. Although the differential diagnosis for epigastric pain is broad, which include acute coronary syndrome, gastric and duodenal ulcer, acute pancreatitis, gastroenteritis and the first stage of appendicitis, other diagnosis such as HSP should be included, especially if there is an inflammation of duodenum. In general, patients with HSP who present with abdominal pain as the initial disease-related symptom have a significantly higher probability of developing nephrotic syndrome. The clinical presentation of HSP is severe in adult patients and the renal prognosis for HSP is poor compared with that of children. The percentage of patients with HSP nephritis that progress to renal failure or end stage renal disease has been reported to be around 16 % in adults. In our present case, the renal function may worsen in the future. In summary, there are some adult patients with HSP whose renal prognosis are worse than that of children. Clinician must keep in mind that abdominal pain can be the initial symptom of HSP, which can lead to renal failure in the end.

ATYPICAL CASE OF THROMBOCYTOPENIA Claire Campbell; Eugene Lee. California Pacific Medical Center, Pacifica, CA. (*Tracking ID #1939648*)

LEARNING OBJECTIVE 1: Recognize the clinical and laboratory manifestations of atypical Hemolytic Uremic Syndrome (HUS) as a cause of thrombocytopenia.

LEARNING OBJECTIVE 2: Review the management of atypical HUS, including the use of Eculizimab, a terminal complement inhibitor.

CASE: A 39-year-old Asian female with no significant past medical history presented with 2 weeks of gingival bleeding and epistaxis. She also noted increased fatigue, frequent urination, and dark urine. She denied any fevers, chills, headaches, change in mental status or recent diarrheal illness. Her physical exam was significant for elevated systolic blood pressure of 170, gingival bleeding and petechiae over her bilateral lower extremities. There were no signs of hepatosplenomegaly or lymphadenopathy. Significant laboratory findings included platelets of 6,000, hemoglobin of 8, creatinine of 2.24, and BUN of 28. Peripheral smear did not reveal schistocytes. After platelet transfusion, her platelet count dropped. High dose intravenous steroids and a dose of intravenous immunoglobulin (IVIG) resulted in no change in her platelets. ADAMST13 activity was normal, C3 was low, C4 was normal, and LDH was elevated. Stool shiga toxin and CD 59 were negative. Bone marrow biopsy was negative. Given her renal failure, negative stool antigen, low C3, and lack of response to steroids and IVIG, atypical HUS was suspected. She received five cycles of plasmapheresis with modest improvement in her platelets and renal function. After receiving one dose of Eculizimab, an inhibitor of the complement pathway, her platelet count improved to 76,000 and her creatinine dropped to 1.73. She was then scheduled for weekly Eculizimab as an outpatient.

DISCUSSION: Hemolytic uremic syndrome should be suspected in patients presenting with thrombocytopenia, renal dysfunction and hemolytic anemia. Ten percent of HUS is not caused by shiga toxin or bacteria such as *Streptococcus pneumoniae*. Atypical HUS is caused by genetic abnormalities of complement regulation. In those patients without diarrheal illness, atypical HUS should remain high on the differential, but etiologies such as leukemia, paroxysmal nocturnal hemoglobinuria, HIV, ITP and TTP should be excluded. No gold standard test exists for atypical HUS, but given its high mortality rate, frequency of progression to end-stage renal disease, and limited treatment options, it must be considered. In this patient, atypical HUS was exemplified by low C3, normal C4, hemolytic anemia, thrombocytopenia, and renal failure. Her failure to respond to platelet transfusion and steroids are typical as well. Plasmapheresis may temporarily improve thrombocytopenia, hemolytic anemia, and renal failure, but recurrence occurs in up to 70 % of

patients depending on the complement mutation. No randomized clinical trials exist, but use of plasmapheresis may decrease mortality from 50 to 25 %. Renal transplant is contraindicated given rejection rates as high as 90 %. Eculizimab, an antibody that blocks terminal complement formation, has been shown in phase 2 trials to improve renal failure, decrease dialysis requirements, increase platelet counts, and improve quality of life. Eculizimab is also hypothesized to reduce recurrence rates. Our patient had a drastic improvement in platelet count and renal function with a single dose, significantly more than with five cycles of plasmapheresis. Because it is a weekly to bi-weekly infusion, management can occur as an outpatient, as was the case with our patient. This case highlights how Eculizimab holds great promise for the treatment of atypical HUS.

ATYPICAL PRESENTATION OF NEUROMYELITIS OPTICA Zachary D. Horne; Paul Koffer; Benjamin Lloyd. The Reading Hospital, West Reading, PA. (Tracking ID #1939244)

LEARNING OBJECTIVE 1: Recognize the challenges in differentiating neuromyelitis optica (NMO) from multiple sclerosis (MS)

LEARNING OBJECTIVE 2: Recognize the importance of aggressive treatment in NMO

CASE: The patient is a 37 year old male with a history of cutaneous marginal zone B-cell lymphoma s/p XRT 3 years prior with a recently unremarkable PET scan who was sent to the ED for back pain, progressive parasthesias, bladder and bowel dysfunction, and abnormal spinal MRI findings. There was no precipitating illness or trauma. In the month prior to admission, the back pain gradually progressed. At the same time, he began to experience numbness and tingling of the right foot which became bilateral and gradually rose to the level of the waist. In the week prior to hospitalization, numbness extended to the umbilicus and groin with difficulty emptying his bladder and moving his bowels. He had no weakness until 5 days prior to presentation. He denied any visual changes or eye pains. CT of the head was negative. Thoracolumbar spine MRI showed an enhancing lesion at the level of T1-T4 and a non-enhancing lesion further inferiorly to the level of T11 as well as a T7 vertebral body lesion. Multiple vertebral spine marrow signal changes were also noted. B12/folate were normal. An LP done in the emergency department showed an increased protein level of 67 mg/dL (nl: 20–45 mg/dL). CSF studies were negative for IgG index, ACE, lyme, oligoclonal bands, or bacterial growth. A serum NMO antibody was ordered as a send out lab. At that time, the differential was felt to include recurrent lymphoma, transverse myelitis, spinal cord tumor, metastasis, neurosarcoidosis, Behcet syndrome, HIV, or less likely NMO or an MS variant. He was given a single dose of 10 mg IV decadron followed by 4 mg IV q6h for 48 h with a 60 mg prednisone taper over 6 days. With steroids his numbness/weakness improved dramatically. Two days later, he only had some numbness in the distal legs and perineum. Repeat MRI of the spine at that time showed moderate improvement of the thoracic cord with decreased enhancement and edema. He was discharge home with the prednisone taper. Following his discharge, the serum NMO antibody returned positive. He returned to the hospital 5 days later, the day following his last dose of prednisone, complaining of recurrent numbness up to mid-chest. He denied any eye pain or visual changes but was again constipated. He was given an infusion of rituximab 1 mg IV and started on solumedrol 500 mg BID for 5 days followed by prednisone 60 mg PO daily as maintenance. His symptoms improved significantly and he was discharged with appropriate follow up in place. He was scheduled for additional a rituximab infusion 2 weeks following discharge. Seven days following the second discharge, however, he returned to the hospital complaining of increasing weakness in both legs and parasthesias below T4. He had had mildly blurry vision while watching TV 3 days prior to returning, but denied current eye pain, visual loss, or diplopia. Repeat spinal MRI showed overall improvement of the originally abnormal thoracic and cervical signals without new or worsening lesions. He was transferred to an outside institution at that time for plasmapheresis and further management.

DISCUSSION: Because they are both demyelinating disorders, NMO and MS can be difficult to differentiate at initial presentation. Key differences between the two diseases include the prevalence of abnormal findings on brain MRI in MS, CSF neutrophilic pleocytosis with anti-myelin oligodendrocyte glycoprotein in NMO, higher levels of glial fibrillary acidic protein in NMO than MS, and the presence of anti-aquaporin 4 water channel IgG antibodies in NMO. Unvalidated diagnostic criteria for NMO have been proposed for the differentiation of NMO from MS, but not all cases fit these criteria, as there is a spectrum of NMO-like disorders, such as in our patient who presented without initial visual symptoms. A small minority of NMO cases can be monophasic, but the vast majority have a relapsing course which can present with optic neuropathy and myelopathy in any order or simultaneously. Most of the disability from NMO results from these relapses, unlike in MS where

secondary progression is the culprit. Thought here are no randomized-controlled trials evaluating the efficacy of various treatment regimens for NMO, current treatment proposals include early and aggressive steroid immunosuppression with high-dose methylprednisolone to be followed shortly thereafter by plasmapheresis. Maintenance immunosuppression should be utilized for up to 5 years because of the risk of relapse.

AUTOIMMUNE HEMOLYTIC ANEMIA WITH VTE: COMMON COMPLICATION OF A RARE DISEASE Sonikpreet Sonikpreet; Karthikeyan Venkatachalam; Jasleen Kaur; Alaeddin Maeza; Sarwan Kumar. Crittenton Hospital/ Wayne state university, Rochester, MI. (Tracking ID #1938391)

LEARNING OBJECTIVE 1: Autoimmune hemolytic anemia (AIHA) is a rare disorder in which RBCs are prematurely decreased by either IgG or IgM auto-antibodies. VTE is a more serious, acute and often lethal complication of AIHA. There are many mechanisms described for the prothrombotic state in patients with AIHA; despite the thrombotic implications, risk of VTE is often overlooked.

CASE: We are presenting a case of 76 y/o female with AIHA associated with extensive proximal DVT. Seventy-six year old F with PMH of PUD & HTN was admitted with complaint of SOB on exertion since 1 month and near-fainting episode a week ago. On admission, her Hb was 3.8. Pertinent physical examination findings revealed conjunctival pallor but no evidence of bleeding, lymphadenopathy or Hepatosplenomegaly. Lab studies revealed elevated LDH, high retic count, Hct 11.8, MCV 128.4 and spherocytes on peripheral smear. Further investigations showed positive IgG Ab on coomb's test. GI and MM work up was negative. Patient's Hb started improving after blood transfusion and IV steroids. After 1 week, she presented with right leg swelling found to have DVT involving right common & proximal femoral veins; left common femoral & popliteal veins.

DISCUSSION: Although rare in incidence, AIHA is the most common cause of acquired hemolytic anemia. Several studies including a review of 47 patients with AIHA supporting the existence of a prothrombotic state in patients with AIHA revealed that PE was the most common cause of death. But the risk for PE is often neglected, leading to fatal consequences.

AUTOIMMUNE NECROTIC MYOPATHY AS A RARE SIDE EFFECT OF STATIN THERAPY Colleen Pater; Alda Maria Gonzaga. University of Pittsburgh Medical Center, Pittsburgh, PA. (Tracking ID #1937103)

LEARNING OBJECTIVE 1: Pursuit of an alternative unifying diagnoses when a disease course is not proceeding as expected in the outpatient setting

LEARNING OBJECTIVE 2: Recognition of autoimmune necrotic myopathy as a rare side effect of statin therapy

CASE: A then-70 year old Vietnamese female was noted on routine screening to have hyperlipidemia in July 2009. Her LDL did not significantly improve with lifestyle change, so she was started on monotherapy atorvastatin in October 2009. She tolerated the medication well for approximately 2 years, during which time her LDL cholesterol improved to goal. In February 2012, the patient presented for evaluation of falls and generalized weakness. She reported difficulty climbing stairs and lifting her arms and legs, as well as diffuse achiness. Physical exam was notable for bilateral, symmetric, proximal muscle weakness. Laboratory evaluation showed mild elevation of muscle enzymes with significant elevation in creatine phosphokinase (CPK) to 6300. Symptoms were felt consistent with statin-induced myopathy, and atorvastatin was stopped at that time; ezetimibe was started for hyperlipidemia. The patient reported clinical improvement in muscle weakness over the next month although CPK remained elevated at 5500, prompting a rheumatology referral. In March 2012, rheumatology evaluation noted a decreasing CPK, with a negative myositis panel, ANA, Sjogren antibodies (patient also complained of dry eyes), and serum protein electrophoresis. Electromyography was consistent with myopathic process and a left bicep muscle biopsy showed chronic and moderately active inflammatory myopathy. Differential diagnosis at the time included polymyositis/dermatomyositis, inclusion body myositis, and statin-induced myopathy. Interestingly, the myositis panel resulted in an S35 immunoprecipitation with bands suggesting the presence of an unidentified autoantibody. No immunosuppressive medications were started as CPK began downtrending and the patient slowly started improving, both subjectively and on physical exam. However, in August 2012, CPK rose again although the patient reported her strength was almost back to baseline. Ezetimibe was stopped. CPK remained elevated through March 2013 and the patient again presented with a slight decrease in muscle strength, both subjectively and on physical exam. She also was experiencing early symptoms of dysphagia. At this point, the patient was started on prednisone 1 mg/kg daily. MRI of bilateral thighs in May 2013 was normal and repeat electromyography again showed a diffuse chronic and active myopathic process.

Muscle biopsy of left deltoid in May 2013 showed mild subacute, active necrotizing myopathy that seemed most likely autoimmune related; the clinical correlation was felt to be related to HMG-CoA autoantibody. After approximately 2 months of steroid therapy, the patient's strength began to improve and a taper with weekly methotrexate therapy was started. Since then, the patient has continued to recover strength and her CPK has normalized, even with a decrease in steroids and methotrexate. She continues to focus on dietary modifications to lower her cholesterol.

DISCUSSION: Statin-induced myopathy is a well-known side effect of statin therapy and ranges in severity from asymptomatic elevations in muscle enzymes to life-threatening rhabdomyolysis. Most patients present within the first 6 months of therapy, with resolution of symptoms an average of 2 months after cessation of therapy. This patient's initial presentation was consistent with statin-induced myopathy, but her symptoms did not improve with statin cessation. Further outpatient evaluation yielded a diagnosis of necrotizing myopathy. Recent case reports and small series indicate an immune-mediated necrotizing myopathy associated with statin use that persists after statin withdrawal. Symptoms can relapse with the addition of other lipid-lowering agents. Patients improved with immunosuppressive therapy and had frequent relapses when treatment was tapered, suggesting an immune-mediated etiology. Further investigation found a novel autoantibody at 200 and 100kd with a strong association to the immune-mediated necrotizing myopathy and very recently the autoantigen has been identified as HMG-CoA reductase, the pharmacologic target of statins. It is unknown at this time whether our patient's S35 immunoprecipitate is this autoantigen, but certainly the remainder of her clinical presentation and course are consistent with autoimmune statin-associated necrotizing myopathy. Thus, the pursuit of a different unifying diagnosis when our patient's disease did not progress as expected uncovered a rare complication of statin therapy and re-directed her medical therapy appropriately.

AVOIDING DIAGNOSTIC PITFALLS IN THE RECOGNITION OF DRESS SYNDROME: CONSIDER "SAYING YES TO THE DRESS!" Hili Rosen; Daniel I. Steinberg; Alfred Burger. Beth Israel Medical Center New York, New York, NY. (Tracking ID #1936000)

LEARNING OBJECTIVE 1: Recognize that lamotrigine is a cause of DRESS syndrome.

LEARNING OBJECTIVE 2: Recognize that DRESS syndrome and ACEI induced angioedema can look similar in presentation

CASE: A 70 year-old female with HTN, CAD on an ACE inhibitor (ACEI) and schizophrenia treated with lamotrigine for 2 months presented to the ER with facial puffiness of unclear duration. Angioedema due to her ACEI, accupril, was diagnosed. Accupril was stopped, and the patient was given one dose of dexamethasone, and discharged. Two days later, she returned to the ER with continued facial puffiness along with a full body rash and sore throat. On admission, vitals were T: 99.7, P: 102, RR: 18, BP: 97/62, O₂: 96 %. Physical exam revealed diffuse macular rash with desquamation, lip fissures, and cervical lymphadenopathy. Labs from her initial ED visit were significant for AST=585U/L, ALT=655U/L, AlkP=144U/L, TBili=2.1 mg/dL, eosinophils 14 %. On current admission, labs were AST=1272U/L, ALT=1229U/L, AlkP=156U/L, TBili=2.3 mg/dL, eosinophils 12 %. The patient reported no abdominal symptoms, no history of liver disease, and no alcohol use. Hepatitis panel was negative for hepatitis A and C, and indicated previously cleared hepatitis B. Ultrasound of her abdomen showed no liver disease or obstruction. Drug reaction with eosinophilia and systemic symptoms (DRESS syndrome) caused by lamotrigine was diagnosed. Upon review, it was felt her initial ER presentation was early signs and symptoms of DRESS rather than ACEI induced angioedema. During the patient's hospitalization, her bilirubin peaked at 9.4 mg/dl (direct=5.3 mg/dl) and INR at 2.4 within days of each other. On third day of admission, the patient was started on prednisone 50 mg. Her symptoms and labs normalized over the next 2 weeks and the patient was discharged.

DISCUSSION: Drug reaction with eosinophilia and systemic symptoms is a drug hypersensitivity reaction that commonly presents with a desquamative skin rash, peripheral blood eosinophilia, and involvement of other organs. Lamotrigine is one of the most common causes, and has been reported to cause DRESS in 1/1,000 to 1/10,000 exposures. Liver involvement is often mild, with transient transaminitis and elevated alkaline phosphatase levels. We present a case of DRESS that was initially missed, as it was felt to be ACEI induced angioedema instead. This case highlights the importance of medication reconciliation, including medication durations, and of conducting a thorough review of all potential medication side effects in patients presenting with angioedema-like symptoms. Also, more careful consideration of the initial LFT abnormalities could have allowed for broadening of the differential diagnosis, reducing clinicians' bias towards ACEI induced angioedema, and recognition of the "illness script"—the pattern of history and physical findings—for

DRESS. A separate clinical learning point is that case reports have found that DRESS patients with a high bilirubin and INR have increased mortality and increased need for liver transplantation. In our patient, this association did not hold true. Clinicians should be aware that patients with these lab abnormalities may still do well, as our patient did.

B IS FOR BACTERIA: FEVER, NIGHT SWEATS, AND UNINTENTIONAL WEIGHT LOSS Victoria Chia; Roxana Aminabhksh; Xiangdong Xu; Ramin Motarjem. UCSD, La Jolla, CA. (Tracking ID #1923851)

LEARNING OBJECTIVE 1: A subacute course of systemic symptoms requires a broad differential diagnosis. Though rare, Whipple's disease is important for clinicians to keep in mind.

CASE: A 48-year-old Hispanic man presented with 2 weeks of spiking fevers, night sweats, and unintentional weight loss of 10 lb in 30 days. He denied diarrhea, abdominal pain, hematemesis, and melena. Of note, he endorsed 1 year of bilateral hip osteoarthritis. Physical exam revealed bilateral inguinal and left axillary lymphadenopathy. The patient was found to be anemic and leukopenic with hemoglobin of 9.0 and WBC of 2.7. Abdominal CT showed mesenteric and retroperitoneal lymphadenopathy. The patient was admitted for workup for neoplastic and infectious etiologies. Throughout hospitalization he continued to spike periodic fevers and was transfused for hemoglobin of 7.6 on hospital day 3. Nutrition was consulted due to weight loss and poor oral intake. Infectious workup ruled out HIV, CMV, EBV, hepatitis, and tuberculosis. Upper endoscopy showed Candida esophagitis which was treated with nystatin. The patient was discharged on day 5 with improved energy and appetite. Duodenal biopsy pathology revealed numerous PAS-positive, AFB-negative rod-shaped microorganisms engulfed by foamy histiocytes consistent with Whipple's disease, confirmed by PCR assay on axillary lymph node biopsy. One month of daily intravenous ceftriaxone was initiated, achieving a dramatic clinical response within 2 weeks. This was followed by 1 year of oral antibiotic therapy.

DISCUSSION: First described by George Hoyt Whipple in 1907, Whipple's disease is caused by the bacteria *Tropheryma whippelii* and has an estimated worldwide incidence of 12 new cases per year. [1] It is described as presenting in stages, with a prodrome of oligoarthralgia preceding diarrhea and malabsorption. [2], [3] It is diagnosed by histopathology showing PAS-positive, AFB-negative stain of infected tissues, and PCR assay of biopsy specimens. [4] Although the causative organism primarily infects the gastrointestinal tract, the disease can also have cardiac [5], [6] and neuropsychiatric [7], [8] manifestations. Based on his clinical presentation of "B" symptoms and lymphadenopathy, non-Hodgkins lymphoma and HIV were highest on the differential for our patient. This case illustrates the potential for Whipple's disease to present with systemic symptoms consistent with hematologic malignancy or immune deficiency. We recommend that physicians be aware of the variable presentation of Whipple's disease and to consider a prodrome of oligoarthritis in raising suspicion in a patient presenting with systemic symptoms. BE CAREFUL WHAT YOU ASK FOR: SYSTEMIC LUPUS ERYTHEMATOSUS AND IMMUNOSUPPRESSION Merrill H. Stewart. Tulane University School of Medicine, New Orleans, LA. (Tracking ID #1939986)

LEARNING OBJECTIVE 1: Identify common non-HIV populations at risk for Pneumocystis pneumonia (PCP)

LEARNING OBJECTIVE 2: Know when to start PCP prophylaxis in patients on chronic immunosuppressive agents for rheumatologic disease.

CASE: A 43 year-old woman presented with 5 days of chest pain and subjective fever. The chest pain was noted to be sub-sternal, constant, and pleuritic. She also endorsed a cough productive of white sputum and shortness of breath. Her past medical history was remarkable for Systemic Lupus Erythematosus on chronic

prednisone and hydroxychloroquine for 1 year, with a recent decrease in her prednisone dosage. She was tachypneic, hypoxic to 90 % O₂ saturation on room air, with bilateral basilar crackles and decreased breath sounds at the left base. The JVP was not elevated, with a tachycardic regular rhythm on auscultation. No pulmonary embolus was seen on computed tomography. Chest X-Ray revealed diffuse bilateral pulmonary infiltrates with bilateral pleural effusions. A good left ventricular ejection fraction and small pericardial effusion were seen on an echocardiogram. White blood count was elevated at 13.9 thousand cells/ μ l, and sputum stain was positive for *Pneumocystis jirovecii*. She was treated with IV Trimethoprim-Sulfamethoxazole and high dose corticosteroids resulting in clinical improvement.

DISCUSSION: Despite its association with HIV, any immunocompromised population is at risk for PCP, particularly those on chronic glucocorticoid therapy like our patient, or with a hematologic malignancy. Other groups include those with rheumatologic diseases, solid organ and hematopoietic transplants, primary immunodeficiencies, and severe malnutrition. Among those on chronic glucocorticoid therapy, the highest risk of infection is seen when an additional immunosuppressive agent such as cyclophosphamide, rituximab, methotrexate, or hydroxychloroquine is used. Often PCP is seen in these populations when the glucocorticoid dosage is reduced. Guidelines for PCP prophylaxis in the non-HIV immunosuppressed population are primarily based on consensus. In general patients who receive greater than 20 mg daily of prednisone for 1 month AND have an additional cause of immunosuppression (malignancy, additional immunosuppressive drug) should be on prophylaxis. An exception being when prednisone is used with methotrexate for rheumatoid arthritis for which no prophylaxis is needed. Recommended therapy for prophylaxis in the non-HIV population is identical to the HIV population, with Trimethoprim-Sulfamethoxazole being first line treatment followed by atovaquone and dapsone. Trimethoprim-Sulfamethoxazole has been associated with an increased incidence of lupus flares, so atovaquone is often used as a first line agent in these patients. We see that our patient was on both prednisone and hydroxychloroquine for many months therefore she most likely would have benefited from some prophylaxis that could have prevented her infection and hospitalization.

BELL'S ISN'T RINGING Brian Cruz; Paul Jacob. Tulane University Health Sciences Center, New Orleans, LA. (*Tracking ID #1926996*)

LEARNING OBJECTIVE 1: Identify the common symptoms of lateral medullary infarction

LEARNING OBJECTIVE 2: Recognize stroke as a potential cause of peripheral facial nerve palsy.

CASE: A 61-year-old man presents with dysphagia after inability to swallow his morning medications. He also complains of weakness, headache, and vomiting. He has hypertension and a history of a stroke with minimal residual deficits. He is prescribed antihypertensives but frequently misses doses. He is in no acute distress. He has complete left-sided facial weakness but facial sensation is intact. It is difficult for him to swallow and his voice is hoarse. He has right-beating nystagmus on gaze to the left. Gait is not tested given concern for falls but he has full strength in all extremities. Blood pressure is 243/122 mmHg. The remainder of his physical exam and vital signs are normal. Computed tomography scan reveals an old area of encephalomalacia within the right frontal lobe and chronic small vessel disease, but no acute intracranial hemorrhage. Initial diagnosis is Bell's palsy and hypertensive urgency. The following day he continues to have left facial paresis and nystagmus, and also has uvula deviation to the right on palatal raise. Magnetic resonance imaging of the brain reveals a focal ischemic lesion located at the pontomedullary junction extending along the left cerebellar peduncle, within the perfusion territory of the posterior inferior cerebellar artery (PICA). Other, less well-defined anomalies are seen in the left cerebellar hemisphere in the PICA distribution. The location is consistent with lateral medullary infarction.

DISCUSSION: Strokes are common and require immediate recognition. Stroke syndromes that lack characteristic features, however, can easily be missed. Also, there is considerable variability in the findings of certain stroke syndromes. Our patient was initially misdiagnosed with Bell's palsy, which did not explain his nystagmus, difficulty swallowing, or "weakness", which was determined to be disequilibrium. His symptoms were due to an occlusion in his posterior inferior cerebellar artery leading to lateral medullary infarction. The features of lateral medullary syndrome, also known as Wallenberg syndrome, are variable depending on the areas damaged, and typically only some of the features are present. Damage to vestibular nuclei leads to vertigo, nystagmus, and vomiting. Spinothalamic tract injuries cause loss of contralateral pain and temperature sensation, whereas descending sympathetic tract damage causes ipsilateral Horner syndrome. Damage to fibers of CN XI and X causes hoarseness, dysphagia, ipsilateral paralysis of palate, and decreased gag reflex.

Cerebellar injury leads to ataxia and lateropulsion to the ipsilateral side. A PICA infarction causing facial nerve palsy is exceedingly rare, as the facial nerve nucleus in the pons typically receives its vascular supply from the anterior inferior cerebellar artery (3). However, there are variations in arterial anatomy and an occlusion of the PICA has been documented to cause peripheral facial nerve palsy (4). Given the importance of early treatment in improving outcomes for stroke patients, the internist must definitively rule out stroke whenever new neurological deficits are present before attributing the changes to another cause.

BEWARE THE KETTLEBELL Matthew A. Calzetta; Meredith B. Barnes. Tulane University Health Sciences Center, New Orleans, LA. (*Tracking ID #1926108*)

LEARNING OBJECTIVE 1: Recognize potential serious complications that may follow common exercises

LEARNING OBJECTIVE 2: Learn risk factors and preventive measures to avoid such complications

CASE: A 44 year-old Caucasian woman presented with a one-day history of worsening low back pain and tenderness. The pain was aggravated by movement and minimally relieved by over-the-counter pain medications. One day prior to presentation, she had participated in her first hour-long kettlebell exercise class. She denied any incontinence, fevers or weight change. On exam, paraspinal muscle, but not vertebral, tenderness from the level of T9 to the sacrum was seen. Flexion, extension and rotation of the spine were severely limited by pain. Straight leg raise was negative bilaterally. There were no neurological deficits. Dorsalis pedis pulses were 2+. Laboratory studies revealed a total creatine kinase (CK) of 25,700, AST of 1160 and ALT of 406. Urinalysis showed moderate blood with no red blood cells on microscopy. Initial electrolytes were within normal limits. Plain spinal films showed no fractures. MRI spine ruled out compartment syndrome of the paravertebral musculature, but showed diffuse lower musculature inflammation. Aggressive intravenous fluid hydration with normal saline was started. The total CK continued to rise to a peak of 52,000 on day 3 before decreasing to 10,000 on the day of discharge at hospital day 6. The only electrolyte changes were mild asymptomatic hypokalemia and hypophosphatemia following fluid administration. Renal function remained normal.

DISCUSSION: Rhabdomyolysis is defined as the release of striated muscle contents into the circulation following traumatic or nontraumatic events. The contents of muscle cells consist of electrolytes, myoglobin and sarcoplasmic proteins, including creatine kinase, aldolase, lactate dehydrogenase, alanine aminotransferase and aspartate aminotransferase. Clinically, it is defined based on elevated serum creatine kinase (CK) levels of more than 1000 U/L. Rhabdomyolysis is classified into traumatic and non-traumatic causes. Crush syndrome is the typical traumatic cause. Nontraumatic causes include exertion-induced, including strenuous exercise, seizures, alcohol withdrawal syndrome, muscle hypoxia, genetic defects, infections, body-temperature changes, metabolic and electrolyte disorders, drug-induced, toxin-induced and idiopathic. Rhabdomyolysis clinically presents with limb weakness, myalgia, edema and dark urination. The major complications are acute kidney injury (AKI) secondary to myoglobinuria, with an incidence that ranges from 13 to 46 % of cases, and disseminated intravascular coagulation. This case demonstrates exercise-induced rhabdomyolysis without complication. Rhabdomyolysis has been demonstrated in military recruits, professional athletes and individuals participating in regular exercise. There are no reports of kettlebell-induced rhabdomyolysis in the literature. Risk factors that increase the likelihood of rhabdomyolysis from exertion include: eccentric contractions, in which tension is applied during muscle extension causing more muscle damage than observed with concentric contractions, hot weather with high relative humidity, competitive exercise, higher socioeconomic status, poor physical condition, restrictive clothing that impairs heat dissipation, certain medications and supplements, including diphenhydramine, SSRIs, caffeine and performance-enhancing supplements, and hypokalemia secondary to impaired potassium-induced vasodilation in muscle. This case highlights the need for individuals seeking to try new, intense exercises should see their primary care physicians for pre-performance evaluation and education.

BEYOND SKIN DEEP: AN ELUSIVE DIAGNOSIS Kathryn Sweeney. UNC Chapel Hill, Chapel Hill, NC. (*Tracking ID #1939062*)

LEARNING OBJECTIVE 1: Diagnose skin lesions when initial biopsies are unrevealing.

LEARNING OBJECTIVE 2: Recognize the clinical features of cutaneous lymphoma.

CASE: The patient is a 76-year-old man who presented to the Emergency Department with a lower extremity wound of 3 months duration that had become progressively larger with ulceration and foul-smelling drainage. He had seen his local primary care physician who referred him to Dermatology. Two punch biopsies were

performed and non-diagnostic. He was treated with courses of Trimethoprim-Sulfamethoxazole and Dicloxacillin without improvement. His medical history was significant for tophaceous gout and CKD. The patient lived on a farm and gardened frequently. He was a widower and a lifelong non-smoker. Physical exam was notable for large, necrotic, ulcerative lesions (5×4 cm and 6×3 cm) on an erythematous base with eschar and foul-smelling drainage on the left lower leg. Admission labs were significant for an elevated creatinine (1.68) and mild pancytopenia (WBC 2.7, Hemoglobin 11.4, Platelets 103). Differential diagnosis on admission included infection (particularly fungal or atypical mycobacteria), vasculitis, pyoderma gangrenosum, and non-melanoma skin cancer. A punch biopsy showed suppurative and granulomatous dermatitis. Wound culture grew *Pseudomonas aeruginosa*. Because three punch biopsies failed to yield a diagnosis, an excisional biopsy was pursued. Pathology from the excisional biopsy revealed extensive cutaneous involvement by large atypical lymphocytes that were strongly and diffusely positive for CD20, CD10, CD45, and Bcl-6. The patient's biopsy and clinical presentation led to a diagnosis of *Primary Cutaneous Diffuse Large B-cell Lymphoma, Leg Type*. Staging with bone marrow biopsy and PET/CT did not reveal evidence of extracutaneous disease. The patient is currently undergoing therapy with R-CHOP (rituximab, cyclophosphamide, doxorubicin, vincristine and prednisone).

DISCUSSION: Primary cutaneous lymphomas are those lymphomas with skin manifestations but no evidence of extracutaneous disease. They can be further classified according to several histological, immunohistochemical and clinical features. Primary cutaneous lymphoma has an annual incidence of 1:100,000 and is the second most common site of extranodal Non-Hodgkin lymphoma (with the gastrointestinal tract being the most common). Twenty percent of primary cutaneous lymphomas are primary cutaneous B cell lymphoma, and 4% can be further classified as primary cutaneous diffuse large B cell lymphoma, leg type. Patients with primary cutaneous diffuse large B cell lymphoma, leg-type often present with red nodules or tumors on the lower leg that grow rapidly. Diagnosis is generally performed by biopsy. As was seen in our patient, excisional biopsies are preferred to punch biopsies due to greater yield. Treatment usually consists of rituximab and anthracycline-based chemotherapy. Primary cutaneous diffuse large B cell lymphoma, leg-type tends to occur at an advanced age (median 77 years) with a relatively poor prognosis (5-year disease specific survival of 41%). Compared to other cutaneous lymphomas, it has a greater tendency to relapse and disseminate to extracutaneous sites. It is essential to maintain a broad differential diagnosis when evaluating skin lesions. It is also important to employ more comprehensive diagnostic strategies when initial tests are unrevealing. For example, our patient had three non-diagnostic punch biopsies before an excisional biopsy revealed his diagnosis. When considering skin lesions that do not heal with usual measures, malignancy should always remain on the differential.

BIG PATIENT, BIG PROBLEM: GASTROINTESTINAL DYSMOTILITY IN A PATIENT WITH ACROMEGALY Meghan Gilroy; Emily Beck; Paul Aronowitz. UC Davis Medical Center, Sacramento, CA. (Tracking ID #1936092)

LEARNING OBJECTIVE 1: Recognize gastrointestinal manifestations of acromegaly.

CASE: A 57-year-old man presented to the emergency department with a chief complaint of enlarged tongue. Family members had noticed enlargement of his tongue and forehead over the past several months. He also complained of chronic constipation. On physical exam, the patient was found to have macroglossia, frontal bossing, and extremely large hands and feet. Serum IGF-1 was 771 ng/mL (reference range 81–225 ng/mL) and serum growth hormone following a two-hour glucose tolerance test was 7.75 ng/mL (reference range <2 ng/mL). The diagnosis of acromegaly was made. MRI of the brain revealed a pituitary prominence suggestive of microadenoma. The patient was scheduled for resection and octreotide therapy was initiated. Despite aggressive bowel regimen and cessation of opioid pain medications, constipation persisted. Barium swallow demonstrated esophageal dysmotility; small bowel follow through revealed delayed gastric emptying and prolonged small bowel transit.

DISCUSSION: Acromegaly is a rare clinical syndrome characterized by elevated serum levels of growth hormone (GH) and insulin-like growth factor-1 (IGF-1); incidence is 3 cases in 1 million per year. The syndrome is most commonly caused by primary GH excess with benign pituitary neoplasms accounting for over 90% of cases. Less common etiologies include ectopic GH secretion, familial disorders of GH excess, and neoplastic overproduction of GH-releasing hormone. Common clinical manifestations of acromegaly include acral enlargement and hypertrophy of the tongue, frontal bone and jaw. Elevated GH has visceral effects as well, including enlargement of kidneys, liver and spleen, but does not generally affect organ function.

Gastrointestinal manifestations include constipation and higher prevalence of cholelithiasis, colon polyps and colorectal cancer. Constipation is a result of impaired gastrointestinal motility. Large bowel and small bowel transit times have been shown to be prolonged in acromegaly, which predisposes patients to small bowel bacterial overgrowth. This is presumed to be caused by both the increased length of the intestine and excess GH and IGF-1. Treatment for acromegaly includes resection of the culprit adenoma if present and administration of a somatostatin analogue such as octreotide, which suppresses growth hormone secretion by negative feedback. Somatostatin analogues decrease gastrointestinal transit, which can exacerbate constipation. Acromegaly and octreotide therapy likely accounted for the gastrointestinal dysmotility discovered in our patient.

BIZARRE NEUROLOGICAL SYMPTOMS WITH THUNDERCLAP HEADACHE MAY STEM FROM REVERSIBLE VASOCONSTRICTIONS Masato Yoshihara¹; Hidenori Oguchi¹; Mitsunori Iwase¹; Aya Ogura²; Yasuhiro Ito²; Yasuyuki Kishigami³. 1TOYOTA memorial hospital, Toyota, Aichi, Japan; 2TOYOTA memorial hospital, Toyota, Aichi, Japan; 3TOYOTA memorial hospital, Toyota, Aichi, Japan. (Tracking ID #1929116)

LEARNING OBJECTIVE 1: Note that reversible cerebral vasoconstriction syndrome (RCVS) presents various symptoms and associated disorders.

LEARNING OBJECTIVE 2: Recognize that RCVS does not always present reversible pathophysiological state.

CASE: The first case is a 55-year-old female with a history of migraine and taking some painkiller drugs occasionally. The day of admission, the patient suddenly felt thunderclap headache right after defecation. Since there were no significant physical signs including neurological deficits, emergency physicians chose to observe her carefully with administration of acetaminophens. Then, the pain was favorably controlled. Magnetic Resonance Image (MRI) performed on the fourth day after the onset showed cortical subarachnoid hemorrhage (cSAH) at the right parietal lobe. Cerebral angiography revealed vasoconstriction of the right anterior cerebral artery. Accordingly, the patient was diagnosed with RCVS associated with cSAH. Additionally the single photon emission computed tomography (SPECT) was performed, which detected decreased venous flow at the corresponding cSAH lesion. The patient was treated with a calcium channel blocker and the sequential magnetic resonance angiography (MRA) was performed, which showed improvement of the vasoconstriction. Although the patient favorably progressed, the decreased venous flow in SPECT unchanged even after the diagnosis of RCVS. The second case is a 36-year-old pregnant woman with no significant past obstetrical history. The patient began to feel headache at the beginning of labor. Right before and after the birth, two times of convulsion occurred and she was transferred to our hospital. On arrival, the patient was agitated, but there were no significant vital signs or physical signs. Computed tomography (CT) image showed hemorrhage of the left putamen and sedatives were administered. MRI performed on the same day did detect cerebral edema of the bilateral posterior lesions. On the third day, MRI showed the cerebral edema resolved and the patient was diagnosed with posterior reversible encephalopathy syndrome (PRES). The patient progressed favorably with intravenous magnesium sulfate and weaned from the sedatives on the fourth day. The initial MRA revealed no evidence of vasoconstriction, however, the MRA on the seventh day after the admission showed remarkable vasoconstrictions of the bilateral middle cerebral arteries and the basilar artery, which were consistent with RCVS. There were no symptoms including neurological deficits and the patient was discharged on the fourteenth day. Interestingly, the vasoconstriction in MRA had remained for 2 months after the diagnosis of RCVS.

DISCUSSION: RCVS is characterized by reversible multifocal narrowing of the cerebral arteries preceded by thunderclap headaches with or without associated neurologic deficits. Although this constriction generally resolves spontaneously within 3 months, RCVS develops a unique set of clinical imaging features such as subarachnoid hemorrhages, lobar hemorrhages and cerebral infarctions. Approximately 90% of RCVS patients follow favorable clinical outcome. However, 10% develop severe deficits, and some of them eventually die. Moreover, even among the patients with no clinical sequela, irreversible decreased venous flow on SPECT can be detected, which suggests potential loss of brain functions. The calcium channel blocker is considered to reduce headaches, but has no proven effects on hemorrhagic and ischemic complications. In summary, we experienced two female cases of RCVS, which presented different clinical manifestations and radiographic findings. Careful observation and appropriate prognostic evaluation are essential for any patient who present with thunderclap headache, which can be the initial symptom of RCVS or other fatal diseases such as subarachnoid hemorrhage.

BONE MARROW GRANULOMA: A DIAGNOSTIC CLUE Gregory Madden; Pinar Oray-Schrom. Yale New Haven Hospital, New Haven, CT. (*Tracking ID #1923773*)

LEARNING OBJECTIVE 1: Discuss the differential diagnosis and investigative approach to a patient with bone marrow granulomas.

CASE: A 77 year old woman with history of hypertension, diabetes, uveitic glaucoma, and gout underwent a bone marrow biopsy for workup of incidental cytopenias and abnormal serum protein electrophoresis (M-protein 0.4 g/dL). The biopsy was diagnostic for monoclonal gammopathy of undetermined significance (5–10 % plasma cells) and demonstrated non-caseating granulomas. No pathogens were identified. She presented to the hospital several months later with shortness of breath. Vitals signs were within normal limits. Exam was notable for jugular venous distention, leg edema, and rales. Chest X-ray demonstrated pulmonary edema and calcified hilar nodules. Echocardiography measured her ejection fraction 30 % and she was diagnosed with new-onset congestive heart failure. Cardiac catheterization revealed diffuse, tri-vessel disease but no intervention was done. A suspicion for nonischemic cardiomyopathy prompted cardiac MRI, showing thick ventricles and areas of delayed enhancement consistent with cardiac sarcoid. The diagnosis of systemic sarcoidosis was further supported by evidence of hypercalcemia (11.3 mg/dL) and elevated ACE level (85 U/L). She responded well to medical therapy of her heart failure and remains independent at home. Her sarcoidosis was deemed quiescent and required no treatment.

DISCUSSION: Granulomas are collections of fused macrophages surrounded by a rim of activated T-cells formed in an attempt to contain bacteria, fungi, or other foreign material. Granulomas on bone marrow biopsies are rare and incidence is less than 3 %. According to one recent retrospective study of 57 cases of bone marrow granulomas, 33 % were identified as infectious, 21 % sarcoidosis, 9 % malignancy, 6 % drug or therapy-related, and 21 % unknown (Brackers de Hugo et al. 2013). Among bacteria, intracellular pathogens are most common: Mycobacteria (TB and non-tuberculous), Bartonella, Salmonella (typhoid fever), and Coxiella burnetii (Q fever, characteristic “doughnut” shaped granuloma). Invasive fungal infection should be suspected in immunocompromised individuals. HIV is independently associated with bone marrow granulomas in addition to other viral infections such as EBV, CMV, and HSV. Sarcoidosis is the single most common diagnosis related to bone marrow granulomas. Bone marrow granulomas are identified in 10 % of all sarcoid patients but may be present in over half of patients with sarcoidosis-related anemia or leukopenia. Among malignancies causing granulomas on marrow biopsy, lymphomas, leukemias, and myelomas have all been described. Finally, therapy-related bone marrow granulomas can be due to drugs (amiodarone, procainamide) or *Bacillus Calmette-Guérin* (BCG) in patients vaccinated against tuberculosis or treated for bladder cancer. Differential diagnosis of bone marrow granulomas should begin with appreciation for signs and symptoms of a systemic illness. Infection, sarcoidosis, malignancy, medications, BCG exposure, and sarcoidosis should be considered. Bone marrow samples containing granulomas should be stained with Grocott Methenamine Silver (fungi), Warthin-Starry (Bartonella), acid fast (mycobacteria), and Gram stains with appropriate cultures sent. PCR testing may also be useful. Although bone marrow granulomas can be an important diagnostic clue, no cause will be identified in up to one fifth of patients.

BORTEZOMIB-RELATED CARDIOMYOPATHY Zachary D. Horne; Paul Koffer; Anthony A. Donato. The Reading Hospital, West Reading, PA. (*Tracking ID #1938840*)

LEARNING OBJECTIVE 1: Recognize the role of both anthracycline and non-anthracycline chemotherapies in new-onset cardiomyopathy

CASE: A 62 year-old male veteran with a history of multiple myeloma being treated for the last 6 months with weekly first-line bortezomib and dexamethasone who presented with subacutely progressing dyspnea and an acute decline in exercise tolerance over the 2 days prior to admission. Prior to the initiation of chemotherapy, baseline echocardiogram showed normal cardiac size and function with an ejection fraction (EF) of 65 %. He denied increased swelling of his legs, inability to lie flat, or paroxysmal nocturnal dyspnea. He was afibrile, tachypneic, and in normal sinus rhythm, with normal oxygen saturation breathing room air. On examination he was noted to have 10 cm of jugular venous distention as well as diffuse inspiratory wheezes. Brain natriuretic peptide was elevated at 1692 pg/mL (nl: 0=100 pg/mL) and troponins were elevated at 0.86 ng/mL (nl: <0.06 ng/mL). He was also found to have acute on chronic renal insufficiency and thrombocytopenia. Cardiac ultrasound revealed dilated cardiomyopathy, with ejection fraction 43 %. He responded well to diuresis with intravenous loop diuretics and initiation of carvedilol, but could not tolerate angiotensin inhibitors due to angioedema. Due to his lack of chest pain, renal insufficiency, thrombocytopenia, and elevated LFTs, a cardiac catheterization was felt

not to be indicated. His dyspnea improved to the point of being able to participate in short periods of physical therapy and he was discharged to cardiac rehabilitation. The patient ultimately passed away 3 months after discharge following an episode of gram-negative neutropenic sepsis.

DISCUSSION: As long-term survival of malignancies increases, the long-term side effects of chemotherapy are becoming more prevalent issues for physicians. The cardiotoxic effects of many chemotherapy agents are well known, and are most closely associated with anthracyclines, cyclophosphamide, and tyrosine-kinase inhibitors such as trastuzumab. Proteosome inhibitors such as Bortezomib are uncommon causes of cardiac decompensation and have been documented in only a few case reports. Recommendations from the 2010 European Society for Medical Oncology Guidelines provide that all patients undergoing chemotherapy treatment have a clinical evaluation for cardiovascular function and comorbidities, including a baseline echocardiogram, especially in patients being treated with anthracyclines, trastuzumab, or with cardiovascular risk factors (age >60, prior coronary artery disease, or prior mediastinal irradiation).

BRAIN ABSCESS: AN UNUSUAL COMPLICATION OF ODONTOGENIC INFECTION Rajesh Mourya1; Runa Shrestha2; Renuka Vivekanandan1. 1Creighton University Medical Center, Omaha, NE; 2SUNY Upstate Medical University, Syracuse, NY. (*Tracking ID #1933122*)

LEARNING OBJECTIVE 1: Brain abscess, commonly caused by gram positive cocci, is a localized, suppurative inflammation of the brain parenchyma. Common causes of brain abscess include local extension (from ear, para-nasal sinuses), direct trauma and hematogenous spread. Odontogenic infections are rarely associated with brain abscess.

CASE: A 77-year-old, African - American male, with past medical history of type 2 diabetes mellitus , essential hypertension, and benign prostatic hyperplasia, was brought to the emergency department with a 1 week history of fever, progressive headache, vomiting followed by confusion, lethargy and 1 episode of generalized tonic clonic seizure. On examination, he was febrile with temperature of 101.2° Fahrenheit, was lethargic and disoriented. Meningeal signs were negative. Computed tomography of the head was abnormal, therefore magnetic resonance imaging of the brain was done which revealed a 4.2×1.8×2 cm bilobed mass in the right inferior frontal lobe and right basal ganglia, suggestive of brain abscess. Maxillo-facial x-ray showed evidence of periodontal abscess. Complete blood count, basic metabolic panel, urine analysis, and chest x-ray were within the normal limit. The patient was empirically started on broad spectrum antibiotics including vancomycin, ceftriaxone and metronidazole. He underwent surgical drainage of the brain abscess and extraction of the infected teeth along with drainage of the periodontal abscess. *Streptococcus viridans* was isolated from the pus aspirates. Blood cultures were negative. Vancomycin was stopped and ceftriaxone and metronidazole were continued. After the drainage of the brain abscess and antibiotic therapy, we noticed marked improvement in his neurological status. The patient was discharged to a skilled nursing facility on intravenous ceftriaxone and metronidazole to complete 8 weeks therapy. Repeat computed tomography of the head after few months showed complete resolution of the abscess. Patient has been doing well without any residual neurological deficit.

DISCUSSION: Brain abscess as a complication of odontogenic infection is uncommon. There are few case reports documenting the association of brain abscess with odontogenic infection. Brain abscess is associated with high morbidity and mortality. Early detection and initiation of treatment, that include surgical drainage and prolong antibiotics therapy, is the key to the management of brain abscess. Maintaining good oral hygiene, and early recognition and treatment of odontogenic infections may decrease the risk of brain abscess.

BRAIN DRAIN: A CASE OF TRANSIENT HYDROCEPHALUS AND SEIZURE DUE TO NEUROCYSTICERCOSIS Haley Kensing; Roger D. Smalligan; Miles Raizada; Mashrafi Ahmed. Texas Tech Univ Health Science Center, Amarillo, TX. (*Tracking ID #1938850*)

LEARNING OBJECTIVE 1: Diagnose neurocysticercosis.

LEARNING OBJECTIVE 2: Recognize neurocysticercosis causing transitory hydrocephalus.

CASE: A 34-year-old Hispanic male who immigrated from Mexico 15 years ago presented with status epilepticus. The patient has a history of seizures that began at the age of 10. The patient has had four episodes of status epilepticus: 27 years ago, 10 years ago, 3 years ago, current presentation. The patient reports that every episode has occurred at night when the patient was lying down. The episode lasts

approximately 3 min and consists of severe headache, confusion, foaming from the mouth, and tongue biting. The patient had significant history of worm infestation in childhood. An initial Head CT showed hydrocephalus with dilated lateral & third ventricles and blunted sulci. Few punctate foci of calcification were present in left frontal lobe. Another Head CT 24 h apart showed complete resolution of the hydrocephalus. An MRI with contrast indicated a 1 cm complex cyst like mass in the 4th ventricle. The patient was started on phenytoin. No surgical intervention was recommended. *Taenia solium* antigen and antibody tests came back negative.

DISCUSSION: Internists see patients with seizures on almost a daily basis, and in this country seizures secondary to neurocysticercosis are not on the top of our differential. However, 50 million people worldwide have cysticercosis caused by ingestion of the egg stage of *Taenia solium*. Once the eggs hatch within the intestine, the oncospheres invade the bowel wall and disseminate hematogenously. There is involvement of the CNS 60–90 % of the time. The intraventricular involvement occurs in only 7–20 % of patients. Although the primary infection does not commonly occur in the United States, we still encounter neurocysticercosis in immigrants from Central and South America. Diagnosis of neurocysticercosis is generally made based off of clinical suspicion and imaging. Our patient was from Mexico and had a history of worm infestation. The two calcifications in the cerebral cortex and cystic lesion within the 4th ventricle confirmed our suspicion of neurocysticercosis. Although the serology testing was negative for both antigen and antibody to *T. solium*, this is most likely due to the fact that the primary infection was over 30 years ago and the cysts appeared calcified rather than active. The transitory obstructive hydrocephalus can most likely be explained by a migratory scolex within the fourth ventricle that at time migrated to obstruct the outflow of the cerebral aqueduct. Bruns' syndrome describes this ball-valve mechanism that results from a migrating cyst during a change in head position. Our patient's seizure episodes have always occurred at night or in the early morning when the patient was supine leading us to believe that scolex repositions itself during this time resulting in obstructive hydrocephalus and seizures. Treatment of neurocysticercosis includes destruction of the parasite and prevention of seizures. Albendazole is the antiparasitic drug of choice and it is strongly recommended to use corticosteroids concurrently to prevent inflammation and further brain damage. The location of the intraventricular cyst within the fourth ventricle prevented it from being accessed by rigid endoscope. Therefore, open resection would be the only way to remove the cyst, which was considered inappropriate at this time as the risks outweighed the benefits. Treatment with albendazole and corticosteroid was also considered to try and shrink down the scolex, but other attempts in the literature have shown inconsistent efficacy and poor outcomes. Since the patient has only had four seizure episodes and this was the only confirmed case of transitory hydrocephalus, it was elected to begin phenytoin to increase the seizure threshold until such time when more rigorous therapy may be indicated.

BREAKING BAD: THE IMPORTANCE OF RECOGNIZING PHYSICIANS IMPAIRED BY SUBSTANCE ABUSE DISORDERS Rebecca Glassman; Howard Libman; Erina Matsumoto. Beth Israel Deaconess Medical Center, Boston, MA. (*Tracking ID #1925951*)

LEARNING OBJECTIVE 1: Understand the epidemiology of substance abuse among physicians in the United States

LEARNING OBJECTIVE 2: Identify resources available for health care professionals with substance abuse disorders

CASE: A 54-year-old physician with a history of HIV infection and depression presented to the emergency room with altered mental status, after failing to arrive at his medical office. He was somnolent and minimally responsive, and laboratory studies were noteworthy for a toxicology screen positive for amphetamines. He was admitted to the intensive care unit for further management. Overnight, the patient was treated with lorazepam for agitation. When interviewed the following day, the patient communicated that he had used crystal methamphetamine the night prior. He was encouraged to seek help through the Massachusetts' Physician Health Services, and expressed that he had been told to do so by several previous providers. He also reported a recent admission to a nearby psychiatric hospital for suicide attempt while under the influence of methamphetamine. Given evidence of repetitive abuse and failure to follow through with Physician Health Services, a report was sent to the Massachusetts State Medical Board.

DISCUSSION: The prevalence of substance abuse among health care providers is an estimated 6–8 %, similar to the general population but concerning given the level of responsibility placed in their hands. Studies have shown that large workloads and chronic work-related stress lead to early burnout among physicians. To counteract the effect on mental health, physicians have been found to abuse drugs for

performance enhancement (stimulants) and for self-treatment of pain, anxiety, and depression (opioids and benzodiazepines). In 1973, the American Medical Association published a report entitled "The Sick Physician," which brought to light the prevalence of physician impairment secondary to substance abuse and prompted the creation of state and local programs. All 50 states now have impaired-physician programs sponsored by the state medical society aimed at providing physicians with rehabilitative services. In Massachusetts, this program is called Physician Health Service. It is independent of the state licensing boards and therefore free of punitive action unless the practitioner does not comply with treatment guidelines. For those who do not comply or have a severe enough disability to compromise their professional activities, state medical boards should be informed for both ethical and legal reasons. It is important to recognize the services available to physicians with substance abuse issues so that they can receive treatment early before endangering their patients.

BROADEN YOUR DIFFERENTIAL! LYME AS THE NEW "GREAT IMITATOR" Brin Freund; Abby Spencer. WPAHS, Pittsburgh, PA. (*Tracking ID #1932217*)

LEARNING OBJECTIVE 1: 1. To recall Lyme disease in patients with neurologic signs and symptoms.

LEARNING OBJECTIVE 2: 2. To outline the presentation of nervous system Lyme, neuroborreliosis. 3. To revisit the importance of thorough history taking and examination and re-evaluation of unsuccessful treatments.

CASE: A 64 year old male without significant medical history presented to the emergency department (ED) in June status post ground level fall with fever, testicular pain, headache, sore throat, malaise, cough, nausea, and abdominal pain. Neurological exam and labs were unremarkable. Discharge diagnosis was viral syndrome. He followed up with his primary care physician with cough and an annular truncal rash thought to be secondary to pertussis. Azithromycin and Robitussin AC were prescribed. He presented to the ED the following month with persistent testicular pain. He was evaluated by urology and prescribed Percocet for pain and antibiotics for epididymitis. Within a month he had three additional ED visits for persistent testicular and abdominal pain, constipation, bloating, weight loss, anorexia, and urinary retention. Repeat imaging demonstrated ileus versus constipation, possibly opiate induced. He decreased opiate intake during this time. Review of systems did not note presence or absence of neuropathy. Neurological exam was not documented. Colonoscopy showed possible ileus and impacted stool. Opiates were discontinued. Over a few weeks, his gastrointestinal symptoms persisted and he presented to another primary care physician. At this point, he also reported back and hip pain with leg weakness. He reiterated recurrent falls and was using a walker for balance. He reported terrible withdrawal symptoms from stopping the opiates and was overall miserable. Neurological exam elicited decreased reflexes and hip flexion strength with sensory deficits in the thigh and dorsal foot, right greater than left. Thoracolumbar MRI showed moderate spinal stenosis and disc disease. This prompted referral to neurosurgery who confirmed that findings did not support his symptoms and clinical exam. The neurology team was consulted and performed neurodiagnostics.. EMG demonstrated right-sided motor polyneuropathy in L2-L4. Extensive workup produced positive lyme serology in serum and CSF. He was admitted for LP and high dose Ceftriaxone was initiated. Near-complete resolution of gastrointestinal, testicular, and neurological symptoms was seen at 3 weeks. He walked into his hospital follow-up appointment with his primary care physician with full strength and no complaints.

DISCUSSION: Roughly 30,000 cases of Lyme disease are diagnosed in the U.S. yearly. Presenting signs and symptoms can be non-specific and involve many organ systems. Although not commonly associated with Lyme, testicular involvement has been noted in the literature and discomfort is usually due to swelling and pain. About 10–20 % of Lyme cases involve the nervous system. Cranial and peripheral neuropathies and meningitis are well-known presentations in the U.S. Radiculopathy is more common in Europe as part of an infrequently encountered entity, Bannwarth syndrome. Sensory and motor symptoms are common. Autonomic involvement is less cited. Back and neuropathic pain are common, often overshadowing neurological deficits. As a result, workup is usually exhaustive before considering Lyme as the etiology of radiculopathy. Diagnosis of Lyme disease requires two-tiered antibody testing. CSF serology confirms central nervous system involvement. Imaging can delay diagnosis as it often demonstrates incidental and clinically insignificant findings but is one of the first tests ordered to workup radicular symptoms. Neuromuscular studies are necessary to pinpoint lesions and help guide further testing for etiology. Antibiotics are the standard treatment of Lyme. Oral medications are sufficient for early non-disseminated disease. However, when involving the central nervous system IV therapy is prescribed. Ceftriaxone is often the preferred agent in the US. This patient presented with multiple complaints all of which were at first attributed to opiate use. Given the multiple visits to the ED with persistent and worsening symptoms

despite discontinuation of opiates, the diagnosis could have been re-considered and the patient re-evaluated more comprehensively. This case illustrates that plans of care should be re-assessed when symptoms persist despite initiating adequate treatment. By completing a thorough review of systems and physical examination while keeping a broad differential in mind, diagnoses may be missed less often.

BRUCELLOSIS IN A TRAVELER WITH FEVER AND KNEE PAIN Thuyet Ho, University of California, San Diego, San Diego, CA. (*Tracking ID #1935253*)

LEARNING OBJECTIVE 1: Recognize the clinical presentation of brucellosis and the necessary evaluation to rule out complications.

LEARNING OBJECTIVE 2: Treat brucellosis in a patient who does not have access to home antibiotic infusion.

CASE: A 17 year old Kuwaiti man with no significant past medical history presented with 1 week of fever, diaphoresis, malaise, and left knee pain. The patient was visiting his brother-in-law in California for the past 3 weeks; he reported he was in his usual state of health until the onset of fevers and diaphoresis occurring 1 week prior. Then he woke up with acute left knee pain on the day of presentation. Physical exam showed significant sweating with mild swelling and severe tenderness to palpation of the left knee. Labs demonstrated mild transaminitis, thrombocytopenia, and coagulopathy. After an arthrocentesis and pan-culture were performed, intravenous Vancomycin was started empirically. A more thorough history revealed travels around the Saudi peninsula, exposure to birds, no recent sexual contact, and ingestion of unpasteurized camel milk several months prior to presentation. Repeat exam revealed a I/VI systolic murmur at the left lower sternal border and tenderness now localized to the pes anserine bursa. The bursa was aspirated and sent for culture. Patient remained intermittently febrile with minimally productive cough and generalized aches and pain. Thrombocytopenia and transaminitis continued to worsen. In the setting of camel milk ingestion, doxycycline was added given the suspicion for brucellosis. By the third day, blood cultures grew gram negative bacilli and pes anserine bursa eventually grew *Brucella melitensis*. Patient's clinical symptoms improved when the antibiotics regimen was transitioned to oral doxycycline and intravenous gentamicin. Negative transthoracic echocardiography and MRIs of the spine and left leg ruled out endocarditis, spondylitis and osteomyelitis, respectively. Hepatitis serology, HIV, CMV serology, Cryptococcal antigen, malarial smear, and tuberculosis screen were negative as well. Ideally the patient would be sent home on doxycycline and intravenous gentamicin. However, due to his status as a visiting foreigner, he did not qualify for home infusion service. He was discharged on oral doxycycline and rifampin for at least 6 weeks with arrangement to follow up in infectious disease clinic in Kuwait.

DISCUSSION: Brucellosis is a zoonotic infection which can present in a broad clinical spectrum. It is transmitted to humans by contact with infected animal fluids or derived food products. This case illustrates the initial diagnosis and work up of fever in a traveler from the Middle East. When the risk factor of unpasteurized camel milk ingestion was identified in the setting of high grade fever and liver dysfunction, the focus was narrowed to brucellosis. It is important to recognize that *Brucella* may cause focal infection of any organ system. In this case, it was necessary to rule out endocarditis due to the murmur and positive blood culture, spondylitis due to back pain, and osteomyelitis due to bursa infection as these findings would change the course of treatment. Finally, it is important to know that treatment with oral doxycycline for 6 weeks and intramuscular streptomycin or intravenous gentamicin for 2 weeks is first-line therapy. However, if a patient does not have access to home infusion, then at least 6 weeks of oral rifampin can be substituted for the aminoglycoside. Relapse and treatment failure are not uncommon. Patients should be educated on avoiding risks for contracting *Brucella* and should follow up closely to monitor for relapse or treatment failure. In this case, it was important to have an Arabic interpreter by bedside to educate and engage the patient in treating this disease.

CALCIPHYLAXIS IN A PATIENT WITHOUT RENAL FAILURE Allison J. Kwong; Joseph Ebinger; Peter Hanna; Matthew Spinelli; Paul D. Blanc. University of California, San Francisco, San Francisco, CA. (*Tracking ID #1937191*)

LEARNING OBJECTIVE 1: To recognize, diagnose, and treat calciphylaxis in a patient with normal renal function.

CASE: Our patient is a 65-year-old Hispanic woman with a history of insulin-dependent diabetes mellitus, seronegative rheumatoid arthritis on methotrexate, and paroxysmal atrial fibrillation on warfarin, who presented to her primary care clinic with hyperpigmentation of her bilateral lower extremities, which progressed over the next 8 months to a symmetric livedoid rash. An outpatient skin biopsy of her right leg was performed but initially non-diagnostic. In the month following her biopsy, she began to describe intense pain at the biopsy site, where she had developed retiform purpura and associated ulceration. She was referred for admission to our medical center for expedited workup and symptom control. Slides from her prior skin biopsy

were re-reviewed. Based on her clinical picture and histopathologic findings of intravascular and extravascular calcium deposition, a diagnosis of non-uremic calciphylaxis was made, most likely due to the use of warfarin. She had a normal creatinine, parathyroid hormone, vitamin D level, calcium, phosphorus, and calcium-phosphate product. Warfarin was withdrawn, and rivaroxaban was started in its place for primary stroke prevention given her history of atrial fibrillation. In consultation with our dermatology colleagues, we elected to treat her calciphylaxis with infusions of sodium thiosulfate 25 g three times weekly for 8 weeks. With this therapy, she experienced marked clinical improvement and resolution of the ulcer.

DISCUSSION: Calciphylaxis is most often associated with renal disease or abnormal parathyroid function, which cause derangements in calcium and phosphorus levels. These can lead to pathologic vascular calcification and microvascular occlusion, and thus the severe pain of cutaneous calciphylaxis and a high mortality due to sepsis. Non-uremic calciphylaxis exhibits these same histopathologic features of arteriolar calcification and microthrombi; however, the underlying pathophysiology has yet to be elucidated. It is an exceedingly rare, though increasingly recognized entity, associated in existing case series with female sex, white race, and obesity. Hypoalbuminemia, the use of warfarin or glucocorticoids, liver disease, and hypercoagulability have been identified as risk factors. Conventional therapies for calciphylaxis focus on the regulation of calcium and phosphorus levels with phosphate binders, cinacalcet, dialysis, and even parathyroidectomy, but these interventions are irrelevant in patients with normal renal function and electrolytes. Sodium thiosulfate—currently approved only for cyanide poisoning—is also thought to have some role in the chelation of calcium. It has recently emerged as an effective, off-label treatment option for calcific uremic arteriolopathy. Sodium thiosulfate has since been applied in non-uremic calciphylaxis with similar success, though the existing literature is still limited to observational data in fewer than 10 patients. The medication is generally well-tolerated, its main complications being nausea, vomiting, and an anion gap metabolic acidosis. Our patient developed self-limited episodes of atrial fibrillation related directly to her infusions; these were ultimately controlled with beta-blockade and a slower infusion rate. Alternate medications, such as bisphosphonates and cinacalcet, have also been proposed in the literature for the treatment of non-uremic calciphylaxis, but to date, sodium thiosulfate appears to be the most promising. In conclusion, we describe a case of warfarin-induced calciphylaxis, successfully treated with sodium thiosulfate, and aim to increase awareness of this rare diagnosis and its treatment in non-traditional patients.

CALCIPHYLAXIS OF EVIL Catherine Trimbur¹; Simon Hong². ¹Montefiore Medical Center, Bronx, NY; ²Montefiore Medical Center, Bronx, NY. (*Tracking ID #1939009*)

LEARNING OBJECTIVE 1: Recognize the clinical presentation and pathogenesis of calciphylaxis (calcific uremic arteriolopathy)

LEARNING OBJECTIVE 2: Understand the treatment and prognosis for patients with calciphylaxis

CASE: A 35 year-old woman with a history of diabetes and end-stage renal disease on hemodialysis presented with 4 days of nausea, vomiting, and bilateral flank pain. On admission, she was noted to have fever of 100.6 F, WBC of 16.4 and non-contiguous, hyperpigmented, indurated lesions on the left lower quadrant of her pannus, bilateral thighs, and right flank. The skin was exquisitely tender to light touch but not warm or erythematous. Labs revealed Ca of 7.9, Ph of 6.2 and PTH of 198. Patient was started on empiric antibiotics for cellulitis, without improvement. Biopsy of the site showed subcutaneous microvascular calcification and thrombosis. Diagnosis of calciphylaxis was made. The area biopsied did not heal in subsequent days, and she developed a black eschar. The patient was started on IV sodium thiosulfate with dialysis, a phosphate binder, calcimimetic and pain management. On discharge, she continued to have progression of lesions with areas of blackened skin necrosis.

DISCUSSION: Calciphylaxis, or calcific uremic arteriolopathy (CUA), is a rare disorder characterized by painful ischemic cutaneous necrosis on areas of skin with high adiposity. First described in 1898 by Bryant and White, then elaborated in animal models by Hans Selye in 1962, CUA has increased in incidence as a result of higher rates of end stage renal disease and raised awareness. The proposed mechanism of pathogenesis is mural calcification of arterioles of the dermo-hypodermic layers leading to intimal fibrosis of arterioles. The resultant arteriolar narrowing leads to decreased flow states, causing thrombus formation. Thrombi obstructing flow in the vasculature of the dermis is what ultimately leads to necrotic ulceration of the skin. Often associated with end stage renal disease, pathogenesis is thought to involve dysregulation of parathyroid, vitamin D, phosphate and calcium levels, as calcium-phosphate product (CPP) puts patients at increased risk for

calcification. However, elevated CPP is neither sensitive nor specific and many patients with CUA have normal calcium and parathyroid levels, suggesting deeper levels of pathogenesis not yet elucidated. Patients with CUA generally present with exquisitely painful areas of skin necrosis, commonly on the abdomen, buttock and thigh, though can occur elsewhere. The initial decrease in blood flow as a result of intimal thickening leads to livedo reticularis and plaque-like subcutaneous nodules, which are usually signs of early disease. As blood flow continues to diminish and thrombi form, complete occlusion of vessels lead to ischemic ulceration, often leading to eschars that are highly susceptible to superinfection. This presentation often leads to delayed diagnosis of CUA, as it appears to be a skin infection. While diagnosis can be made via skin biopsy or clinically, biopsy is often avoided due to poor wound healing and risk of infection. Prognosis of CUA is extremely poor, with a progressively worsening clinical course. One year mortality rates approach 46 % and are higher if infection develops. Due to low incidence, there are no randomized controlled trials establishing treatment plan, but treatment is generally aimed at reducing CPP and PTH levels, wound care, including surgical debridement, and pain control.

CANDIDA TROPICALIS INFECTION IN A PATIENT WITH ESRD Shenelle-Marie Wise; Kate Hust. Tulane University Health Sciences Center, New Orleans, LA. (*Tracking ID #1926150*)

LEARNING OBJECTIVE 1: Recognize the clinical manifestations of and risk factors for candidemia, and initiate appropriate evaluation for disseminated disease.

LEARNING OBJECTIVE 2: Compare and contrast the prevalence, virulence and treatment of Candida tropicalis to Candida albicans and other non-albicans species

CASE: A 22-year-old man presented with 1 week of fevers, nausea and vomiting. He was febrile to 101° Fahrenheit but alert, oriented, and able to discuss his full medical history, which included end-stage renal disease with an indwelling hemodialysis catheter. Given his elevated white blood cell count, fevers, and tachycardia, he was admitted with sepsis. Over the following days his mental status gradually declined, and he was unable to respond to questions or follow commands. Blood cultures drawn on admission grew Candida tropicalis. Echoangiogram revealed vegetations on the aortic and tricuspid valves. MRI revealed multiple small lesions consistent with septic emboli in the frontal lobe, parietal lobe, and cerebellum.

DISCUSSION: Candidemia is an important cause of nosocomial bloodstream infections encountered by hospitalists. The clinical manifestations of candidemia vary from minimal fever to full-blown sepsis that is indistinguishable from severe bacterial infection. Invasive candidiasis is defined by hematogenous spread to multiple viscera (e.g., eye, kidney, heart valves, brain). The susceptibility to candida is increased in patients with indwelling catheters. Patients with end stage renal disease are further at risk for infection because of impairment in cell-mediated immunity and granulocyte function. Candidemia is diagnosed with fungal blood cultures, but additional studies should be considered to evaluate for disseminated disease. Due to risk for invasive infection, all patients with candidemia should undergo an ophthalmologic examination, even in the absence of ocular symptoms, to evaluate for endophthalmitis or chorioretinitis. Echocardiogram is recommended to evaluate for endocarditis. Central intravenous catheters should be removed in these patients as it leads to more rapid clearance of fungemia. Higher mortality has been documented when catheters remain in place despite treatment with an anti-fungal agent. Although C. albicans is the most common cause of candidemia, there has been increased isolation of non-albicans species of Candida in recent years. This has been due to the increasing numbers of immunocompromised patients, long-term use of in dwelling catheters, and the use of broad-spectrum antibiotics. In the US, the most prominent strains have been C. tropicalis, C. glabrata, C. parapsilosis, and C. krusei. Clinical and experimental observations have suggested that morbidity and mortality rates are higher for the non-albicans species of Candida compared to C. albicans. This is likely secondary to emerging anti-fungal resistance and increased infections in the immunocompromised patients. C. tropicalis has shown a moderate level of fluconazole resistance but is usually susceptible to amphotericin B and the echinocandins. The choice of anti-fungal therapy depends on relevant comorbidities, evidence of multi-organ involvement, history of recent azole exposure, and local prevalence of different Candida species. Fluconazole is the standard therapy for clinically stable therapy without risk factors for resistance. Therapy may be escalated to echinocandins in patients who are neutropenic and/or unstable and in those with risk factors for azole-resistance. For patients at risk for echinocandin resistance (eg, prior recent exposure to an echinocandin), or who develop candida endocarditis, amphotericin B should be used until anti-fungal susceptibility testing results are available. Treatment duration is usually 2 weeks in patients without end organ involvement. In patients with candidal endophthalmitis, a 6-week duration is required, and with candidal endocarditis valve replacement is required along with 6 weeks of antibiotics.

CANNABINOID HYPEREMESIS SYNDROME - TRULY AN OXYMORON! Sathish kumar Krishnan; Hitu Khaira; Venu M. Ganipiseti. St. Francis Hospital, Evanston, IL. (*Tracking ID #1926420*)

LEARNING OBJECTIVE 1: Recognize cannabinoid hyperemesis syndrome (CHS) is characterized by episodic vomiting, abdominal pain and compulsive hot showering in chronic marijuana users.

LEARNING OBJECTIVE 2: Identify that the rarity of this condition can cause a diagnostic confusion leading to expensive and extensive investigations with a delay in treatment.

CASE: A 32 year old male presented to the emergency department (ED) with a three-day history of nausea, 10–15 episodes of vomiting a day and colicky abdominal pain. He denied eating anything out of the ordinary, sick contact or travelling recently. He denied any alcohol, tobacco or illicit drug use. Vitals were normal. On physical exam, his abdomen was soft and he had mild diffuse tenderness. There was no guarding or rigidity. Murphy's sign was negative. Complete blood count, comprehensive metabolic panel, amylase and lipase were within normal limits. He was treated with intravenous fluids, morphine and anti-emetics. He had been hospitalized five times in the previous 2 years for similar symptoms. During this period, five CT scans and three ultrasound scans of the abdomen, and an esophagogastroduodenoscopy (EGD) were performed, all of which were normal. In one of those encounters, he had reported smoking marijuana. During this admission, he spent most of his day in the shower. When questioned, he reported symptomatic relief with hot showers. A urine toxicology screen was performed which was positive for cannabinoid. A diagnosis of cannabinoid hyperemesis syndrome was established. But, the patient left against medical advice. Two months later, the patient presented with same complaints and his urine toxicology showed cannabinoid. It was explained that marijuana was the cause of his symptoms and he was advised to abstain from smoking marijuana. On follow up in 5 months, he remained free of symptoms.

DISCUSSION: Marijuana is well known for its anti-emetic effect. Paradoxically, chronic use results in hyperemesis. The pathogenesis remains obscure. Patients are typically young adults with a long history of cannabis use. They present with recurrent episodes of nausea, vomiting, and dehydration. The exact incidence and prevalence are unknown. It is likely that this condition is under-recognized and under-diagnosed. Patients usually remain misdiagnosed for a considerable period. In one case series, the average number of ED visits was 7, prior to diagnosis. The lack of understanding and the delayed diagnosis can lead patients to self-medicate with the very substance that is causing the symptoms. As such, patient education is critical. The most intriguing component is the compulsive hot showering and is present in nearly all cases. When questioning a patient's social history, it may be worthwhile to inquire about hot showering patterns, especially in those who deny their use of illicit drugs. It has been proposed that hot bathing may act by correcting the cannabis-induced disequilibrium of the thermoregulatory system in the hypothalamus. Hence, it is important to recognize CHS as it may be misdiagnosed as psychogenic vomiting or 'drug seeking behavior'. It can prevent invasive and unnecessary workups, and lead to reduction in health care costs and morbidity.

CARBON MONOXIDE POISONING: A DIAGNOSIS NOT TO BE MISSED!

Runa Shrestha¹; Rajesh Mourya²; Brian A. Changlai¹. ¹SUNY Upstate Medical University, Syracuse, NY; ²Creighton University, Omaha, NE. (*Tracking ID #1935530*)

LEARNING OBJECTIVE 1: Carbon monoxide (CO), an odorless, colorless, tasteless gas, is formed by incomplete combustion of hydrocarbon from wood or fossil fuels. CO poisoning is the leading cause of poisoning deaths in the United States and often attributed to poor ventilation and malfunctioning machinery. The vague and variable manifestation with which it presents makes CO poisoning a diagnostic challenge.

CASE: A 61-year-old male, with history of hypertension, was brought to the emergency department by his co-workers when he was found to be unresponsive at work. He had been driving a forklift around a small enclosed warehouse for 3 h and developed a mild headache and dizziness before passing out. In the emergency department, he regained consciousness; however he complained of severe headache and unsteadiness. On examination, his vitals were stable but he was lethargic, ataxic and had facial flushing. Meningeal signs were absent. Diagnostic tests including complete blood count, basic metabolic panel, liver function test, ammonia level, coagulation panel and cardiac injury panel were within the normal limit. Electrocardiogram, chest x-ray and computed tomography of the head were normal. Carboxyhemoglobin level turned out to be 36 % (normal range is 0.2 to 6.5 %) and the patient was diagnosed with acute, severe CO poisoning, placed on 100 % oxygen via face mask and was immediately transferred to higher center for hyperbaric oxygen therapy (HBO). After 2 sessions of hyperbaric oxygen therapy, each of 90 min, there

was complete resolution of the neurological symptoms. Repeat carboxyhemoglobin level after the hyperbaric oxygen therapy was 1.6 %. The patient was discharged home the next day without any neurological sequelae.

DISCUSSION: The manifestation of CO poisoning can be non-specific, ranging from mild headache to seizure, myocardial ischemia and coma, and may mimic any type of cardio-neurological disease. Due to the high affinity of carbon monoxide to hemoglobin, CO poisoning leads to severe impairment of tissue oxygenation resulting in end-organ damage and can be fatal if undetected or misdiagnosed. The diagnosis is suggested by a history of exposure to smoke or combustion products and a physical examination revealing insult to the nervous system. It is confirmed with an elevated carboxyhemoglobin level. Physicians should always consider hazardous environments as a possible etiology of a patient's condition. Early detection and initiation of treatment with 100 % oxygen delivery and removal of the source improve morbidity and mortality. Patients exhibiting signs of severe poisoning (altered mentation, CO level more than 25 %, end organ damage) should be treated with HBO therapy. Public education and CO detectors are important prevention measures.

CARCINOID SYNDROME MASQUERADE AS AN ACUTE CORONARY SYNDROME Ajay Dharod; Peter R. Lichstein; Ramon Velez. Wake Forest Medical Center, Winston Salem, NC. (*Tracking ID #1927139*)

LEARNING OBJECTIVE 1: Identify clinical symptoms of carcinoid tumors recognizing that symptoms only occur with hepatic and pulmonary carcinoids.

LEARNING OBJECTIVE 2: Recognize cardiac involvement occurs in up to 50 % of patients with carcinoid syndrome.

CASE: Ms. R, a 48 year old non-smoking Caucasian female with hypertension, diabetes mellitus, hepatitis C, hyperlipidemia and anxiety, presented to the emergency room with 10/10, heavy, non-radiating, mid-sternal chest pressure that began while doing the dishes. She immediately took both alprazolam and Aspirin 325 mg without relief. She also complained of new-onset dyspnea, nausea without vomiting, dizziness, lightheadedness, diaphoresis, facial flushing, intermittent diarrhea, and rigors. A home blood pressure cuff revealed readings of 200 s/110 s. Her mother and sister both suffered from fatal myocardial infarctions and her brother underwent CABG. Her pain was initially 10/10 but improved with nitroglycerin in the ER. Vital signs revealed blood pressure 179/110 and pulse 130. On physical exam, Ms. R had facial flushing, wheezing throughout all lung fields and pitting edema at her ankles. EKG, high-sensitivity troponin-I and CXR were unremarkable aside from sinus tachycardia. Labs were notable for AST 129 and ALT 104. Morning cortisol, TSH, BNP, lipid profile, and HbA1c were normal. Renal artery duplex was unremarkable. CT PE ruled out pulmonary embolism but revealed an incompletely characterized enhancing mass in the liver. Abdominal MRI revealed a hypervascular mass centered within the caudate lobe concerning for hepatocellular carcinoma in the setting of background hepatomegaly and hepatic steatosis. Fine needle aspiration of the liver mass revealed a low-grade metastatic neuroendocrine tumor. 24 h-Urine 5HIAA (hydroxyindoleacetic acid) was 15.0 (Ref <6), Chromogranin A was 154 (Ref <15), 5-Hydroxytryptamine was 97 (Ref 26–265) and 24 h-Urine VMA (Vanillyl Mandelic Acid) was 2.0 (Ref <6). She was diagnosed with carcinoid syndrome. Octreotide scan did not locate a primary. The mass was deemed unresectable given close proximity to the inferior vena cava. She underwent chemoembolization complicated by bronchospasm, flushing, initial hypertension with subsequent hypotension and cardiomyopathy with EF 37 %, elevated right heart pressures and tricuspid regurgitation requiring intubation. After recovery, adenosine stress revealed no-inducible ischemia, EF 56 % and pliable tricuspid valve. She underwent second chemoembolization and, despite octreotide premedication, again required intubation. Post recovery, she underwent resection of the carcinoid liver tumor. Ms. R suffered with continued diarrheal symptoms after her chemoembolization which improved with Somatostatin analogue treatment. She had no further episodes of chest pain.

DISCUSSION: Clinical symptoms (flushing, diarrhea, bronchoconstriction and telangiectasias) arise in patients with hepatic and pulmonary carcinoids secondary to secretion of vasoactive substances directly into the central venous system, bypassing hepatic metabolism (Moller JE, 2003; Fink, 2001). In Ms. R's case, the presence of hepatic metastases allowed for her presentation with neuroendocrine crisis (flushing, bronchoconstriction, hypertension & hypotension). Chest pain has been reported in 1–19 % of patients and coronary artery spasm may occur during flushing episodes (Hage, 2003; Powell, 2011). Interestingly, chromogranin A concentration is an independent predictor of long-term mortality and heart failure hospitalizations in patients with acute coronary syndromes (Jansson, 2009). To our knowledge, there is no literature describing a direct relationship between carcinoid syndrome and acute coronary syndromes. Vasoactive substances cause cardiac valve leaflet fibrous endocardial plaques, classically on the tricuspid and pulmonary valves (Farb, 2000; Otto CM, 1999). Right-sided heart failure with worsening dyspnea, edema, ascites and cardiac cachexia occur with progressive disease (Moerman, 2012). Ms. R's

presentation of carcinoid crisis with bronchospasm, hypertension and hypotension twice in the setting of tumor ablation may relate to an acute exacerbation of underlying progressive right heart failure. Hypertensive carcinoid crisis is rare with few case-reports in the literature. Carcinoid hypertensive crisis typically occurs peri-operatively related to the stress of anesthesia and surgery by an unclear mechanism. Both hypertensive and hypotensive carcinoid crises can be managed with pre-, intra-, and post-operative Octreotide treatment (Yates, 2010; Warner, 1994). Overall prognosis is poor with mean survival of 1–2 years post diagnosis. Treatment is directed at medical therapy for right heart failure and treatment of hepatic metastasis with systemic chemotherapy, chemoembolization, radiofrequency ablation, and surgical resection if possible. Somatostatin analogues, serotonin antagonists, and alpha-adrenergic blockers provide partial symptomatic relief (Oberg, 2004; Strossberg, 2011; Strossberg, 2013).

CARDIAC TAMPONADE AS THE INITIAL PRESENTATION OF UNDIAGNOSED LUNG CANCER Hirva Mamdani; Dipen Kumar Modi; Theresa Vettese. Wayne State University, Detroit, MI. (*Tracking ID #1939146*)

LEARNING OBJECTIVE 1: To recognize cardiac tamponade as a possible initial presentation of underlying malignancy especially in high risk patients

LEARNING OBJECTIVE 2: To recognize the importance of good history and physical exam in the diagnosis of cardiac tamponade

CASE: A 59 years old African American man with extensive smoking history presented with complaints of exertional shortness of breath and dry cough of 1 month duration. He also had unintentional loss of about 10 lbs over 2 months prior to presentation. He did not have any fever, chills, night sweats, orthopnea, or PND. He also did not have any prior history of or exposure to tuberculosis or incarceration. On admission, he was found to be afebrile, but hypotensive (90/60), tachycardic (113), and tachypneic (respiratory rate 22/min). On physical exam, he was in mild distress, had jugular venous distension, muffled heart sounds, and diminished breath sounds on the left. EKG showed sinus tachycardia with low voltage QRS complexes. A bedside echo showed large pericardial effusion, diastolic collapse of right atrium and ventricle with paradoxical septal motion, and plethoric inferior vena cava. The patient was diagnosed with cardiac tamponade and was immediately taken for pericardiocentesis with removal of about 800 cm³ of hemorrhagic fluid. Lab studies were remarkable only for mild normocytic anemia. The patient showed significant hemodynamic and symptomatic improvement. Subsequently pericardial fluid cytology returned back positive for malignant cells concerning for adenocarcinoma. Subsequent CT thorax showed a left sided lung mass with left pleural effusion. Finally the patient was diagnosed with adenocarcinoma of lung with CT guided biopsy.

DISCUSSION: Malignant involvement of the pericardium is not an uncommon phenomenon, especially in patients with lung cancer, breast cancer, lymphomas, leukemias, and melanomas. It can manifest as pericardial effusion, cardiac tamponade, or constrictive pericarditis. Cardiac tamponade as the first clinical presentation of the underlying yet undiagnosed malignant process is uncommon. There have been a few case reports and small case series reporting lung cancer, breast cancer, adenocarcinoma of Fallopian tube, soft tissue sarcomas, primary cardiac sarcoma, metastatic hepatocellular carcinoma, and renal cell cancer presenting with cardiac tamponade secondary to malignant pericardial effusion. Having a high index of suspicion from history (including risk factors for malignancy) and physical exam as well as initial imaging studies are of utmost importance in timely diagnosis of the nature of the disease. Physical exam features of hypotension, tachycardia, pulsus alternans, pulsus paradoxus, distended neck veins, positive Kussmaul's sign, and muffled heart sounds are important diagnostic clues. EKG is usually low voltage and may show electrical alternans. Echocardiography shows pericardial effusion along with diastolic collapse of the right sided heart chambers, increased respiratory variation in the peak mitral and tricuspid inflow velocities, and IVC dilatation. Initial therapeutic intervention with pericardiocentesis and/or pericardial window placement allows for rapid symptomatic relief. Fluid cytology is very useful in detecting the presence of the malignant cells and the nature of the underlying malignancy. However, its clinical utility is limited by its low sensitivity. Long term management is largely dependent on the extent and histologic features of the underlying malignant conditions. Different treatment options include systemic chemotherapy and/or radiotherapy in case of sensitive tumors such as lymphoma, leukemia, or breast cancer. Local sclerotherapy with intrapericardial instillation of various sclerosing agents such as tetracycline, bleomycin, or cisplatin can also be attempted. In some cases, pericardectomy is necessary to prevent recurrent malignant pericardial effusion. In most of the cases, the condition is usually incurable and above modalities only offer palliation.

CASEATING GRANULOMAS, TB OR NOT TO TB? Bishr Alhafiez; Arati K. Kelekar. Oakland University William Beaumont School of Medicine, Huntington Woods, MI. (*Tracking ID #1939071*)

LEARNING OBJECTIVE 1: To expand the possibilities in the differential diagnosis of caseating granulomas

CASE: A healthy 64 year old male with no significant past medical history presented with one episode of hemoptysis. He also complained of 3 weeks of left sided chest pain. He denied any history of fever, chills, night sweats, weight loss, dyspnea, palpitations, dizziness, or cough. The patient was not a smoker. He was a war veteran. Laboratory studies showed a mild neutrophilia. A chest X-ray revealed a large left upper lobe mass. A computerized tomography of the chest confirmed the presence of a 10 cm mass in the upper lobe of the left lung. Tissue analysis of a specimen obtained through transbronchial biopsy showed caseating granuloma with lamellated fibrous capsules and epithelioid histiocytes with central necrotic debris. No atypical or malignant cells were seen. This histology raised concern for tuberculosis. However, sputum culture for AFB, Quantiferon testing and AFB staining of the biopsy tissue were all negative. A suspicious looking osseous lesion in the T6 vertebral body was biopsied. It revealed high-grade malignant spindle and epithelioid cell neoplasm. He was started on radiation therapy and received two cycles of chemotherapy with gemcitabine and docetaxel.

DISCUSSION: Primary lung sarcomas are rare and compromise less than 1 % of all primary lung tumors. They are associated with worse survival compared to other types of lung cancer. Epithelioid tumors are a rarer subtype of lung sarcomas. They are highly vascular and rapidly growing which predisposes them to tissue necrosis. This case raises the importance of considering lung sarcoma in the differential diagnosis of tuberculosis. It is prudent to suspect this diagnoses especially if the clinical presentation is not typical for tuberculosis.

CATASTROPHIC ANTIPHOSPHOLIPID SYNDROME IN A PATIENT WITH LUNG MALIGNANCY Aakriti Gupta; Liam Zakko. Yale New Haven Hospital, New Haven, CT. (*Tracking ID #1940029*)

LEARNING OBJECTIVE 1: To learn about the clinical presentation of catastrophic anti-phospholipid antibody syndrome in the setting of malignancy

LEARNING OBJECTIVE 2: Review the importance of chart documentation, outpatient and inpatient physician communication, and chart review

CASE: Patient is a 67 year old lady with history of stage IIIA adenocarcinoma of the lung (diagnosed in 5/2013) who received 3 cycles carboplatin/paclitaxel and radiation treatment and extensive right lower extremity deep vein thrombosis (DVT) in 6/2013 that was anticoagulated with lovenox. As an outpatient, she was noted to have thrombocytopenia and her anticoagulation was held in 9/2013. Around the same time, she developed severe abdominal pain and significant diarrhea that lasted more than a week when she presented to the emergency department where she was febrile to 100.6 F with tachycardia. Exam was notable for subungual splinter hemorrhages, multiple erythematous macules and painful nodules in her palms and soles bilaterally. Laboratory tests revealed platelet count of $42000/\text{cm}^3$, mild transaminitis and hyperbilirubinemia. Chemistry panel was unremarkable (creatinine 1.0 mg/dl). Imaging of the abdomen showed mild ascending colitis as well as a non-specific heterogeneity in the liver. Infective endocarditis workup was unrevealing. We initiated antibiotics for infectious colitis. Her course over the ensuing week was complicated by worsening thrombocytopenia ($11000/\text{cm}^3$), new infiltrate in right lung without fever or leukocytosis, new atrial fibrillation with ST depressions in V3-V6 leads and elevated cardiac enzymes. Finally, she developed acute kidney injury (creatinine 2.7 mg/dl) and oliguria with evidence of schistocytes on blood smear. At this time, chart review revealed that patient had been tested for antiphospholipid (aPL) panel in June as an outpatient that was markedly positive for anticardiolipin IgM, antiphosphatidylserine, beta-2-glycoprotein IgA, lupus anticoagulant and dilute viper venom test which were positive on repeat testing by us. Bone marrow biopsy revealed a large intravascular thrombus in the marrow. We diagnosed our patient with catastrophic antiphospholipid antibody syndrome (APS) thought to be triggered from discontinuation of anticoagulation and infectious colitis in the setting of lung malignancy with likely clot formation in the pulmonary vasculature, coronary arteries, liver, microvascular renal vessels, bone marrow, and microangiopathic hemolytic anemia. We treated her with anticoagulation, high dose steroids, plasmapheresis, IVIG, and rituximab with significant improvement in her organ function and her lab abnormalities including improvement in platelet count to $145000/\text{cm}^3$.

DISCUSSION: According to revised Sapporo criteria, definite APS is considered when there is presence of clinical evidence of vascular thrombosis/pregnancy morbidity (extensive DVT in our patient) AND serologic confirmation of aPL at

least 12 weeks apart. Initially described in patients suffering from systemic lupus erythematosus, APS may occur in the setting of multiple autoimmune conditions and malignancies. Catastrophic APS is an accelerated form of this condition involving evidence of multiorgan involvement over a short period of time, laboratory confirmation of presence of aPL and histopathologic confirmation of small vessel occlusion, all of which were present in our patient. Manifestations commonly include thromboses in cerebral, pulmonary, cardiac, hepatic, or renal vasculature. Our patient was unique in having an intravascular thrombus in the bone marrow as well. Rapidly occurring and fulminant thrombotic complications seen in patients with malignancies should raise suspicion for catastrophic APS, and these patients may benefit from early and aggressive treatment of this often fatal syndrome. Treatment involves anticoagulation, plasmapheresis, pulse dose steroids and plasmapheresis, all of which our patient received. Finally, diagnosis and treatment of the patient was delayed since the initial diagnosis of APS was not documented in the chart. This case demonstrates the significance of thorough chart review and timely communication amongst the inpatient and outpatient providers.

CELLULITIS WITH AN ARRHYTHMIC TWIST Allison C. Heacock. The Ohio State University Wexner Medical Center, Columbus, OH. (*Tracking ID #1939154*)

LEARNING OBJECTIVE 1: Diagnose Brugada Pattern and Brugada Syndrome

LEARNING OBJECTIVE 2: Recognize provoking factors for Brugada Syndrome and indications for implantable cardioverter-defibrillator placement

CASE: 43 yo male prisoner was admitted for left arm erythema, swelling and fever. He had received a prison tattoo 2 weeks prior to admission. Approximately, 10 days later he began to have swelling, erythema and decreased range of motion of his left elbow. He was treated with Bactrim but symptoms worsened and he developed a fever to 101° Fahrenheit. During review of symptoms the patient endorsed occasional substernal chest pressure occurring at rest with no associated symptoms. The pain was self-resolving. He denied any past medical history or surgical history. He was a former smoker. His cardiac family history was notable for coronary artery disease in his mother and maternal aunt and sudden cardiac death in a maternal uncle. He was taking no medications. On physical exam the patient was afebrile after receiving acetaminophen. He had left arm erythema and swelling of his elbow. The remainder of his exam was within normal limits including his cardiovascular exam. The patient was admitted and started on antibiotics. An electrocardiogram (ECG) was done due to his recurrent chest pain. This showed sinus tachycardia, incomplete right bundle branch block, "saddle back type" ST elevated in V2 with atypical ST elevation in lead V1 and V3. No t wave inversion. Troponins $\times 3$ were normal. An ECG on hospital day two showed normal sinus rhythm with complete resolution of the RBBB and ST elevation. The patient was diagnosed with type 2 Brugada Syndrome, which was likely provoked by his fever. His ECG findings had resolved with defervescence of his fever. His chest pain was determined to be non-cardiac in origin and not secondary to his Brugada syndrome. The patient was discharged with anticipatory guidance including a list of medications and other Brugada Syndrome provoking factors to avoid.

DISCUSSION: Brugada syndrome is an autosomal dominant disorder characterized by typical ECG findings including right bundle branch block and ST elevation with increased risk for ventricular tachyarrhythmia and sudden cardiac death. Sudden cardiac arrest may be the initial presenting symptom in up to one third of patients. The typical ECG findings can also be found in asymptomatic patients without diagnostic clinical criteria and is defined as Brugada pattern. The typical ECG findings of type 1 Brugada pattern are "coved type" ST elevation with negative t waves in more than one right precordial lead (V1-V3). Type 2 is characterized by "saddle back type" ST elevation in more than one right precordial lead (V1-V3) with positive t waves. In order to diagnose a patient with Brugada syndrome as opposed to Brugada pattern they must have one of these typical ECG findings plus one of the following: History of documented ventricular tachycardia (VT) or ventricular fibrillation (VF), family history of sudden cardiac death at less than 45 years of age, family history of type 1 Brugada syndrome ECG changes, unexplained syncope, nocturnal agonal respiration or inducible VT during electrophysiology study. Our patient met criteria for Brugada syndrome due to his Type 2 Brugada ECG findings and family history of sudden cardiac death in his maternal uncle. There are several provoking factors of the Brugada ECG pattern. These include medications such as sodium channel blockers, beta blockers, tricyclic or tetracyclic antidepressants, lithium and local anesthetics. Other factors include vagal maneuvers, hypokalemia, hyperkalemia, hypercalcemia, alcohol and cocaine toxicity and fever. Data from a retrospective review by Amin et al. showed that fever was associated with Brugada ECG changes and was present in 4 out 22 patients with cardiac arrest. These findings may resolve with removal of provoking factors. This occurred in our patient when his ECG returned to normal after his fever defervescence. The most important risk

factor of sudden death in Brugada Syndrome is a history of ventricular tachyarrhythmia or syncope. The use of electrophysiology studies to induce VT/VF has not been shown to be predictive of risk and should not be used in risk stratification. The only treatment that has been shown to improve mortality from tachyarrhythmia is implantable cardioverter-defibrillator (ICD) and should be considered as first line therapy in all patients with Brugada syndrome and syncope, ventricular tachycardia or ventricular fibrillation. In conclusion, risk stratification of asymptomatic Brugada syndrome is ill defined but diagnosis should be made in order to provide patients with education on avoiding provoking factors and for ICD implantation on those patients with highest risk for sudden cardiac death.

CEREBRAL SALT WASTING SYNDROME OR SIADH: HYponatremia IN A PATIENT WITH METASTATIC BRAIN LYMPHOMA SeyedAmirhossein Afsharimani; Samaneh Dowlatshahi; Harvey Friedman. St. Francis Hospital, Evanston, IL. (*Tracking ID #1926324*)

LEARNING OBJECTIVE 1: Hyponatremia is common in the setting of central nervous system (CNS) disease which is usually attributed to SIADH. However, cerebral salt wasting (CSW) is another potential cause of hyponatremia, which is characterized by excessive natriuresis, hypernatremia and volume depletion with associated cerebral pathology.

LEARNING OBJECTIVE 2: Although clinical presentation of SIADH and CSW is similar, in CSWS, there is relative or overt hypovolemia whereas SIADH is associated with normal or hypervolemia. It is essential to differentiate these two disorders, in order to provide appropriate therapy.

CASE: A 59 year old female with history of diffuse large B cell lymphoma of breast on second cycle of R-CHOP chemotherapy, and recently diagnosed brain metastasis in right and left frontal parietal area, presents with increasing weakness. Her lips and tongue were dried because he had little oral intake of food and fluid for 15 days. Initial vital signs were significant for a BP: 76/53 mmHg, and a heart rate of 120/min. His serum sodium level was 131 mmol/l, potassium was 3.6 mmol/l, chloride was 98 mmol/l, urine sodium was 228 mmol/l, plasma osmolality was 273 mOsm/kg, urine osmolality was 540 mOsm/kg, and urine specific gravity was 1.014. The serum blood urea nitrogen level was 8 mg/dL, uric acid was 1.2 mg/dL, and creatinine was <0.20 mg/dL. Hormone levels from the laboratory test revealed normal antidiuretic hormone (ADH), renin, and, aldosterone level. Urine output showed 3.1 mL/kg/h. She was started on IV fluid replacement with normal saline which improved her BP to 85/65 mmHg. However, excessive urine output continued and increased up to 4 mL/kg/h. Although the urine sodium level and volume were not normalized, his serum sodium level increased to 133 mEq/L after sodium chloride infusion. Patient has been on dexamethasone high dose for 3 weeks before admission for excessive brain edema on recent imaging which resulted in a suppressed cortisol level. Patient was started on fludrocortisone 0.1 mg BID. Her sodium level improved to 136 mmol/l after 5 days of treatment and fludrocortisone was held. On the 5th day of treatment his urine sodium was 95 mmol/l.

DISCUSSION: CSW was once thought to be a misnomer, however recent studies have shown that it not only exists, but also is not uncommon among patients with acute or chronic brain injuries. This condition can have significant negative consequences if not properly diagnosed and treated. It is important to differentiate CSW from SIADH. The key in diagnosis of CSW lies in volume status evaluation. The goal in treatment of CSW syndrome is to replace sodium and volume, and this can be achieved with combination of isotonic saline, hypertonic saline, and mineralocorticoids.

CERVICAL NECROTIZING FASCIITIS: CLINICAL MANIFESTATION AND MANAGEMENT Shenelle-Marie Wise; Kate Hust. Tulane University Health Sciences Center, New Orleans, LA. (*Tracking ID #1926148*)

LEARNING OBJECTIVE 1: Recognize the clinical manifestations of and risk factors for cervical necrotizing fasciitis.

LEARNING OBJECTIVE 2: Identify the differential diagnosis for necrotizing fasciitis and its appropriate diagnostic evaluation and treatment.

CASE: A 29-year-old woman presented with 1 week of fevers and pain along her left neck. A week prior to admission she complained of a sore throat and developed a small lump on her mandible, which increased in size, became erythematous, and painful. On presentation, her temperature was 102° Fahrenheit, and physical exam revealed erythema and tenderness extending from her left anterior neck to the 3rd intercostal space. CT scan revealed cellulitis and edema of the anterior left neck extending to left anterior chest wall with extensive periodontal disease and periapical abscess. Treatment was started with broad-spectrum antibiotics, but with worsening of

the erythema and pain overnight, she was taken to the operating room for surgical exploration. Deep neck abscesses were drained and necrosis of both subcutaneous fat and muscle layers was debrided. Surgically obtained cultures grew Group A streptococcus. Her hospital course involved serial surgical debridements until her symptoms improved.

DISCUSSION: Necrotizing fasciitis is a rapidly progressing soft tissue infection that carries a significant mortality rate despite intensive treatment. More commonly seen in the abdomen, perineum, and lower extremities, the neck, owing to its rich vascular network, is a rare site for this condition. Given its rarity but high mortality, internists should consider this diagnosis in patients who present with neck pain and progressive and painful cellulitis. It is characterized by widespread destruction of the subcutaneous tissues and fascia, and gas formation in anatomic spaces. Overlying skin and muscles are spared initially but may undergo necrosis with disease progression. Cervical necrotizing fasciitis is most commonly caused by dental infections, especially from the mandibular molars. Less common causes are minor trauma leading to an opening in the skin, peritonsillar abscess, insect bites, and hypodermic needle infection. Conditions predisposing necrotizing infections include diabetes, drug use, obesity, immunosuppression, recent surgery, and traumatic wounds. Cervical necrotizing fasciitis has a reported mortality rate of 7 % to 20 %, depending on the extent of neck involvement. When the disease progresses into the thorax with descending necrotizing mediastinitis the mortality rate increases to 41 %. The affected area is usually erythematous, swollen, warm, and exquisitely tender. The process progresses rapidly over several days, with changes in skin color from red-purple to patches of blue-gray. In advanced infection, high fever and systemic toxicity are generally observed. This is in contrast to necrotizing cellulitis which may present with thin, dark wound drainage and gas formation in the skin but pain, swelling and systemic toxicity are not prominent features. Numerous case reports have documented pyoderma gangrenosum misdiagnosed as necrotizing fasciitis. Pyoderma is an inflammatory dermatologic condition that presents with ulceration and tissue necrosis similar to infectious processes. It is often a diagnosis of exclusion and should be considered if there is no symptom improvement with antibiotics and cultures remain inconclusive. Additionally, pyoderma is often associated with pathergy, a phenomenon that may lead to worsening necrosis with surgical debridement. Laboratory findings are generally nonspecific. Abnormalities may include leukocytosis with a marked left shift, coagulopathy, and elevations in the serum creatine kinase, lactate, and creatinine. Soft tissue x-ray, CT scan and MRI are most helpful if gas is visualized in the tissue, but more often, imaging studies demonstrate soft tissue swelling. Surgical exploration is the only way to definitively establish the diagnosis, facilitate early debridement and allow specimens to be obtained for cultures. In addition to surgical debridement, mainstays in management are early airway protection and broad-spectrum antibiotics against group A streptococci, anaerobes, and methicillin-resistant *Staphylococcus aureus*. Acceptable regimens include administration of a carbapenem or beta-lactam/beta-lactamase inhibitor for activity against gram-positive, gram-negative, and anaerobic organisms. Clindamycin should be included for its effects against toxin-producing strains of streptococci and staphylococci, and an agent with activity against methicillin-resistant *Staphylococcus aureus* such as vancomycin, daptomycin, or linezolid should be added. Antibiotic treatment should be tailored to Gram stain, culture, and sensitivity results when available.

CHANGE IN MENTAL STATUS AND RECURRENT HYponatremia ATTRIBUTABLE TO BEER POTOMANIA Naba R. Mainali; Ranjan Pathak; Madan R. Aryal; Richard Alweis. Reading Health System, West Reading, PA. (*Tracking ID #1933869*)

LEARNING OBJECTIVE 1: To be able to diagnose hyponatremia secondary to beer potomania.

LEARNING OBJECTIVE 2: To identify the indications of treatment with hypertonic saline in hyponatremia caused by beer potomania.

CASE: Introduction: Beer Potomania is a syndrome manifested by severe hyponatremia and mental status changes (agitation, confusion and seizures), seen in patients who consume excessive beer and have poor dietary intake. Early recognition is important as hyponatremia, if not symptomatic, corrects simply with normal diet and cessation of alcohol. Case Report: A 64-year-old chronic alcoholic woman presented with altered mental status, difficulty walking and confusion of 10 h duration. She progressively became more confused and agitated, and developed ambulatory dysfunction without loss of consciousness or witnessed seizure. She gave the history of drinking up to 20 cans of beer a day without significant food intake for 5 consecutive days. She had two similar episodes in the past requiring ICU admission, treated with 3 % hypertonic saline initially but was switched to normal saline due to too rapid correction. Physical exam revealed tachycardia, agitation and mild confusion with unstable gait. Laboratory tests revealed sodium 112 mEq/L, potassium 2.7 mEq/L, chloride 77 mEq/L, bicarbonate 15.9 mEq/L, blood alcohol level 0.27 % (by volume), ALT 59 U/L, AST 120 U/L, serum uric acid 3.6 mg/dL, plasma osmolality 241 mOsm/Kg, urine osmolality 99 mOsm/Kg, urine sodium 19 mEq/L and negative urine toxicology. Other hyponatremia like dehydration, SIADH were thus excluded. She was given normal saline and responded well.

DISCUSSION: Beer potomania is a disorder where dietary sodium and protein insufficiency lead to dilutional hyponatremia that is often seen in chronic alcohol abusers. The clinical picture and laboratory values are consistent with water intoxication (hyponatremia, hypochloremia and hypokalemia). The pathophysiology involves inability of kidneys to excrete sufficient amount of free water due to the loss of normal renal urea gradient. Aggressive correction of chronic hyponatremia with hypertonic saline should not be attempted unless there are complications like seizure due to high risk of central pontine myelinolysis.

CHEST PAIN IN A YOUNG WOMAN DUE TO IVC FILTER FRAGMENT IMBEDDED IN THE SEPTAL WALL OF THE RIGHT VENTRICLE Yagna R. Bhatrai; Gabriel S. Lerman; Manzoor Rather; Eric Green; Martin O'Riordan. Mercy Catholic Medical Center, Upper Darby, PA. (*Tracking ID #1927306*)

LEARNING OBJECTIVE 1: Understand the risks of inferior vena cava (IVC) filter fracture and embolization.

LEARNING OBJECTIVE 2: Detect and prevent possible complications by appropriate screening and retrieving if no longer indicated.

CASE: Introduction: The fracture of an inferior vena cava filter (IVC) and its subsequent migration is a well-documented complication of the Brad Recovery IVC filter. While the lung constitutes the major destination of these fragments, migration to the ventricular chamber is a rare complication. Case: A 46-year-old woman with a history of COPD, depression, and prior IVC filter presented with non-radiating, left sided chest pain for several days, associated with occasional palpitations and exertional dyspnea. She was not on any regular medications. Physical exam was normal aside from chest pain and mild wheezes. A chest x-ray, EKG, and blood work (including cardiac biomarkers) were normal. A CT chest angiogram revealed a linear foreign body in the septal wall of the right ventricle and normal pulmonary arteries. An echocardiogram showed an echo dense linear structure protruding from RV septal wall into the RV cavity, without evidence of pericardial effusion. She underwent successful retrieval of the filter via interventional radiology. A visual inspection showed an IVC filter with missing tynes. She was symptomatically better after retrieval. We decided to leave the IVC fragment embedded in the RV septum because we felt the risk of removing a foreign body imbedded in the myocardium (probably for several years) outweighed the benefits.

DISCUSSION: The most common complications after IVC filter placement are recurrent PE, thrombosis of the IVC, and local access site complications. Filter fractures with embolization is relatively rare, with an estimated incidence of 1 to 2 % of cases. Two published studies have looked at a total of 83 patients with filter fractures. The incidence increased with longer filter dwell times and with certain types of filters. The majority of filter embolizations were in the lungs, and most are clinically "silent." However, both right ventricular embolization complicated by cardiac tamponade have been reported. Although retrieval of the main filter body is typically successful, removal of the embolized fragments have had variable success. Patients with any retrievable filter should understand the risks associated with fracture and embolization. Evaluation for filter embolization should be considered in patients with a history of long term IVC filters who present with unexplained chest pain or shortness of breath.

CHEST PAIN MIMICKER: ACUTE GASTRIC VOLVULUS Praveena N. Iruku; Tareq Khader; Anna Maria Affan. St Vincent Charity Hospital, Cleveland, OH. (*Tracking ID #1933868*)

LEARNING OBJECTIVE 1: Diagnose the uncommon fatal causes of chest pain

LEARNING OBJECTIVE 2: Manage acute gastric volvulus

CASE: Case Presentation: This is a 66 year old female with past medical history of asthma and heart burn who presented to the emergency room with severe chest pain and left sided shoulder pain. Chest pain is described as sudden onset, left sided and epigastric in location, steady, and 10/10 in intensity, associated with some shortness of breath and nausea. She denied any abdominal pain, vomiting, diarrhea, loss of appetite or weight. She complained of some early satiety and bloating. She did not do any unusual weight lifting or activity. Her past history is significant for cholecystectomy and mesh repair for umbilical hernia. Social history is unremarkable. Physical examination demonstrated normal vital signs. Patient was alert, oriented and in moderate pain distress. Neck and shoulder exam were unremarkable. Chest auscultation revealed very prominent bowel sounds, otherwise normal air entry. Abdominal exam was unremarkable except for mild epigastric tenderness. Contrast Tomographic (CT) scan with a pulmonary embolism (PE) protocol revealed a large bilateral diaphragmatic hernia with possible obstruction and stomach rotated along its own long axis. There was no evidence of PE or myocardial ischemia. Multiple attempts to pass a nasogastric tube failed. Exploratory laparotomy showed major portion of the stomach, splenic flexure and transverse flexure of the colon in the chest. Fundoplication was performed to prevent recurrence.

DISCUSSION: Gastric volvulus is defined by abnormal rotation of the stomach of more than 180° thereby creating a closed loop obstruction. It is mainly composed of three types, organoaxial, mesenteroaxial, and combined type. Organoaxial is the most common type of volvulus which means that the stomach rotates around its own long axis and is associated with large diaphragmatic hernia. Strangulation and necrosis commonly occur with organoaxial gastric volvulus and have been reported in 5–28 % of cases. The classic triad of gastric volvulus, described by Borchardt in 1904, consists of severe epigastric pain without vomiting, inability to pass a nasogastric tube and sometimes severe pain at the top of left shoulder which may be due to internal bleeding irritating the diaphragm upon respiration. Diagnosis is based on clinical suspicion, radiographic studies and endoscopy. Treatment is surgical and non operative mortality is very high. In conclusion, acute gastric volvulus is an important and timely diagnosis to make in any clinical setting given the increase in fatality with delay. It is an uncommon encounter and needs a high index of suspicion. We present a case of acute gastric volvulus and diaphragmatic hernia presenting with severe chest pain. The diaphragmatic hernia may be from diaphragm injury during her previous surgeries and it might have been complicated with adhesions leading to traction on the diaphragm and diaphragmatic hernia.

CHLORPROMAZINE-INDUCED HEPATITIS Anita Mulye; Tara Lagu. Baystate Medical Center, Springfield, MA. (*Tracking ID #1936726*)

LEARNING OBJECTIVE 1: Diagnose drug-induced hepatitis with significant clinical signs and symptoms, imaging, and procedures (ie biopsy)

LEARNING OBJECTIVE 2: Recognize adverse effects of medications commonly prescribed

CASE: A 34yo woman with a history of bipolar disorder and attention-deficit hyperactivity disorder presented with a one-month history of nausea and vomiting of non-bloody non-bilious emesis, and anorexia. Three days prior to presentation, the patient developed severe right upper quadrant abdominal pain. On presentation to the emergency department, the patient was afebrile and other vital signs were stable, but she was noted to be severely jaundiced with scleral icterus and abdominal exam revealed right upper quadrant that was tender to palpation without rebound or involuntary guarding. HIDA scan indicated possible common bile duct dilation and abdominal ultrasound revealed a contracted gallbladder with possible non-shadowing stones. Computed tomography of the abdomen was unrevealing for acute processes and ERCP revealed no obstructive etiologies. Serum anti-mitochondrial antibody, anti-smooth muscle antibody was negative, and ceruloplasmin were all either negative or within normal limits, ruling out primary biliary cirrhosis, autoimmune hepatitis and Wilson's disease, respectively. Anti-nuclear antibody was positive but with only a 1:400 titer. The patient subsequently underwent liver biopsy, which revealed significant cholestasis with marked eosinophilia, inflammation and bile duct edema. These findings were felt to be most consistent with drug-induced hepatitis. The team conducted a detailed review of the medications the patient had taken in the months prior to presentation, revealing metoclopramide 10 mg, clonazepam 0.1 mg three times daily, lithium 300 mg daily, methylphenidate 36 mg daily, chlorpromazine 25 mg three times daily (of which the patient was advised to take two at a time), ondansetron 4 mg every 8 h as needed. Her lithium dose had been increased a week prior to admission to the above dose with the intention to taper clonazepam. The patient also developed a diffuse pruritic urticarial type rash with eosinophilia several days after presentation.

DISCUSSION: Drug-induced hepatitis occurs in 1 out of every 1000 to 100,000 patients and is more common in women (1,2). The clinical manifestations of most drug-induced hepatitis resemble viral hepatitis with malaise, jaundice and transaminitis. However, different pharmacological entities have specific patterns of injury (i.e. hepatocellular, cholestasis, autoimmune, fibrosis, etc.). In cholestatic injury, there are four histological types: pure (canalicular, bland or noninflammatory), cholestatic, ductopenic, and sclerosing cholangitis (7). Symptoms typically develop within 1–6 weeks of initial ingestion of the medication and may continue evolving even after the agent is withdrawn (1,8). Some drugs have a strong allergic component, causing fever, rash, lymphadenopathy, and hepatic injury. Although chlorpromazine is typically associated with cholestasis, it is possible that a mild form of this "reactive metabolite syndrome" was the source of this patient's pruritic rash as this developed several days after the patient began having other signs of hepatic injury (3,4). Chlorpromazine-induced hepatitis occurs in 0.2–2 % of patients (8), with 80–90 % of cases developing within the first 4 weeks (5). The mechanism by which chlorpromazine decreases canalicular function and bile flow has been hypothesized to be due to poor genetic sulfoxidation of free radicals and hydrocarbons making

affected patients more susceptible to cholestasis (9). Light microscopy shows cholestasis and a predominance of mononuclear and eosinophilic cells, although hepatocellular injury and granuloma formation is possible as well (6). In the case of our patient, liver functions tests and bilirubin trended down with removal of the offending agent to near-normal levels approximately 42 days after initial presentation, and her abdominal pain gradually dissipated as well. The hypersensitivity or reactive metabolite syndrome improved with triamcinolone cream within 24 h of treatment. The etiology of her emesis and remains unclear, however her remaining symptoms are gradually resolving and thought to be due to chronic hepatitis from the inciting injury.

CHOLESTEROL AND CRAMPS: A PROBLEM OF PROLIFIC PRESCRIBING PATTERNS Jeffrey K. Hom, University of California, San Francisco, San Francisco, CA. (*Tracking ID #1939358*)

LEARNING OBJECTIVE 1: Recognize the risk factors for muscle injury associated with HMG-CoA reductase inhibitors

CASE: A 54 year-old man with type 1 diabetes mellitus, hyperlipidemia, hypertension, and stage III chronic kidney disease presented to clinic with 2 days of “leg cramps”. The discomfort was “a sore ache” in both his calves that was worst at night. He denied a preceding viral prodrome, trauma, restless legs, dehydration, or distal paresthesias. He had taken gabapentin without relief. His other medications were amlodipine, atorvastatin, enalapril, insulin, and tramadol. His exam was notable for diffusely tender gastrocnemius muscles, without warmth, swelling, discoloration, or palpable cord. His distal extremities were well-perfused, with 2+ pedal pulses, and his sensation was intact to monofilament. He had full strength and ambulated without difficulty. Labs revealed an elevated creatine kinase (CK) (2605 U/L), creatinine (1.83 mg/dL, up from 1.65 mg/dL), and glucose (363 mg/dL). A urinalysis had been ordered but not obtained. Two weeks prior to presenting his atorvastatin had been increased from 20 mg to 40 mg nightly for persistently elevated LDL. Given the suspicion for statin-induced myositis, the patient's atorvastatin was discontinued and aggressive hydration was recommended. Repeat labs 3 days later showed a CK of 459 U/L and a creatinine of 1.46 mg/dL. His cramps resolved over the following 2 weeks and his CK had returned to normal 1 month after his initial presentation.

DISCUSSION: One in four adults in the United States over age 45 is prescribed an HMG-CoA reductase inhibitor (“statin”), a number sure to increase under the new ACC/AHA guidelines. Muscle injury is known side effect of statins and should remain a concern in all patients taking them, regardless of the duration of treatment. The degree of injury ranges from myalgias to rhabdomyolysis, and patients may complain of cramps, aches, fatigue, or weakness. The mechanism by which muscle toxicity occurs is not well understood. While the incidence varies among statins due to differences in absorption and metabolism, higher doses are associated with greater risk. Other risk factors include hypothyroidism and renal and liver diseases. Additionally, because many statins are metabolized by cytochrome P450 3A4 (CYP3A4), concurrent use of medications that inhibit or compete for this enzyme, including amlodipine, increases susceptibility to developing myopathy. Myositis, as was suspected in this patient, is uncommon, occurring in 0.5–0.9 % of patients on statin monotherapy for hyperlipidemia. Resolution of symptoms and normalization of CK occur following withdrawal of the medication. For patients who develop muscle injury other than rhabdomyolysis, a trial of pravastatin or fluvastatin, two statins with less intrinsic muscle toxicity and not metabolized by CYP3A4, can be considered with close monitoring. While the occurrence of statin-induced myopathy is rare, the burden of disease from this adverse effect should not be overlooked when greater than 255 million prescriptions for cholesterol-lowering medications are written annually in the United States.

CHORDOMA: A RARE CAUSE OF PROGRESSIVE NEUROLOGIC SYMPTOMS AND HORNER'S SYNDROME Marjan M. Hovaida, UCSD, San Diego, CA. (*Tracking ID #1936961*)

LEARNING OBJECTIVE 1: Recognize chordomas as rare bone tumors that commonly present as chronic, progressive neurologic symptoms refractory to routine management

LEARNING OBJECTIVE 2: Coordinate multidisciplinary care for complex patients

CASE: A 59 year old female with history of morbid obesity, diabetes mellitus complicated by CKDIII, hypertension and OSA presented to her primary internist with persistent left arm and neck pain and tingling for 9 months refractory to physical therapy that prevented her from typing at work. She also complained of dry eyes and progressive shortness of breath, previously attributed to worsening OSA with up-titration of her CPAP settings. Physical exam was notable for an obese Hispanic

female with left neck fullness and left miosis and ptosis consistent with Horner's syndrome. CT neck/thorax demonstrated a large, infiltrating pre-vertebral mass extending 20 cm from the lower clivus to the upper chest, displacing the trachea, posterior to the descending aorta and encasing the left subclavian, vertebral and common carotid artery. The patient was referred to ENT with laryngoscopy showing a patent but narrowed airway. Subsequent tracheostomy with exploration and biopsy identified metastatic adenocarcinoma on frozen section. However, formal pathology identified a classic type chordoma with cytokeratin and EMA positivity. Radiation Oncology recommended maximal resection with post-operative proton beam radiotherapy to residual disease and areas at risk for recurrence. Coordinated tumor de-bulking and spinal cord decompression was performed by Orthopedics, Neurosurgery and ENT, however tumor could only be partially removed due to high risk location. Repeat imaging demonstrated residual tumor within the spinal canal at the cervico-thoracic junction and mediastinum. She underwent 30 sessions of radiation, although repeat imaging showed increased tumor size and necrosis. Patient's course was also complicated by multiple ED visits and hospitalizations for pain control, neurologic complaints and infection requiring close follow-up with her primary. After multiple discussions, patient and family requested focus on comfort-oriented treatment and was subsequently enrolled in hospice, although she was discharged after 6 months given her stable clinical status.

DISCUSSION: Chordomas are rare bone tumors characterized by slow growth, frequent local recurrence and rare systemic spread. They arise from embryonic remnants of the notochord and can be spheno-occipital (35 %), vertebral (15 %), or sacro-coccygeal (50 %). Approximately 7–10 % of chordomas are cervical and typically present in the 5th-6th decade without gender predilection. Nerve impingement, progressive pain and headaches are common symptoms. Radiographically, chordomas are usually solitary, lytic lesions ranging from 1 to 10 cm. In this case, the large size and considerable extension of the tumor were uncommon. Immunohistochemistry typically demonstrates positivity for EMA or cytokeratin. Initial treatment consists of wide, local excision, which is associated with longer survival and delayed recurrence, although as in this case, complete resection is often difficult secondary to involvement of vital structures and thus adjuvant radiation is employed. Limited literature reviews of molecular based therapy have also demonstrated symptomatic, and rarely, radiological response. Ultimately, chordomas are challenging to manage and often require a multi-disciplinary approach, demonstrating the importance of the primary provider in care coordination, advocacy and ongoing assessment of patient symptoms and goals of care through this complicated course.

CHRONIC PAIN CAUSED BY SCHWANNOMATOSIS Sheila Laleman; Christopher M. Wittich. Mayo Clinic, Rochester, MN. (*Tracking ID #1936577*)

LEARNING OBJECTIVE 1: Differentiate Schwannomatosis from Neurofibromatosis

LEARNING OBJECTIVE 2: Identify, manage, and treat Schwannomatosis

CASE: A 59-year-old Caucasian man presented for general medical exam with painful masses on his midback and right elbow. The midback mass was first discovered incidentally 4 years prior on CT to investigate for metastatic thyroid cancer. On serial CT scans, the mass had been stable. The mass was now painful with a constant, focal, and non-radiating area of “pin prick” pain near the medial scapular border at T6. There were no alleviating factors and the pain was more noticeable when he sat quietly. He first noted the enlarging right elbow mass about 2 years prior. He described a tingling, dysesthetic quality of the 4th and 5th digits of the right hand. His past medical history was significant for papillary thyroid cancer status post thyroidectomy with no evidence of recurrence and cavernous hemangiomas in the liver. No family history of tumors or neurofibromatosis. On examination, his hearing was normal. A soft tissue growth was palpated posteriorly at the level of T6. Deep palpation reproduced left medial scapular border tenderness. He had a mobile mass in the right proximal elbow just above the cubital tunnel. Palpation of the mass caused tingling sensations into his 4th and 5th digits. He had normal ulnar motor function in his extrinsic and intrinsic muscles of his hand. Thoracic MRI revealed a dumbbell shaped T2 hyperintense, T1 hypointense uniformly enhancing mass at the left T5-6 neural foramen measuring 1.6×2.3×0.9 cm. It contacted the left lateral margin of the dura without extending into the spinal canal, all consistent with a schwannoma. Right upper extremity MRI revealed a heterogeneous soft tissue mass that involved the right ulnar nerve. It was ovoid in shape with a well-defined margin measuring 4.5×2×1.9 cm, also consistent with a schwannoma. A head MRI was negative for vestibular nerve involvement. He underwent surgical resection of the right ulnar nerve tumor and pathology revealed a benign schwannoma. Gabapentin was recently initiated for long-term management of his pain.

DISCUSSION: We describe a case of multiple, peripheral schwannomas causing pain in a 59-year-old man. Schwannomatosis is a rare form of neurofibromatosis (NF) characterized by multiple schwannomas of cranial, spinal, and peripheral nerves. It is an uncommon disorder resulting in 0.58 cases per 1,000,000 yearly. In contrast to other forms of NF, patients with schwannomatosis do not develop vestibular tumors, deafness, or malignancies. Segmental schwannomatosis that affects only one body segment occurs in about one-third of patients. Schwannomatosis is a disease of adulthood (median age of diagnosis = 40 years). The main debility from schwannomatosis is chronic pain rather than neurological deficits. Pharmacologic management of schwannomatosis includes symptomatic pain relief with gabapentin, opioids, NSAIDs, tricyclic antidepressants, and SNRIs. Surgical management can include excision of the schwannoma. This case highlights that schwannomatosis 1) is a subset of NF, 2) does not have vestibular nerve involvement, 3) does not cause deafness or malignancies, and 4) can cause severe chronic pain.

CLINDAMYCIN CAUSES A MACULOPAPULAR RASH WITHOUT EOSINOPHILIA IN PRIMARY INFECTIOUS MONONUCLEOSIS Albert Do^{1,2}; Donald Curran^{2,1}. ¹Yale-New Haven Hospital, New Haven, CT; ²West Haven Veterans Affairs Hospital, West Haven, CT. (*Tracking ID #1933467*)

LEARNING OBJECTIVE 1: Recall diagnosis and treatment principles for infectious mononucleosis in a patient presenting with acute pharyngitis, and appreciate the possibility of clindamycin administration resulting in a non-infectious diffuse maculopapular rash, as well as other reported adverse dermatologic syndromes associated with clindamycin use.

LEARNING OBJECTIVE 2: Recognize other antibiotics reported in the literature to be associated with non-infectious rash in infectious mononucleosis, including amoxicillin, azithromycin, and levofloxacin.

CASE: A 28 year-old male who had received all childhood vaccinations, presented to clinic with fevers to 101 °F, sore throat, and odynophagia for the past 4 days. His exam revealed severe left anterior cervical tenderness with lymphadenopathy. He exhibited pharyngeal erythema without exudates, but was without rash or hepatosplenomegaly. Due to concern for pharyngeal abscess suggested by his severe pain, he was given a 10-day course of clindamycin, though cultures eventually returned negative. On the final day of antibiotic therapy, he suddenly developed a diffuse, mildly-pruritic maculopapular rash without pustules, involving the head, palms, soles, and intertriginous regions including all flexural folds and axillae. No mucous membranes were involved. At this time, his white blood cell count was 8.1/ μ L with 49 % lymphocytosis (49 %) without peripheral eosinophilia (5 %). On consideration of infectious mononucleosis, his anti-heterophile antibody test was found to be positive, with elevated Epstein-Barr virus (EBV) antibody IgM titers elevated at 5.0 (upper limit of normal 1.1) and low IgG levels of <0.9. He was advised to discontinue antibiotics and closely monitor his rash. On follow-up 3 days later, he reported improvement in his symptoms.

DISCUSSION: Infectious mononucleosis (IM) is common, and manifests with lymphadenopathy, fevers, and pharyngitis (in 100 %, 98 %, and 85 % of patients, respectively). Clinically, pharyngitis in EBV and cytomegalovirus infections tend to be milder in severity. Diagnosis involves testing for the presence of anti-heterophile antibodies, with a sensitivity of 70 to 92 %, and a specificity of 96 to 100 %. The mainstay of IM management is supportive: anti-pyretics and analgesics, as well as limitation of contact sports due to splenomegaly, occurring in the first 3 weeks in 50 to 60 % of patients and with the associated risk of splenic rupture. Classically, patients with IM who receive ampicillin or amoxicillin develop a non-infectious maculopapular rash not thought to be a drug allergy. However, it has also been described with azithromycin, levofloxacin, piperacillin/tazobactam, and cephalexin. Clindamycin is a lincosamide antibiotic used in a variety of infections, including methicillin-resistant *Staphylococcus aureus* and anaerobic bacterial infections. A range of adverse dermatologic effects associated with clindamycin have been reported in the literature, including drug-induced hypersensitivity syndrome (DIHS), drug-related rash with eosinophilia and systemic symptoms (DRESS), and acute generalized exanthematous pustulosis. Unique to this case is the lack of eosinophilia or pustules, thus representing a clinical entity distinct from DRESS, DIHS, or acute generalized exanthematous pustulosis. In addition, this patient presents with a primary EBV infection, rather than a reactivation syndrome. Viral reactivation has been postulated to be the mechanism of action in clindamycin-associated rash. However, acute EBV infection in this patient suggests involvement of another mechanism, though the mechanism of this rash has not been elucidated to date.

CLUBBED WITH A REMINDER TO TEST FOR HIV Mona Siddiqui¹; Michael T. Melia². ¹Johns Hopkins University School of Medicine, Arlington, VA; ²Johns Hopkins University School of Medicine, Baltimore, MD. (*Tracking ID #1939407*)

LEARNING OBJECTIVE 1: Recognize the association between clubbing and HIV
LEARNING OBJECTIVE 2: Understand the differential diagnosis of clubbing

CASE: A previously healthy 34-year-old man was evaluated for 24 months of progressive digital clubbing. He denied fevers, night sweats, cardiopulmonary symptoms, travel, or unusual exposures. Physical examination demonstrated no pathologic lymphadenopathy, genital lesions or penile discharge. The patient had dramatic clubbing of all digits and erythematous nail beds.

DISCUSSION: The differential diagnosis for clubbing includes systemic diseases (including malignancy and inflammatory bowel disease) but CBC, CMP, ANA, RF, ESR and CRP were normal. Cardiopulmonary disease (including interstitial lung disease and cystic fibrosis,) was considered but echocardiography, pulmonary function testing, polysomnography and chest CT were unremarkable. Liver disease was on the differential but GGT and viral hepatitis serologies were normal. Infections (including TB and HIV) were considered and although PPD and RPR were nonreactive, HIV antibody test (with Western blot) returned positive. CD4+ lymphocyte count was 401/ μ L and viral load was 205,000 copies/mL. Among one convenience sample of 76 HIV-infected patients, 28 (36 %) had objectively confirmed clubbing, and HIV testing is recommended as part of a diagnostic algorithm. While HIV screening is now recommended for all patients aged 15–65 years, our case highlights the need for diagnostic testing based upon physical examination findings.

CNS LUPUS: A CHALLENGING DIAGNOSIS Alexandra Perel-Winkler. St. Luke's-Roosevelt, New York, NY. (*Tracking ID #1937811*)

LEARNING OBJECTIVE 1: To describe the challenges intrinsic to the diagnosis of CNS lupus.

LEARNING OBJECTIVE 2: To illustrate a clinical picture where an internist should have a high index of suspicion for CNS lupus.

CASE: A 46 year old African American female with a past medical history significant for positive lupus anticoagulant antibody (Ab), chronic leukopenia, and right sided anterior ischemic optic neuropathy, presented with a 2 day history of right sided weakness and slurred speech. The Emergency Department triaged the patient to the stroke team and a workup was initiated for suspected ischemic stroke. The patient's history was significant only for the above. On examination, pertinent positive findings included right-sided upper extremity (RUE) and lower extremity (RLE) weakness of 4/5. No cranial nerve or left sided neurologic deficits noted on initial exam. Notable admission laboratory findings included leukopenia of 2.4, normal platelets and a prolonged partial thromboplastin time of 51.5 s, prolonged prothrombin time of 14.9 and an INR of 1.2. Non-contrast head CT showed a mild hypodensity in the left inferior internal capsule consistent with a recent infarct. Non-contrast MRI brain showed an inflammatory lesion of the left posterior limb internal capsule, cerebral peduncle, and left pons. Brain and neck MRA were unremarkable. On day three the neurologic exam progressively worsened until the patient was found to have a dense right-sided hemiparesis. MRI cervical and thoracic spine were negative for pathology. Lumbar puncture was performed with grossly normal results. On day six a basic rheumatologic panel was sent by the house-staff. Rheumatology was consulted based on the advice from a Neuro-Immunologist who thought the imaging was less consistent with MS. Significant studies showed positive antinuclear Ab, positive double-stranded DNA, elevated B2-glycoprotein IgA, positive ribonuclease protein Ab, positive Smith Ab, positive anti-SSA Ab, with low complement 4. At this juncture a diagnosis of CNS Lupus was made through the integration of the clinical picture, the inflammatory findings on imaging and serology strongly positive for an Systemic Lupus Erythematosus (SLE) flare. Subsequent to diagnosis, the patient has received a total of 10 days of pulse steroids, four cycles of plasmapheresis and two doses of monthly intravenous cyclophosphamide. On discharge from acute rehabilitation her RUE and RLE weakness was graded as 4/5.

DISCUSSION: Neuropsychiatric manifestations of SLE often occur early in the course of the disease, with recent research suggesting up to 39 % present within the first year of diagnosis. While CNS lupus is not a rare disease, it is not commonly confronted by the General Internist. The diagnostic challenge lies in the broad range of clinical presentations as well as non-specific imaging results that often precede the diagnosis. CNS lupus can present with diffuse or focal neurologic findings, mimicking stroke, or as psychiatric in nature. Typically, neurologic manifestations of SLE are generalized, including confusion, lethargy, affective changes or coma, however, cranial nerve and focal CNS involvement does occur. Imaging can demonstrate a broad range of findings, including demyelination of white matter or ischemia, as well as radiographic signs suggestive of cerebritis or vasculitis. In this case, a middle-aged African American woman presented with neurologic findings and a known history for positive lupus anticoagulant. Her age, racial background and history of autoantibodies for lupus anticoagulant confer a higher risk of SLE, as such

CNS lupus should have been considered when this patient presented with neurologic symptoms. It is essential to have a high index of suspicion for CNS Lupus in patients with known positive antibodies associated with SLE and neurologic symptoms in order to prevent a delay in treatment.

CNS TB WITH INITIALLY NEGATIVE AFB Alexis C. Haftka; Ashleigh Porter; Ravish Parekh. Henry Ford Hospital, Detroit, MI. (*Tracking ID #1939078*)

LEARNING OBJECTIVE 1: Assess an atypical presentation of CNS tuberculosis.

LEARNING OBJECTIVE 2: Diagnosis CNS tuberculosis without systemic findings.

CASE: An 82 year-old middle eastern male from Yemen with an extensive past medical history significant for a-fib, diabetes mellitus, cryptogenic cirrhosis, and prostate cancer was initially brought to the emergency room due to altered mental status and acute renal failure. CT scan and MRI revealed multiple ring enhancing lesions located in the left cerebellum and parietal lobe as well as in the right frontal lobe. The initial impression was infectious versus metastatic process as the patient had a recent history of prostate cancer, however, PSA levels were undetectable. The patient was placed on a prophylactic antibiotic regimen that included vancomycin, cefepime, and flagyl and initially had a marginal response with diminishing lesions, decreasing vasogenic edema, and improving mental status. Preliminary testing for infectious causes included an extensive workup including blood cultures, fungitell, PPD skin testing, chest x-ray and CT, bronchiolar lavage with culture, and Quantiferon TB gold which were all negative. Although the initial follow-up MRI showed a preliminary improvement in the size of the brain lesions, a subsequent MRI 1 month later showed profound worsening of the lesions with increasing vasogenic edema and new found mass effect impinging on the fourth ventricle. The patient's course was further complicated by the development of generalized anasarca attributed to worsening renal versus liver function as well as poor nutritional status. The patient's mental status and overall health continued to decline and additionally developed a-fib with RVR and respiratory distress. Furthermore, the patient was transferred to the intensive care unit with hypoxic respiratory failure due to increasing secretions and inability to protect his airway and was intubated for the remainder of his hospital stay. Therefore, brain biopsy was deferred until the patient stabilized 3 weeks later. The diagnosis of CNS tuberculosis was finally confirmed by drainage of the posterior brain abscesses revealing positive AFB cultures. The following day the patient had a bronchial lavage, which was also AFB positive. The patient was started on standard tuberculosis therapy but unfortunately expired after 8 days of antibiotic treatment due to worsening renal failure and electrolyte abnormalities inducing cardiac arrest.

DISCUSSION: Central nervous system tuberculosis is more frequently seen in endemic areas where there is a higher prevalence of tuberculosis. If seen in less prevalent areas, such as the United States, it is thought to be a post-primary result of systemic TB. CNS tuberculosis may present as a tuberculoma, meningitis, or spinal tuberculous arachnoiditis. Based on previous case reports the findings of CNS TB without systemic findings, such as pulmonary involvement, is very rare. Usually patient's will present with seizure as a primary symptom, suggesting our patient had a very atypical presentation. He presented with altered mental status and new onset renal failure. The patient was also negative for AFB, Quantiferon Gold, and PPD. There appeared to be no evidence supporting the diagnosis of TB, especially in the CNS. This makes our case very unusual. For diagnosis purposes CT imaging of the head will show small rings with surrounding edema. As they mature they become larger by coalescing together and becoming lobulated. MRI is thought to be the best imaging study. Biopsy should only be done if the tuberculoma is located in a safe location where there is a decreased chance of causing any injury to the brain. There is mixed views, based on several studies, as to whether biopsy is the best approach to diagnosis. Treatment should always be started when there is a high clinical suspicion for TB for a better clinical outcome. First line therapy includes INH, Rifampin, Ethambutol, Streptomycin, and Pyrazinamide. For the first 2 months of therapy the patient should receive 4 agents (INH, Rifampin, Ethambutol and Streptomycin or Pyrazinamide). After this 2 month period, a patient should remain on therapy for additional 7–10 months of Rifampin or INH. Our patient was immediately started on the intense regimen of INH, Rifampin, Ethambutol, and Pyrazinamide, but unfortunately due to the late diagnosis of CNS TB, our patient was unable to benefit from treatment.

COARCTATION OF THE AORTA AND BICUSPID AORTIC VALVE IN A DISORDERED SCHIZOPHRENIC Cynthia Huang¹; Priya Pillutla². ¹Harbor-UCLA Medical Center, Torrance, CA; ²Harbor-UCLA Medical Center, Torrance, CA. (*Tracking ID #1922738*)

LEARNING OBJECTIVE 1: To recognize the clinical features of coarctation of the aorta (CoA).

LEARNING OBJECTIVE 2: To manage CoA in the contemporary era.

CASE: The patient is a 45 year-old disordered schizophrenic diagnosed with CoA. Cardiac catheterization showed a bicuspid aortic valve (BAV) with moderate-to-severe stenosis (calculated valve area of 1.2 cm²); an infraductal aortic coarctation with pressure gradient of 60 mmHg and a severely dilated aortic root of 5 cm. His care was complicated by his psychiatric illness and he was lost to follow-up but re-presented with heart failure. On physical exam, the patient had a 30 mmHg systolic pressure gradient between upper and lower extremities, delayed carotid upstrokes and a brachial to femoral pulse delay. Cardiovascular exam was notable for a diminished S2, an ejection sound and a harsh 4/6 mid-systolic murmur at the 2nd right ICS. He had a 1/4 holodiastolic murmur at the 2nd right ICS, and a continuous murmur over the posterior inter-scapular areas. His ECG showed LVH with repolarization abnormalities and CXR demonstrated the characteristic "3 sign" and rib notching consistent with rib erosion by dilated collateral vessels. The patient met current ACC/AHA guideline recommendations for intervention based both on the presence of a hemodynamically significant CoA and severe bicuspid AS. However, he lacked capacity to make medical decisions. After extensive discussions, his conservator opted against surgical intervention and to adopt DNR/DNI status.

DISCUSSION: CoA is a relatively common cardiac defect that affects about 7 % of the population with underlying CHD. It is frequently seen in patients with gonadal dysgenesis (e.g. Turner syndrome) and Noonan syndrome. It may also be associated with BAV, subvalvular aortic stenosis (SubAS), mitral valve abnormalities (e.g. parachute mitral valve), ventricular septal defects and cerebral artery aneurysms within the circle of Willis (up to 10 %). Adult patients with isolated CoA tend to remain asymptomatic. Symptoms, if present, tend to be of upper extremity hypertension such as headache, epistaxis, claudication or even intracranial hemorrhage. Mean survival in individuals managed conservatively, is 35 years of age with a 75 % mortality rate by 46 years of age. Sequelae include systemic hypertension, accelerated coronary artery disease (CAD), stroke, aortic dissection and heart failure. In the pre-surgical era, aortic dissection caused 19 % of the overall deaths in these patients (50 % in the setting of associated BAV). Currently, either surgical or percutaneous treatment is the standard of care in adults greater than 50 years of age. The surgical approach is via a left lateral thoracotomy and placement of an interposition graft, an end-to-end anastomosis or a subclavian flap. Transcatheter therapies such as percutaneous balloon angioplasty or stenting of the CoA are considered acceptable alternatives to surgery in the absence of contraindications. Balloon angioplasty alone however, is associated with a higher rate of re-CoA and aneurysm formation. In non-operable patients with CoA, medical management consists of beta-blockers, additional blood pressure control as needed, and endocarditis prophylaxis prior to dental procedures. Beta-blockers, by controlling both heart rate and blood pressure are advantageous in slowing the progression of aortic dilatation/dissection.

COEXISTING PRIMARY HYPERPARATHYROIDISM AND MULTIPLE MYELOMA Yumiko Kinugawa; Christine Kwan. Teine Keijinkai Hospital, Sapporo, Japan. (*Tracking ID #1928987*)

LEARNING OBJECTIVE 1: Recognize that elevated intact parathyroid hormone (PTH) does not exclude multiple myeloma in hypercalcemic patients

CASE: An 86 years old Asian woman with a history of chronic hypercalcemia presents with 2 months' history of worsening upper back pain despite normal x-ray. She reports fatigue, paresthesias from her left buttock to posterior thigh, and numbness on bilateral plantar feet; she denies all other review of systems. Her pain is controlled with acetaminophen and non-steroidal anti-inflammatory drug. The patient's past medical history includes hypercalcemia of unknown etiology $\times 6$ years, spinal stenosis, peptic ulcer disease, hypertension, and constipation; she takes acetaminophen, tramadol/acetaminophen, loxoprofen, carvedilol, olmesartan, amlodipine, magnesium oxide, probiotic, and rabreproxazole. She has no allergies, and her family history is unknown. She does not use tobacco, alcohol, or drugs. On exam, the patient's vital signs are temperature = 36.6 °C, blood pressure = 138/78, heart rate = 100, O₂ saturation = 100 % room air, and respiratory rate = 16. She is in no acute distress; oriented $\times 3$. Significant findings include pain on palpation of 4th and 5th ribs bilaterally in the mid-axillary line, decreased bilateral patellar/Achilles tendon reflexes, and decreased pain/temperature sensation on her plantar feet. No back tenderness and negative straight-leg raising test; the rest of the exam shows no irregularities. Blood work reveals hemoglobin = 10.8 g/dL (baseline = 12), potassium = 4.9 mEq/L, calcium = 11.3 mEq/L, albumin = 4 mg/dL, creatinine = 2.3 mg/dL (baseline = 0.96), and intact PTH = 115 pg/mL (normal = 10–60). Bone scintigraphy reveals hot spots in T8-T9 and 3rd and 6th right ribs. Magnetic resonance imaging of the vertebrae indicates compression fractures on T8-T9. Bone densitometry shows T

score = -1.6 at L1-L4 and -1.4 at femurs. Neck ultrasound and computed tomography reveal a thyroid mass suspicious of parathyroid adenoma. Although TeMIBI scintigraphy shows no abnormal uptake indicative of a parathyroid tumor, surgical intervention for probable parathyroid adenoma is recommended. Meanwhile, bilateral humerus and femur x-ray reveal no lytic lesions. Serum/urine protein electrophoresis show Bence-Jones protein; subsequent bone marrow biopsy confirms multiple myeloma with 34 % plasmacytosis. As she refuses surgery, she is thus started on chemotherapy.

DISCUSSION: Coexistence of primary hyperparathyroidism (pHPT) and multiple myeloma (MM) remains a rare clinical event. Whether the association is fortuitous or not continues to be a topic of discussion; however, a study by Arnulf et al. suggests that the prevalence of monoclonal gammopathies is higher in pHPT compared to controls. Initial manifestations of MM include anemia (73 %), bone pain (58 %), hypercalcemia (28 %), and elevated creatinine level >2 mg/dL (19 %), all of which can also be present in pHPT. No guidelines exist as to when coexisting MM should be suspected in pHPT cases, but several reports suggest that recurrent or treatment-resistant hypercalcemia (surgical or non-invasive) warrants MM work-up. Furthermore, considering that the median age of MM at diagnosis is 66 years and presuming that the prevalence of monoclonal gammopathies is higher in pHPT, screening for monoclonal gammopathies during initial assessment of hypercalcemia in elderly patients is recommended.

COMBINATION THERAPY IN A PATIENT WITH COMBINATION OF RHEUMATOID ARTHRITIS AND MULTIPLE SCLEROSIS Ericka Maximus¹; Adegbenga Bankole². ¹Carilion Clinic-Virginia Tech Internal Medicine Residency, Roanoke, VA; ²Virginia Tech Carilion School of Medicine Department of Internal Medicine: Rheumatology, Roanoke, VA. (*Tracking ID #1938800*)

LEARNING OBJECTIVE 1: Recognize Different Modalities Available to Treat RA/MS

CASE: A 46 year old woman presented in April 2011 with bilateral hand and foot pain, swelling and morning stiffness lasting several hours daily. She had no rashes, ulceration, alopecia, sensory changes, muscle tenderness or weight changes. She has a history of multiple sclerosis (MS) not on treatment at the time of presentation. Physical exam reveals multiple Rheumatoid Arthritis (RA) deformities of bilateral hands with active synovitis including swelling of both metacarpophalangeal joints (MCP). She also had a left knee effusion and crepitations of the right knee. Pertinent labs during her workup include ANA Ab negative in July 2002, CCP Antibody, IgG 24.1 (Ref 0–5 U/ml) in April 2008, Rheumatoid Factor (Ref <30 IU/ML) <30 in April 2008, Sedimentation rate (Ref: 0–20 mm/HR) 24 in April 2011, C-reactive Protein (Ref: <1 mg/dl) 3.2 in July 2011, Sedimentation rate 8 in May 2013 and C-reactive Protein <0.4 in May 2013. Her hand X-rays showed diffuse osteopenia with soft tissue swelling. Large erosions and partial bony ankylosis were also seen. Her foot X-rays also were consistent with diffuse osteopenia and erosions. She was treated with Hydroxychloroquine and Methotrexate for RA. She remained active despite this, and as tumor necrosis factor (TNF) inhibitors are contraindicated in a patient with Multiple Sclerosis, she was started on Abatacept. On combination therapy, both her RA and her MS responded and both diseases have been in remission for over 12 months.

DISCUSSION: The occurrence and clustering of autoimmune disease in patients and families have been reported and well investigated (1). The most common autoimmune disease associated with RA is Sjögren's Syndrome (SS), though almost any disease can be associated with RA. We have known for many decades that tumor necrosis factor (TNF) may be either pathogenic or protective in different clinical situations. In RA this has proved to be of great therapeutic value. However, it is pivotal in the pathogenesis of inflammatory demyelinating disease of the central nervous system like MS. There have been multiple reports of anti-TNF induced and flares of MS (3). There have also been many reports not just of central nervous system neurological disease, but also peripheral disease (4). T cell directed therapies with CTLA4Ig (Abatacept) has been shown to be effective in both RA and MS, and were used successfully in out patient (6). In our patients we were able to maintain remission of both diseases with the use of combination therapy including Abatacept. She followed up with Neurology and had no MS activity or the need for other medications. References: 1. Multiple Sclerosis and Autoimmune Diseases, H. W. G. Baker, J. I. Balla, H. G. Burger, P. COMMON MEDICATION, UNCOMMON COMPLICATION Sue-Wei Luu; Laura S. Lourdes; Umna Ashfaq. University of Florida, Gainesville, FL. (*Tracking ID #1927964*)

LEARNING OBJECTIVE 1: This case highlights the importance of checking the drug-drug interactions in patients on highly active retroviral therapy (HAART). Patient education regarding seeking early treatment for prolonged nonsexual erections is also critical when starting Trazodone.

LEARNING OBJECTIVE 2: Lastly we would like to educate all internists about the importance of early recognition and management, as well as the consequences of ischemic priapism.

CASE: A 33-year-old African American male with human immunodeficiency virus infection, migraine headaches, gastro-esophageal reflux disease and hypertension presented to the emergency department with new onset painful, persistent penile erection of 28 h in duration. His current medications at the time were norvase, lisinopril, propanolol, sumatriptan, topiramate, pantoprazole, trazodone and emtricitabine-tenofovir, truvada, ritonavir combination of HAART. The patient had started taking trazodone 50 mg nightly as needed for insomnia for 9 months; last dose was 36 h prior to presentation. He had no history of priapism or penile trauma. He was evaluated by Urology and treated with therapeutic aspiration of 600 cm³ of blood from the corpus cavernosum and irrigation with complete resolution of symptoms. Within 8 h, the patient had recurrence of painful priapism without response to intracavernous injection of phenylephrine. An Al Ghorab distal penile shunt (involves excising a piece of the tunica albuginea from the tip of the corpus cavernosum) was then placed. The following day he again had recurrent priapism that was refractory to repeat treatment with aspiration, irrigation, and phenylephrine injection. A proximal Quackle's penile shunt was then placed (creating a window between the corpus cavernosum and corpus spongiosum). He was also started on intracavernous pseudoephedrine and oral terbutaline with resolution of erection over 3 days, followed by gradual improvement in pain and swelling over the following 2 weeks. Upon follow-up, the patient reported lack of spontaneous erections suggesting persistent erectile dysfunction for which he was placed on Cialis as needed. Further evaluation revealed that the patient had sickle cell trait (hemoglobin electrophoresis: 62 % Hb A, 34 % Hb S).

DISCUSSION: Priapism is a medical emergency. It has an incidence of 0.73 cases per 100,000 men and ischemic priapism is the most common subtype. Without prompt treatment, ischemic priapism may lead to progressive fibrosis of the cavernosal tissues and erectile dysfunction. While priapism has been described in sickle cell trait, it is not a typical complication under normal circumstances. More significantly, the patient was taking ritonavir and trazodone concomitantly. Ritonavir is a protease inhibitor that inhibits CYP450 enzyme levels, causing greater than expected free levels of other concomitant medications like trazodone that is metabolized through the CYP450 pathway. Due to the temporal relationship of events, this patient's new onset of ischemic priapism was attributed to the combination of ritonavir and trazodone. Trazodone has been known to cause priapism albeit rarely and usually associated with overdose; however, when combined with a CYP450 inhibitor, it is more likely to do so. Therefore, when starting a patient on trazodone, the internist should pay attention to any concomitant medications that may increase the levels of trazodone and educate the patient about seeking medical attention in case of prolonged erections. Early recognition and management is also vital as all the above interventions would have prevented the long term sequela of erectile dysfunction in this patient.

COMPLICATION OF REVERSIBLE POSTERIOR LEUKOENCEPHALOPATHY IN THE SETTING OF SUSPECTED HYPERTENSIVE EMERGENCY MANAGEMENT David Goldberg; Lauren C. Hogshire. Rutgers: Robert Wood Johnson Medical School, Piscataway, NJ. (*Tracking ID #1901180*)

LEARNING OBJECTIVE 1: Recognize Reversible Posterior Leukoencephalopathy Syndrome in the setting of hypertension accompanied by the characteristic findings on neuroimaging.

LEARNING OBJECTIVE 2: Manage Reversible Posterior Leukoencephalopathy Syndrome associated with hypertension appropriately.

CASE: A 48 year old African American woman with a past medical history of poorly controlled hypertension presented with a 3 week history of worsening vision, leg swelling, and intermittent right-sided but diffusely radiating headaches of moderate severity. Vital signs were significant for a blood pressure of 265/155 mmHg on initial evaluation. The physical exam revealed only bilateral nonpitting ankle edema. Electrocardiogram showed normal sinus rhythm and left ventricular hypertrophy. Initial lab work was significant for elevated creatinine. A head CT was not performed on initial assessment. Treatment for suspected hypertensive emergency was begun with an intravenous beta blocker and the patient was admitted. Upon evaluation the next morning, the patient was difficult to arouse with altered mental status. The neurological exam revealed dysarthria as well as focal left sided motor deficits. Blood pressure at this time was 190/100 mmHg. CT of the head showed white matter changes suspicious for RPLS which were confirmed on a subsequent MRI significant for diffuse subcortical lesions worse on the right. MRA was within normal limits. There was no evidence of focal hemorrhage or infarction. Intravenous management was begun with a beta blocker, calcium channel blocker, and vasodilator. By hospital day three, the patient's blood pressure stabilized averaging 180/110 mmHg. She was then transitioned to an oral antihypertensive regimen and her neurological deficits steadily improved to baseline over the next few days. On hospital day six, she was discharged with a blood pressure of 160/90 mmHg. The patient remained well on last follow-up 10 weeks post-discharge.

DISCUSSION: Reversible Posterior Leukoencephalopathy Syndrome (RPLS) is a clinical syndrome of multiple etiologies defined by the characteristic diffuse subcortical white matter hyperdensities seen on CT and MRI. MRA is typically normal. RPLS is rarely encountered, making appropriate recognition and clinical management a challenge. Hypertensive RPLS is believed to develop insidiously as chronically increased intracranial pressure overcomes cerebral autoregulation. The result is endothelial dysfunction and disruption of the blood brain barrier with ensuing subcortical parenchymal edema. Symptoms include headaches, visual changes, mental status changes, and rarely focal neurologic deficits. The literature recommends management of hypertensive RPLS similarly to hypertensive emergency. Both are treated with aggressive reduction of the patient's diastolic pressure to below 110 mmHg without exceeding a 25 % fall from the presenting mean arterial pressure. This case illustrates the sudden onset of severe focal neurologic deficits mimicking stroke in a patient being managed for symptomatic severe hypertension. We hypothesize that the patient had previously undiagnosed chronic RPLS at presentation. While prompt blood pressure control is recommended for the treatment of RPLS, in this case the patient's underlying disorder left her unable to compensate for the rapid iatrogenic decrease in blood pressure, precipitating her acute decompensation.

CONCRETIO CORDIS: A CHALLENGING IMITATOR AND OFTEN DELAYED DIAGNOSIS Zakaria Almuwaqqat, saint francis hospital, Evanston, IL.
(Tracking ID #1938684)

LEARNING OBJECTIVE 1: Importance of clinical evaluation and maintenance of high degree of suspicion in diagnosis of constrictive pericarditis.

LEARNING OBJECTIVE 2: Early diagnosis and referral for pericardectomy is essential for treating heart failure and preventing cardiac and liver complications.

CASE: We present a case of 76 year old male patient who was referred for Exercise stress test because of symptoms of dyspnea and dizziness on exertion together with abnormal liver function tests. Symptoms had been present for 6 weeks. Further questioning revealed symptoms of lower limb oedema and weight gain. He had lately become less active and not exercising, he had history of substance abuse 30 years ago, stopped smoking 30 years ago and denies excessive ETOH consumption. His Physical examination revealed a raised jugular venous pulse, Mild ascites, hepatomegaly and peripheral edema. Exercise Dobutamine stress Echo revealed Right ventricular hypertrophy with normal LV motion and systolic function, Complete transthoracic Echo was done revealing Normal LV size and contractility, Batrial enlargement, exaggerated septal motion in early diastole, diminished LV filling during inspiration with dilated inferior vena cava and no respiratory variation, interestingly there was no demonstrable pericardial abnormality. Laboratory tests showed normal values for full blood count, BUN, electrolytes and Creatinine. His bilirubin level was 2.5, alanine Amino-transferase (ALT) 35 IU/l and alkaline phosphatase (ALP) 169 IU/l. An ECG showed sinus rhythm with non specific ST/T changes. An abdominal ultrasound was suggestive of hepatic vein dilatation. A CXR showed extensive pericardial calcification, Chest CT was confirming calcific constrictive pericarditis, patient had uneventful surgical partial pericardectomy after which he had improvement in his dyspnea and peripheral edema.

DISCUSSION: Constrictive pericarditis is an uncommon condition, often of unknown etiology but can be caused by infections, inflammation of the pericardium, radiation therapy or occupational exposure, its initial presentation often mimics myocardial and non-cardiac diseases. This case illustrates one such presentation with Dyspnea and dizziness on exertion and abnormal Liver function test. Echocardiographic examination was consistent with combination of left and right sided heart failure. Early diagnosis and referral for pericardectomy is essential for treating heart failure and preventing cardiac and liver complications. Constrictive pericarditis was first described as "Concretio Cordis", diagnosis can be difficult and often delayed, presenting usually with symptoms and signs of right heart failure. In this time constrictive pericarditis presented with symptoms of left sided heart failure due to diastolic dysfunction due to impaired Left ventricular filling. Other modes of presentation may mimics non cardiac disease such as ascites and pulsatile hepatomegaly (50 %) and less comonly as liver disease and hepatic coma. Evaluation of Jugular venous distention and wave form is essential to avoid missing the diagnosis. Etiology of constrictive pericarditis is diverse and range from idiopathic most commonly (attributed to previous pericardial injury) to post cardiac surgery, pericarditis, radiotherapy, medications, infectious and inflammatory diseases. Pericardial calcification on chest x ray varies depending on the etiology representing about half the cases of idiopathic pericarditis. Cardiac catheterization is the definitive investigation, revealing classical pressure waveforms confirming the pathophysiology of constriction, Echocardiography may help in diagnosis and chest imaging should be considered for visualization of pericardium although thickened pericardium isn't essential for diagnosis. Surgical pericardectomy remains the definitive treatment for symptoms relief and avoid complication especially liver dysfunction.

CONDITION THAT MAY MIMIC RHEUMATOID ARTHRITIS Eriko Kanehisa; Junwa Kunitatsu; Tatsuya Sato; Junko Maeda; Riri Watanabe; Atsuto Yoshizawa. National Center for Global Health and Medicine Hospital, Tokyo, Japan.
(Tracking ID #1935376)

LEARNING OBJECTIVE 1: Recognize that clinicians should consider human T-cell lymphotropic virus type 1 (HTLV-1)-associated arthropathy (HAAP) when a patient from the endemic area of HTLV-1 presents with seronegative arthritis with an erosive joint, mimicking rheumatoid arthritis (RA).

LEARNING OBJECTIVE 2: Recognize that HAAP can occur prior to the onset of adult T-cell leukemia/lymphoma (ATLL).

CASE: A 56-year-old Japanese woman was presented with 8-year history of repeated symmetric polyarthralgia (shoulders, wrists, knees, and ankles). The symptom was occasionally associated with low-grade fever and fatigue, aggravated by over-exercise, and resolved spontaneously. Her past medical history contained miliary tuberculosis, hypertension, and dyslipidemia. She was born in Miyazaki Prefecture, which is one of an endemic area of HTLV-1 in Japan. Both her mother and sister were known HTLV-1 carriers. Physical examination revealed tender and swelling of left knee. Neither lymphadenopathy nor hepatosplenomegaly were noted. Laboratory studies showed normal complete blood count, liver function, serum creatinine kinase, serum calcium, and thyroid function. C-reactive protein and ESR were also normal. Anti-HBV, HCV, and HIV antibodies were all negative. Rheumatoid factor (RF) and anti-cyclic citrullinated peptide antibody (ACPA) were negative. Considering her birthplace, we decided to screen her HTLV-1 status to determine an etiology of the arthritis, and that showed positive by western blot analysis in the serum. MRI of the right wrist revealed active synovitis and bony erosions including proximal carpal bones. This pattern raised the possibility of RA, but we strongly suspected HAAP because of her HTLV-1 positivity. In this case, the synovial fluid could not be taken. However, we closely follow her in the outpatient clinic as a HAAP. To date, she is well without emerging an overt leukemia or lymphoma.

DISCUSSION: HAAP can take two forms: a leukemia-associated arthritis in patients with frank HTLV-1 leukemia and a RA-like syndrome in HTLV-1-positive patients who do not have leukemia. In the former syndrome, the joint tissue and synovial fluid contain infiltrating HTLV-1-positive malignant T-cells. In the latter syndrome, the histology of arthritis is very similar to that seen in classic RA, so to speak, "non-leukemic HAAP". HAAP in the absence of leukemia is distinguished by negative RF and positive serologies for HTLV-1. In this case, her HTLV-1 serology was reported as positive. However, little clinical consideration was warranted for the diagnosis of ATLL. Most infected individuals do not experience any symptoms, and approximately only 2–6 % of individuals with HTLV-1 develop ATLL. Correct diagnosis of arthritis is often challenging. Few data have been published describing the HAAPs, and its clinical presentation and disease course can vary. Fortunately, our patient had a definite family history of HTLV-1 carriers, which promptly provided us useful information for differential diagnosis. Even in a high prevalence area, a lot of people may not know his or her own HTLV-1 status. Clinicians should consider HAAP when

a patient from the endemic area of HTLV-1 manifested an erosive joint without positive diagnostic clues, such as major anti virus-specific antibodies, hormone levels, RF, and ACPA.

CONFUSION AND HYPOGLYCEMIA IN AN ELDERLY WOMEN Eunice Chuang, Mount Auburn Hospital, Cambridge, MA. (*Tracking ID #1940061*)

LEARNING OBJECTIVE 1: To recognize hypoglycemia as a cause of confusion.

LEARNING OBJECTIVE 2: To recognize hypoglycemia as a presentation of insulinoma, even in elder patients.

CASE: 88 year-old woman with a 44 year old diagnosis of a “touch of hypoglycemia” was admitted for an episode of confusion, dysarthria and right facial droop. Forty four years earlier after she was told she had a “touch of hypoglycemia”, she started diligently multiple daily small meals. In recent months, she noticed increasing episodes of weakness and nausea coinciding with capillary blood glucose of 40–60 mg/dL. These episodes were progressively more difficult to control with dietary regimen. During hospitalization, she was noted to have blood glucose (BG) levels below 45 mg/dL, in coincidence of which she was confused. Confusion resolved after she ate and blood glucose normalized confirming the Whipple’s triad. Laboratory tests obtained after 12 h fast while the patient was confused: BG 48 mg/dL (70–99 mg/dL) and inappropriately Detectable C-Peptide (1.41 ng/mL; >0.6), Insulin (6.9 mU/L; ≥3) and Proinsulin (61.4 pmol/L; <18.8). Normal Beta-hydroxybutyrate 0.12 mmol/L (<0.28 mmol/L) and 8 AM Cortisol 8.6 ug/dL (5.0–23.0 ug/dL). Sulfonylureas and Insulin Autoantibodies were negative. Abdominal ultrasound, CT and octreotide scan were consistent with 7×8 mm lesion distally in the body of the pancreas consistent with insulinoma. At 89 years of age, she underwent middle pancreatectomy without complications. Pathology confirmed benign unifocal insulinoma. Her symptoms resolved completely.

DISCUSSION: Insulinomas usually present with neuroglycopenic symptoms. The duration of symptoms is on average 1.5 years prior to diagnosis. There are sparse data of long standing functional insulinoma in the elderly. The purpose of this case is to report an unusual presentation of insulinoma in an elderly woman with symptomatic hypoglycemia for 44 years prior to the diagnosis. Her hypoglycemia was controlled by conservative dietary measures alone prior to diagnosis of insulinoma. This is an unusually benign, although symptomatic course of insulinoma over several years, still eventually resulting in life-threatening symptoms if not diagnosed and treated appropriately. Aging and recurrent severe hypoglycemic episodes impair the usual “protective” counterregulation responses to hypoglycemia and likely accounted for the emergence of uncontrollable symptoms in this elderly patient.

CONSERVATIVE MEDICAL TREATMENT ON NON-OCCLUSIVE MESENTERIC ISCHEMIA (NOMI) COMPLICATED WITH HEPATIC PORTAL VENOUS GAS (HPVG) Yuka Naito; Akiko Eiri; Hiroki Aihara; Masaki Tago; Jun Tokutomi; Motoshi Fujiwara; Motosuke Tomonaga; Tsuneaki Yoshioka; Masaki Hyakutake; Itaru Kyoraku; Shu-ichi Yamashita. Saga Medical School Hospital, Saga, Japan. (*Tracking ID #1917116*)

LEARNING OBJECTIVE 1: Indication of conservative treatment without surgical intervention on NOMI and HPVG.

CASE: An 81-year-old woman was admitted to our hospital because of severe abdominal pain and vomiting. She had been hospitalized in another psychiatric hospital for years because of her depression and dementia. She also had long history of severe constipation due to psychotic medications. Her bowel movement was controlled by daily prescription of laxatives until the day of admission when she started to have abdominal pain and vomiting after lunch. The abdominal CT scan without enhancement at the hospital showed massive gas in the portal vein and the lumen of small intestine, so she was transferred to our hospital. On examination, the temperature was 36.4°C, the blood pressure 117/60 mmHg, the pulse 92 beats per minute, the respiratory rate 20 per minute, and the oxygen saturation was 95 % while the patient was breathing ambient air. Although her abdomen was silent, tenderness was not severe without guarding. The abdominal CT scan with enhancement revealed a wide range of bowel ischemia and emphysema in intestinal wall with the enhancement of adipose tissue of mesentery in addition to portal venous gas. There was no thrombus in the mesenteric artery and vein. We diagnosed her illness as non-occlusive mesenteric ischemia (NOMI) and hepatic portal venous gas (HPVG). As her vital sign deteriorated into shock, so we considered surgery on her necrotic intestines. However, her previous psychiatric condition, older age and extensive range of intestinal ischemia made it difficult to indicate surgery that might have resulted in significant bowel resection. In addition, because of the absence of peritoneal irritability, improvement of shock only with infusion of crystalloid, the lack of

marked increase of LDH and CK or severe acidosis, we chose the conservative medical treatment with fasting, intravenous fluid infusion and antibiotics. By the 14th hospital day, her condition gradually improved and intestinal ischemia and edema and HPVG disappeared on abdominal CT. Then, she started oral intake again without any problems. She was transferred to another local hospital for rehabilitation on the 22nd hospital day.

DISCUSSION: HPVG in the presence of NOMI is a life-threatening condition that usually requires surgical intervention when the marked ischemia of intestine is suspected on imaging studies such as abdominal CT. However, conservative management can be a choice when peritoneal signs are absent, enzyme leakages such as LDH and CK are low and severe acidosis is absent.

COPPER DEFICIENT MYELONEUROPATHY IN CELIAC DISEASE Siddharth Sheth; Michael Elnicki. University of Pittsburgh Medical Center, Pittsburgh, PA. (*Tracking ID #1939687*)

LEARNING OBJECTIVE 1: Recognize the relationship between copper deficiency and peripheral neuropathy

LEARNING OBJECTIVE 2: Evaluate copper levels in patients with celiac disease (CD) who present with myeloneuropathy

CASE: A 55-year-old Caucasian man with a history of hypothyroidism and celiac disease presented to our general internal medicine service with unintentional 30-lb weight loss and bilateral proximal leg weakness. Symptoms started insidiously and worsened over a five-month period. He had difficulty rising from a seated position and could not ambulate independently. Review of systems was negative for changes in appetite, abdominal pain, diarrhea, or skin rashes. Per chart review, the patient's primary care physician had recently treated B12 deficiency with little improvement in symptoms. Further, celiac disease was diagnosed 5 years ago via endoscopy following workup for gastritis; however, the patient never initiated a gluten-free diet. Physical examination was notable for a thin male with stable vital signs and clear mentation. There was diffuse muscle loss without focal atrophy. Lower extremity sensation and coordination were preserved, but vibratory sense and deep tendon reflexes were diminished. Gait was unsteady and wide-based. Laboratory findings revealed macrocytic anemia with leukopenia (hemoglobin 12.5 g/dL, white blood count $2.6 \times 10^9/\text{L}$, platelets $340 \times 10^9/\text{L}$ and mean corpuscular volume 101.6 fL). Thyroid stimulating hormone, antinuclear antibody, lyme titers, zinc levels were normal. A full body computed tomography scan to assess for malignancy was negative. Additionally, a bone marrow biopsy evaluating for myelodysplastic syndrome showed slight hypocellularity with small lymphoid aggregates. Following neurology consultation, laboratory evaluation revealed markedly decreased serum copper (5 ug/dL, reference range 60–190 ug/dL) and ceruloplasmin (3.1 mg/dL, reference range 22–58 mg/dL) levels. The patient was treated with copper sulfate (1 mg IV weekly) and started on a gluten-free diet. His anemia and neuropathy improved significantly in 3 weeks. He also reported weight gain with strict dietary compliance supplemented by parenteral nutrition.

DISCUSSION: Peripheral neuropathy is a common office and hospital complaint. Diabetes, hypothyroidism, and B12 deficiency are typical causes; however, the differential is vast. In this case, our patient had a history of hypothyroidism and B12 deficiency, which were treated at presentation. He also had celiac disease, which was asymptomatic prior to the onset of weight loss. CD is an autoimmune enteropathy characterized by inflammation of small bowel mucosa. Commonly associated malabsorption deficiencies include low vitamin B12, folate, and calcium. Case reports have linked CD with copper deficiency. The exact location of copper absorption is unknown; however, the small intestine is reportedly involved. In our patient, worsening CD likely caused copper malabsorption, which manifested as the combination of anemia, neutropenia, and myeloneuropathy. More than three million Americans have CD, many of whom are asymptomatic. As awareness increases, general medicine providers will likely diagnose and treat more patients with CD. Copper deficiency-associated neuropathy can be potentially irreversible; therefore, early detection of symptoms with appropriate treatment is paramount to prevent significant morbidity.

CRACK IS WHACK: CHARACTERISTIC FINDINGS IN LEVAMISOLE-INDUCED VASCULITIS Salomon Puyana²; Anar Patel¹; Harish Jasti¹. ¹University of Pittsburgh Medical Center, Pittsburgh, PA; ²University of Pittsburgh School of Medicine, Pittsburgh, PA. (*Tracking ID #1934966*)

LEARNING OBJECTIVE 1: Identify the clinical characteristics of levamisole-induced vasculitis

LEARNING OBJECTIVE 2: Recognize the diagnosis and management of this condition

CASE: A 57 year old female with a past medical history of rheumatoid arthritis presented with 2 days of a painful and progressive erythematous rash on her upper extremities, buttocks and knees. She was on infliximab, methotrexate and prednisone for control of her rheumatoid arthritis. She denied fevers, shortness of breath or chest pain. Social history was remarkable for tobacco use and prior incarceration. Physical exam revealed a slender, ill-appearing female. Vital signs were stable. Cardiac, pulmonary and abdominal exam were unremarkable. Skin exam was significant for erythematous and violaceous circular plaques on her elbows, buttocks, and bilateral knees as well as an eschar on the right middle finger. Laboratory studies were significant for an elevated CRP, low complement levels (C3, C4), and positive p-ANCA. Despite denial of illicit drug use, urine toxicology screen was positive for cocaine metabolites. Microscopic examination of a punch biopsy of a lesion from the mid-back revealed leukocytoclastic vasculitis and fibrinoid necrosis of the blood vessel wall with perivascular neutrophilic infiltrate. The combination of positive ANCA screen, recent cocaine use, and skin biopsy result was highly suggestive of the diagnosis of levamisole-induced vasculitis. The patient was continued on her previous dose of prednisone 20 mg daily and was counseled on abstinence from cocaine use.

DISCUSSION: Levamisole is a synthetic agent derived from imidazothiazole which was previously used as a veterinary antihelminthic and immunomodulator. In recent years, it has emerged as the prevalent adulterant of illicit cocaine in the US. A syndrome related to levamisole is becoming increasingly recognized as a serious and potentially life-threatening complication of cocaine use. Distinctive clinical characteristics suggestive of levamisole-adulterated cocaine use include neutropenia/leukopenia, cutaneous vasculopathy, and the generation of auto-antibodies. Most patients will have a positive urine toxicology screen for cocaine, and the presence of levamisole can be confirmed with gas chromatography-mass spectrometry. The predominant histopathology includes leukocytoclastic vasculitis and/or microvascular thrombosis making biopsy useful in narrowing the differential diagnosis. Commonly implicated auto-antibodies in this syndrome include ANCA, anti-phospholipid antibody, lupus anticoagulant, and anti-cardiolipin antibodies. The mainstay of treatment is abstinence from cocaine, not only for resolution of skin manifestations but also to prevent future recurrences. There is currently insufficient evidence to support the use of corticosteroids in treatment. Rarely, wound debridement and amputation is required to manage extensive skin and soft tissue necrosis. In addition to a high index of clinical suspicion and a detailed history, laboratory and histopathological findings can be helpful in making the diagnosis of levamisole-induced vasculitis.

CRACKING A RARE CASE OF ABDOMINAL PAIN Devika Nair; Deepa Bhatnagar. Tulane University Health Sciences Center, New Orleans, LA. (*Tracking ID #1924938*)

LEARNING OBJECTIVE 1: Discover an example of congenital causes of abdominal pain

LEARNING OBJECTIVE 2: Recognize the appropriate imaging modalities used in diagnosing Nutcracker Syndrome

CASE: A 21-year-old woman presented with a one-year history of intermittent abdominal pain, nausea, and vomiting. She denied any triggering factors, drug use, sick contacts, weight loss, or blood in her stools. Vital signs on presentation were a temperature of 97 F, heart rate of 75 beats/min, respirations of 20/min, and a blood pressure of 143/90 mmHg. She had tenderness to deep palpation in the left lower quadrant as well as left costovertebral angle tenderness. Murphy's sign was negative. Laboratory studies were only significant for microscopic hematuria and a negative urine pregnancy test. Her urine contained no white blood cells and was negative for leukocyte esterase. Her persistent costovertebral angle tenderness in the setting of a relatively normal urinalysis prompted a search for nephrolithiasis. A contrasted abdominal computed tomography (CT) revealed compression of her left renal vein by the left superior mesenteric artery. CT venography revealed a large pressure gradient between the left renal vein and inferior vena cava. It was thus determined that she was suffering from a rare condition known as Nutcracker syndrome. A stent was placed in her left renal vein, and her symptoms resolved completely.

DISCUSSION: Abdominal pain is a common complaint encountered by internists. A careful history and physical examination is essential, but cases like this one emphasize the importance of pursuing further testing when an initial evaluation is unrevealing. Nutcracker syndrome, or renal vein entrapment syndrome, occurs as the result of compression of the left renal vein as it passes between the abdominal aorta and the superior mesenteric artery. Though diagnostic criteria are not established, common manifestations include abdominal pain, nausea, hypertension, and microscopic hematuria. The phenomenon is commonly seen in adolescent females who present with pelvic pain and

dyspareunia. Diagnosis is confirmed with an abdominal CT with IV contrast, but the gold standard test is venography. The left renal vein typically runs inferior to the superior mesenteric artery (SMA) and anterior to the abdominal aorta. Normally, the pressure gradient between the left renal vein and the inferior vena cava is less than 1 mmHg. A gradient of >2 cm on venography is highly suggestive of Nutcracker syndrome. This increased pressure results in the formation of collateral vessels. Communication between these vessels and neighboring renal calyces results in the hematuria that is characteristic of the syndrome. There are currently no specific guidelines for the treatment of Nutcracker syndrome. Patients may undergo observation alone, but those whose symptoms are severe receive renal vein transposition or renal vein stenting. With careful history taking and appropriate diagnostic studies, the morbidity associated with this rare condition can be significantly improved.

CRANIAL MASS IN A YOUNG MALE: TB OR NOT TB Radha S. Mehta; Gautam George; Indumathy Varadarajan. Mount Auburn Hospital, Cambridge, MA. (*Tracking ID #1931849*)

LEARNING OBJECTIVE 1: To diagnose a potentially curable disease by having a high index of suspicion in a patient with atypical manifestations involving several organ systems

CASE: 25-year old male of Vietnamese descent presented with a lump on the left side of head, associated with fatigue, weight loss and night sweats. He has lived in the US all his life and has made short visits to Vietnam and the Dominican Republic. He endorsed prior smoking and a history of tuberculosis in his father. Physical examination was significant for sinus tachycardia and a nontender, nonerythematous, soft, left parietal mass. MRI Brain showed a heterogeneous mass in the diploic space of the left parietal bone that breached the cortex and was associated with epidural and subgaleal components. Chest CT revealed a pleural based mass invading left anterior ribs with accompanying bone destruction. IR-guided biopsy of the bone showed granulomatous inflammation and necrosis. PPD was strongly positive. Induced sputum and bronchoscopy specimen was positive for *Mycobacterium tuberculosis* by PCR and culture. Anti-tuberculosis therapy was initiated.

DISCUSSION: Tuberculosis is a chronic granulomatous infectious disease which can have bizarre manifestations. Disseminated form occurs when *Mycobacterium tuberculosis* bacilli spread from the primary site (usually lungs) to other organs by haematogenous or lymphatic route. Any organ system may be affected in this process of dissemination. Extremes of age and immunosuppression are the major risk factors for dissemination. In disseminated disease, usually the solid organs are affected in its micro nodular or miliary form, which manifests as diffuse enlargement of the organ or as multiple tiny lesions. The macro nodular variety is rare and it appears as a single hypo dense tumor-like lesion or as multiple hypo dense lesions with central enhancement in early lesions and as calcified lesions in advanced disease. Lytic lesions seen in skeletal tuberculosis may resemble other sinister pathology such as leukemia, neuroblastoma and Langerhan's cell histiocytosis. In these clinical circumstances, a tissue biopsy for Tuberculosis PCR may prove to be of crucial diagnostic value. The tuberculin skin test can be a supportive diagnostic tool if positive, but a negative skin test does not exclude the diagnosis due to higher incidence of anergy in military TB. In general, the approach to antimicrobial therapy for treatment of miliary tuberculosis (TB) is the same as for pulmonary TB using the four drug regimen (Isoniazid, Rifampicin, Ethambutol and Pyrazinamide) for the first 2 months followed by two drug regimen for 4–7 months. The exact duration of treatment however is controversial.

CREUTZFELDT-JAKOB DISEASE (CJD) PRESENTING AS RAPIDLY PROGRESSIVE DEMENTIA IN A MIDDLE-AGED VEGETARIAN FEMALE Mark Schwartz; Rory Shallis; Gabriela Ferreira. Rutgers Medical School, New Brunswick, NJ. (*Tracking ID #1935680*)

LEARNING OBJECTIVE 1: What is the differential diagnosis of rapidly progressive dementias?

LEARNING OBJECTIVE 2: What are initial diagnostic tests and when should a referral be made?

CASE: A 57 year-old female presented to the hospital with a 6 month history of rapid cognitive and functional decline, ataxia and urinary retention with associated recurrent urinary tract infections. One year prior to presentation, the patient experienced mood changes, fatigue, and 40 lb weight loss. A psychiatrist started anti-depressant therapy without improvement. A rheumatologist diagnosed the patient with Sjogren's syndrome after labs showed elevated CRP, anti-RNP and anti-SSA, but prednisone did not improve symptoms. The patient became more ataxic, resulting in frequent falls and fractures requiring surgical repair. She eventually required

assistance with all activities of daily living. Significant history included rheumatoid arthritis, B12 deficiency, bilateral knee replacements and carpal tunnel release. There was no history of organ transplantation, blood transfusion, or toxic exposure. The patient was a lifelong vegetarian. Family history was negative for neurodegenerative illnesses. On exam, the patient was alert with garbled speech and non-purposeful movements. There was no evidence of startle reflex or myoclonus. The patient had a labile affect with a short attention span. Neurologic exam revealed normal reflexes, muscle tone and strength. Labs including heavy metal screen and manganese were negative. MRI showed increased signal intensity in bilateral basal ganglia on FLAIR imaging; DWI was not performed. EEG showed bilateral posterior periodic 1.5–2Hz sharp waves during wakefulness that disappeared during sleep. CSF revealed elevated 14-3-3 protein. Diagnosis of sporadic CJD (sCJD) was made on the basis of clinical presentation, typical MRI FLAIR signals, elevated 14-3-3 and characteristic EEG findings. Patient's family declined brain biopsy.

DISCUSSION: Rapidly progressive dementias (RPD) are rare and most are caused by prion diseases which have no effective therapy. In a referral population of 825 cases of RPD (1), 54 % were prion diseases, 28 % were undetermined, and 18 % were nonprion related, and potentially treatable. Of nonprion conditions, 26 % were neurodegenerative, 15 % autoimmune, 11 % infectious, 11 % psychiatric, and 9 % other (vascular, toxic-metabolic, neoplasm related). Because of the rapidity of clinical deterioration and lack of therapies for prion diseases, clinicians must use a systematic approach to identify any potentially treatable causes. Initial diagnostic tests include labs for autoimmune, infectious or other metabolic illness, MRI brain with gadolinium to evaluate for neoplasm, demyelination, vasculopathy or neurodegenerative illness, and a psychiatric evaluation for pseudodementia in select patients. If these are unrevealing, the patient should see a neurologist for further evaluation including EEG, toxins including heavy metal poisoning, and a lumbar puncture including quantification of 14-3-3 protein to rule out CJD. This case illustrates the diagnostic challenges in CJD and RPD, which can present initially with nonspecific behavioral and constitutional symptoms. Diagnosis of CJD relies on clinical suspicion, imaging, EEG, elevated CSF biomarkers, and is confirmed by brain biopsy.

CRITICAL MASS Meghana Dhamdhare. St. Luke's University Health Network, Bethlehem, PA. (*Tracking ID #1901648*)

LEARNING OBJECTIVE 1: Recognize cardiac metastasis as a cause in patients presenting with signs of cardiac failure with past history of tumors. Right ventricular (RV) metastases without either IVC or RA involvement are rare and diagnosis can be missed in view of more common causes like vegetations, thrombus or primary tumors of the heart.

CASE: A 71-year-old, with history of renal cell carcinoma (RCC-clear cell type with sarcomatous changes confined to the capsule), resected 2 years earlier, had been in his usual state of health until he presented with lower extremity edema, anasarca and shortness of breath. Two, biopsied, regional lymph nodes were negative. Echocardiogram revealed a large right atrial mass obstructing the tricuspid valve. He was also found to have a new pulmonary mass and pleural effusions suggestive of aggressive disease. CT scan of his abdomen and pelvis did not show obstruction of his IVC. He was admitted for acute kidney injury with severe hyperkalemia and severe bradycardia necessitating emergent CVVHD. His potassium improved on CVVHD, however while in the intensive care unit he developed mental status changes and worsening hypotension consistent with septic shock. He was started on empiric broad spectrum antibiotics and required vasopressor support. Given the patient's history, metastatic tumor in the right atrium was the presumptive diagnosis. As surgical resection for cure was felt to be unlikely and palliative surgical resection debulking is usually not indicated, the patient was made inpatient hospice according to his family wishes.

DISCUSSION: The differential diagnoses of intracardiac masses include vegetation, thrombus and tumors. Most secondary tumors of the heart originate from leukemia, melanoma, lung cancer, breast cancer, and lymphoma. Cardiac metastases from RCC, which are extremely rare, usually occur in either of two circumstances. First, advanced RCC characteristically extends into the renal vein and the inferior vena cava in 5–15 % of patients, and into the right atrium in about 1 % of patients, thereby obstructing venous return to the heart. Second, there can be a primary tumor that metastasizes to the heart, which occurs in 10–20 % of patients who are dying of widespread, systemic RCC. Right ventricular metastases without either IVC or RA involvement are reported rarely.

CRYOGLOBULINEMIA ASSOCIATED WITH SECONDARY HEMOPHAGOCYTIC LYMPHOHISTIOCYTOSIS (HLH) Shone Almeida; Soo I. Choi. Ronald Reagan Medical Center at UCLA, Los Angeles, CA. (*Tracking ID #1924780*)

LEARNING OBJECTIVE 1: Recognize the importance of identifying secondary causes of HLH

CASE: F.W. is a 43-year-old African American female who was transferred to UCLA with recurrent fevers, arthralgias, facial rash and abdominal pain. She was in otherwise good health until September 2012 when she began to experience persistent fevers, joint pain, and unexplained weight loss. She was admitted to three outside facilities over a 3 to 4 month period with no clear explanation for her symptoms. On evaluation at UCLA, she was noted to have markedly elevated ferritin at >20,000 ng/mL. Additional workup demonstrated anemia, thrombocytopenia, hypertriglyceridemia, and low NK cell activity with subsequent bone marrow biopsy revealing evidence of hemophagocytosis, confirming diagnosis of HLH. Evaluation for secondary cause of HLH revealed evidence of SLE (discoid lesions, pancytopenia with hemolytic anemia, multiple low-titer autoantibodies including + ANA, dsDNA, Sm/RNP, cardiolipin, and ribosomal-P protein antibodies, and hypocomplementemia) as well as inflammatory myositis/myocarditis (CK >7000U/L and elevated troponin with decreased ejection fraction). She also had markedly positive cryocrit at 8 %. She was treated with a modified HLH-94 protocol consisting of pulse IV solumedrol followed by decadron taper and cyclosporine 200 mg twice daily. After a 2 month hospital course she was discharged in good condition.

DISCUSSION: Hemophagocytic Lymphohistiocytosis (HLH) is a rare syndrome resulting from pathologic activation of histiocytes and macrophages, leading to unchecked cytokine production and a persistent inflammatory state. HLH can occur as a primary process, familial disease, or secondary to malignancy, infection, and rheumatologic conditions. This report highlights a case of secondary HLH associated with underlying connective tissue disease with features of Systemic Lupus Erythematosus (SLE) and inflammatory myositis as well as cryoglobulinemia with good response to modified treatment regimen. The association with cryoglobulinemia is notable as there has been no report of HLH in setting of cryoglobulinemia in our review of current literature. Although a rare diagnosis, HLH is an important differential to consider in patients with recurrent fevers of unknown origin. Delay in diagnosis is often the biggest barrier to successful outcome, especially in a disease that carries greater than 50 % 5-year mortality. Additionally, identifying an underlying cause, infectious (i.e. EBV), malignancy, or as in this case, rheumatologic, has significant implications for treatment approach and prognosis.

CRYPTOCOCCAL MENINGOENCEPHALITIS: A CRUCIAL DIFFERENTIAL Sameer K. Avavarala¹; Andrew Kure²; Anne Chen³. ¹Henry Ford Hospital, Detroit, MI; ²Wayne State University School of Medicine, Detroit, MI; ³Henry Ford Health System, Detroit, MI. (*Tracking ID #1923516*)

LEARNING OBJECTIVE 1: Recognize the need to check cerebrospinal fluid (CSF) cryptococcal polysaccharide antigen and cryptococcal culture in any patient with abnormal CSF results.

CASE: A 48 year old homeless male with a past medical history significant for intravenous (IV) drug abuse and recent short term incarceration presented to the emergency room with a chief complaint of having the "worst headache of his life" for 5 days. His headache was associated with neck pain and photophobia. Review of systems was negative for fever, chills, nausea, and vomiting. On physical examination, he was afebrile and there were no signs of meningeal irritation or neurological deficits. He was alert and oriented to person, place, and time. His initial laboratory investigations did not show leukocytosis and his first set of blood cultures were negative. Computed tomography of his head did not show any evidence of an acute intracranial process. Initial CSF analysis revealed 236 leukocytes per microliter (17 % neutrophils and 76 % lymphocytes), glucose of 32 mg/dL, and protein of 117 mg/dL. Immediately after the CSF sample was acquired, the patient was started on intravenous (IV) acyclovir, vancomycin, and ceftriaxone as empiric therapy for both bacterial and viral meningitis. Gram stain, smear for acid fast bacilli, and India ink staining of the CSF were all negative. CSF cultures and fungal cultures were sent. After results demonstrated negative CSF herpes simplex virus polymerase chain reaction and no growth on CSF cultures after several days, all antimicrobials were discontinued. The patient was known to be human immunodeficiency virus (HIV) negative on previous testing, and repeat testing this admission was again negative. The patient clinically improved after 4 days of symptomatic therapy and was discharged with a primary diagnosis of aseptic meningitis. However, 10 days later his CSF fungal cultures identified Cryptococcus neoformans (C. neoformans) and the patient was called back for treatment. He stated that over the past few days, his headache had returned and was accompanied by nausea, vomiting, and a fever. When the patient was re-admitted his lumbar puncture

had an opening pressure of 40 cm of water. He was treated with serial lumbar punctures, IV amphotericin B, and flucytosine. After 2 weeks, he was discharged on oral fluconazole as maintenance therapy with close outpatient follow up.

DISCUSSION: *C. neoformans* is a widespread saprophyte with a global distribution and is acknowledged as a common worldwide opportunistic pathogen. The two most common sites for infection with this encapsulated yeast are the lung and the central nervous system (CNS); although, this organism has been known to infect any organ. Pathogenesis is often related to inhalation of *Cryptococcus* from avian droppings or soil, with potential subsequent hematogenous spread. In the United States, *C. neoformans* is the predominant species with most cases reported as opportunistic infections. *Cryptococcus* causing meningoencephalitis most commonly affects those with an immunocompromised state: patients with Acquired Immune Deficiency Syndrome (AIDS), prolonged treatment with corticosteroids or other immunosuppressant therapy, organ transplantation, advanced malignancy, sarcoidosis and those who have been treated with other immunomodulating medications (i.e. monoclonal antibodies). Over the past few years there have been increasing reports of cryptococcal meningitis infecting patients with no known risk factors. It has been estimated that approximately 20 % of patients who have cryptococcosis without HIV infection have no apparent predisposing disease. An underlying cellular immune dysfunction is known to predispose to this infection and likely contributes to many of these cases. Although cryptococcal meningoencephalitis is an uncommon cause of meningitis, it can result in permanent cranial nerve damage and mortality. Several tests are used to help diagnose cryptococcal meningitis. India-ink preparation has an overall sensitivity of 50 %, and is over 80 % sensitive in those with AIDS. Between 93 and 99 % of patients have cryptococcal polysaccharide antigen in the CSF. In this particular case, our initial suspicion for cryptococcal meningoencephalitis was low due to the absence of risk factors, so CSF cryptococcal antigen was not checked. However, given the increasing number of cryptococcal meningitis cases identified in patients with no apparent risk factors, checking CSF cryptococcal antigen in any patient with abnormal CSF chemistries should be considered, especially given the potentially rapid progression toward permanent neurological damage and death.

CRYPTOGENIC LIVER ABSCESS IN A DIABETIC PATIENT Debjit Saha¹, Sandeep Gupta². ¹Mount Sinai Medical Center, Miami Beach, FL; ²School of Medicine University of California, Irvine, CA. (*Tracking ID #1939721*)

LEARNING OBJECTIVE 1: Recognize the clinical clue of the pyogenic liver abscess in a diabetic patient with string test positive *Klebsiella pneumoniae* bacteremia.

LEARNING OBJECTIVE 2: Prompt initiation of antibiotic treatment and strict glycemic control are key interventions in preventing invasive syndromes and metastatic complications caused by hypermucoviscous *Klebsiella pneumoniae* strains with K1 and K2 serotypes.

CASE: A 53 year old Hispanic man with a history of type II diabetes mellitus presented with chills, fever, nausea, vomiting and abdominal pain over the past 36 h. He complained of epigastric, non-colicky, mild to moderate intensity abdominal pain associated with 5–6 episodes of non-bloody vomiting and shaking chills and high grade fever. Physical exam was significant for a temperature of 103 F, tachycardia (heart rate 134/min) and right upper quadrant abdominal tenderness on palpation without rigidity or rebound. Initial laboratory work-up showed mild leukocytosis (12,000), thrombocytopenia (133,000), hyperglycemia (363), anion-gap metabolic acidosis (anion gap of 20 and pH 7.20) with serum beta-hydroxybutyrate of 21. Liver function tests revealed an AST of 113, ALT of 126, Alk Phosp. of 202 and total bilirubin of 4.8. Abdominal ultrasound showed mild hepatomegaly with no evidence of cholelithiasis or acute cholecystitis. The patient was started with normal saline and insulin infusion. Intravenous levofloxacin and metronidazole was started after blood culture had been drawn. Following day, blood culture grew gram negative rods and patient went in to septic shock. He was shifted to ICU, antibiotics were changed to piperacillin-tazobactum. CT scan of the abdomen with contrast showed a 5 cm heterogeneous cystic/necrotic hepatic lesion in the posterior right hepatic lobe suggesting hepatic abscess. Blood culture grew highly mucoid *K. pneumoniae* with positive string test on day 3 of hospitalization. Antibiotic was changed to Ceftriaxone and IR was consulted for percutaneous drainage. Following drainage, the patient became afebrile, LFT normalized and he was discharged after 4 weeks of intravenous antibiotics without any complications.

DISCUSSION: Our patient presented with diabetic ketoacidosis, precipitated by intra-abdominal infection. DM and specific virulent strains of *K. pneumoniae* were predisposing factors for the development of pyogenic liver abscess in this patient. Several studies have shown that these strains can infect the liver following translocation through intestinal epithelium. The invasive nature of these organisms can cause metastatic infective complications like bacteremia, meningitis,

endophthalmitis and septic pulmonary emboli with empyema. Third generation cephalosporin with IR guided drainage is the standard of care.

CRYPTOGENIC ORGANIZING PNEUMONIA, A RARE AND OFTEN MISDIAGNOSED ENTITY Sonia Rajput, Katherine Yu. UCLA-Olive View Medical Center, Sylmar, CA. (*Tracking ID #1938213*)

LEARNING OBJECTIVE 1: Recognize that cryptogenic organizing pneumonia is a part of the differential diagnosis when presumptive symptoms of pneumonia do not resolve despite antibiotic treatment

CASE: A 54 year-old male without significant PMH presented to the hospital with a 10-day history of dyspnea on exertion and orthopnea. He endorsed a productive cough with non-bloody sputum and night sweats, but denied fevers, myalgia/arthralgia, recent travel, sick contacts or homelessness. His respiratory symptoms failed to improve after a course of Azithromycin prescribed by his primary provider for empiric treatment of CAP vs. bronchiolitis. Upon evaluation, he was afebrile and tachycardic with an oxygen saturation of 90 % on room air. He had crackles bilaterally and no JVD or lower extremity edema. Laboratory analysis revealed hypoalbuminemia and a normal WBC and electrolyte count. Chest Xray showed diffuse patchy infiltrates in both lungs. High-resolution chest CT showed patchy ground glass opacities in a peribronchial distribution with findings suggestive of multifocal pneumonia. He was pan-cultured and started on ceftriaxone and azithromycin for presumed CAP. However, he continued to be tachypneic and O2 dependent despite antibiotic therapy. Coccidiomycosis, histoplasma, legionella, tuberculosis, cryptococcus, PCP and HIV were all subsequently negative, as were sputum and blood cultures. Transbronchial biopsy demonstrated “masson bodies” typically associated with cryptogenic organizing pneumonia. He was started on prednisone with marked improvement of his respiratory status and sent home days later.

DISCUSSION: Cryptogenic Organizing Pneumonia (COP) is a diffuse interstitial lung disease that affects the distal bronchioles and alveolar walls. It is a rare entity and accounts for roughly 6–7/100,000 admissions every year. COP usually presents in the fifth or sixth decade of life. Fifty percent of cases are idiopathic and the rest are associated with connective tissue diseases (e.g. rheumatoid arthritis), and a variety of drugs, including amiodarone. Symptoms such as cough, shortness of breath, and malaise are nonspecific and often get misdiagnosed initially as community acquired pneumonia (CAP). However a key clue is that symptoms usually last for 1–2 months and are refractory to antibiotic treatment. High resolution CT reveals patchy air-space consolidations, ground-glass opacities, and bronchial wall thickening with dilation. Biopsy typically reveals intraluminal plugs of inflammatory debris in alveolar spaces, called Masson bodies, as was seen in our patient. Treatment includes oral or parenteral corticosteroids for moderate or severe respiratory impairment, respectively. For patients who fail steroids, addition of cyclophosphamide is often indicated. Treatment usually lasts 4–8 weeks with improvement of chest imaging anywhere from several weeks up to 3 months. Internists should have a low threshold for COP when presumptive CAP symptoms do not resolve.

DAPTOMYCIN-INDUCED EOSINOPHILIC PNEUMONITIS Camille Folkard, Raymond Munoz. Methodist Dallas Medical Center, Dallas, TX. (*Tracking ID #1939567*)

LEARNING OBJECTIVE 1: Recognize adverse drug reactions of daptomycin
LEARNING OBJECTIVE 2: Manage drug-induced acute lung injury

CASE: Eosinophilic pneumonitis is a relatively rare phenomenon that can be triggered by exposure to certain drugs or environmental agents. Daptomycin-induced eosinophilic pneumonitis typically presents within 2–4 weeks of therapy initiation as acute onset dyspnea, fever and new pulmonary infiltrates on imaging studies. Diagnosis is typically made by demonstrating eosinophilia in bronchoalveolar lavage fluid and a temporal relationship between drug exposure and symptom onset. Peripheral eosinophilia is not required for diagnosis and may be absent early in disease course. A 69 year-old woman with a past medical history of hypothyroidism, systolic CHF, anemia, hypertension, atrial fibrillation and coronary artery disease was admitted to MDMC with worsening shortness of breath and dyspnea on exertion. Several months prior, she had undergone left total knee arthroplasty and subsequently developed an infection of the prosthesis causing bacteremia. Revision was made with operative incision and drainage and exchange of the polyethylene liner by the orthopedic surgeon. Following this, she was found to have ongoing vancomycin-resistant enterococcus infection of the left knee prosthesis and started on IV daptomycin. While continuing treatment with IV daptomycin at a long-term acute care facility, she developed an episode of acute respiratory distress believed to be

drug-induced and was switched from IV daptomycin to oral linezolid. Her respiratory symptoms improved and she was transitioned to Methodist Rehabilitation Hospital. This facility was unaware of the recent adverse drug reaction to daptomycin and after finding the patient pancytopenic secondary to linezolid therapy, started her back on IV daptomycin. Again, the patient developed acute respiratory distress with pulmonary edema and presented to MDMC as mentioned above. On admission, she was afebrile but with diffuse bilateral pulmonary infiltrates present on CXR. The patient was treated with removal of daptomycin (with the patient being already past the recommended antibiotic completion date), improved significantly in the following days and was discharged home.

DISCUSSION: This case demonstrates the value of a complete and thorough history. Daptomycin-induced eosinophilic pneumonitis, although rare, does occur and can present as acute lung injury with recurrences on re-exposure. Recognition is paramount. In this case, some classic presenting features of fever and peripheral eosinophilia were absent, which made the history that much more crucial in making the correct diagnosis. Demonstration of eosinophilia on bronchoalveolar lavage would have made a useful contribution, however the strong temporal association exhibited on two separate occasions and resolution of the symptoms upon removal of the offending agent were sufficient to confirm the diagnosis.

DEEPER THAN THE SKIN: DRESS SYNDROME AS A MEDICATION-RELATED COMPLICATION IN A HIV + PATIENT Meena Zareh¹; Timothy Vossler¹; Stephanie K. Zia^{1,2}. ¹Keck School of Medicine, Los Angeles, CA; ²Keck School of Medicine, Los Angeles, CA. (*Tracking ID #1939849*)

LEARNING OBJECTIVE 1: Recognize clinical features associated with DRESS syndrome

LEARNING OBJECTIVE 2: Recognize the importance and implications of assessing patients' understanding of their medical conditions, medications, and side effects

CASE: A 50 year old African American male with HIV, Hepatitis C (HCV), chronic kidney disease, and hypertension presented with 1 week of a progressive, pruritic rash. Initially localized to the groin, the rash gradually spread to the bilateral upper and lower extremities and lips. The patient was in his usual state of health until 2 months prior to presentation, when he was enrolled in a HCV treatment trial using PEG-interferon, telaprevir, and ribavirin. Shortly thereafter, he experienced periods of shortness of breath and tachypnea, which he attributed to asthma. His HAART therapy consisted of abacavir, raltegravir, and lamivudine; however, the patient was unable to name his HAART regimen. Significantly, in the 5 month period prior to admission, the patient's HAART therapy underwent several modifications, from monotherapy to multi-tablet regimens. On physical exam, the patient was febrile to 101.2°, tachycardic to 130, and tachypneic to 24. A morbilliform rash covered his upper and lower extremities and perineum. Inspection of the oral and anal mucosa and conjunctiva failed to reveal any lesions. Palpation of the inguinal and posterior auricular areas revealed firm, nontender lymphadenopathy. Significant laboratory data on admission included a leukocytosis of 11.0 K/cumm with 1.8 K/cumm eosinophils, a serum creatinine of 4.53 mg/dL, elevated from a baseline of 1.52, and bicarbonate concentration of 6 mEq/dL. In consultation with the allergy/immunology service, his primary doctors administered methylprednisolone at a dose of 0.6 mg/kg/day IV, with no clinically apparent response. After augmenting the dose to 1.5 mg/kg/day, the rash and eosinophilia receded over the next 2 weeks. Multiple recurrences complicated the patient's hospital stay, as each attempt to wean the steroid dose resulted in a flare of symptoms. He developed multiple episodes of bacteremia and a gastrointestinal bleed, requiring four separate admissions to the MICU. The patient's HIV viral load changed from undetectable to detectable, and his CD4 count began to decrease. Ultimately, he died of gram-negative sepsis.

DISCUSSION: Drug rash with eosinophilia and systemic symptoms (DRESS) syndrome is a severe reaction to medication first described in 1936. Historically associated with anti-convulsants such as carbamazepine, recently recognized culprit agents include many different medications, such as allopurinol and sulfasalazine. Signs of DRESS include morbilliform rash, fever, eosinophilia, lymphadenopathy, atypical lymphocytes, and end organ dysfunction. Proper management begins with prompt recognition and hospitalization, followed by removal of the offending drug, initiation of steroid therapy, and appropriate consultation. With an incidence between 1 in 1,000 to 1 in 10,000 drug exposures, DRESS requires a high index of suspicion to diagnose. As seen in this case, identifying the offending drug proves challenging in a patient with a complex medication history and limited health literacy about his condition and regimen. Health literacy, defined as "the degree to which individuals have the capacity to obtain, process, and understand basic health information and services needed to make appropriate health decisions" is integral to patients' ability to adhere to treatment and achieve the best possible health outcomes. Approximately

36 % of US adults have basic or below basic health literacy skills. At-risk groups include African Americans and patients of lower socioeconomic backgrounds. Physicians can improve patients' health literacy by utilizing strategies such as the teach-back method to assess patient understanding. Written materials such as pamphlets and medication lists can be given to patients to help promote patient empowerment and self-management of their conditions. As illustrated in our case, multiple medication changes, along with poor understanding by patients of their own care, can complicate the identification of the offending drug. If DRESS syndrome is suspected, prompt recognition and aggressive therapy should be initiated, with involvement of subspecialists. However, despite early identification and treatment, the mortality of DRESS is nearly 10 %.

DELIVERING THE DIAGNOSIS: ALCOHOLIC FOAMY CELL DEGENERATION Abtin K. Farahmand²; Sabina Sandigursky¹; Anthony A. Holmes¹; Janina L. Morrison^{1,2}. ¹Montefiore Medical Center, Bronx, NY; ²Albert Einstein College of Medicine, Bronx, NY. (*Tracking ID #1936441*)

LEARNING OBJECTIVE 1: Recognize an uncommon clinical presentation of alcoholic liver disease

LEARNING OBJECTIVE 2: Identify pathological characteristics of alcoholic foamy cell degeneration

CASE: A 58 year-old woman presented with intermittent epigastric pain, diarrhea and weight loss for 3 months. Her past medical history was significant for chronic alcohol abuse (1 pint of liquor daily for 20 years) with her last drink 30 days prior to admission. Her exam revealed normal vital signs, anicteric sclera, hepatomegaly, mild epigastric tenderness, and mild abdominal distention. Laboratory findings were notable for WBC 29.7 with 91 % granulocytes, INR 1.6, low albumin (2.2), total bilirubin 1.3, direct bilirubin 0.5, AST/ALT 79 and 8, respectively, alkaline phosphatase 408, and GGT 1352. Infectious work-up including hepatitis and HIV serologies, paracentesis, chest x-ray and urinalysis were unrevealing. Abdominal imaging (ultrasound with doppler and MRCP) revealed hepatomegaly without cirrhosis or vein thrombosis, mild ascites, and cholelithiasis without bile duct dilation. Her leukocytosis persisted, alkaline phosphatase remained elevated, and she underwent a liver biopsy. Liver biopsy revealed hepatocytes with both neutrophilic infiltrate and microvacuolar large-droplet steatosis, consistent with concurrent alcoholic hepatitis and alcoholic foamy degeneration.

DISCUSSION: Alcoholic hepatitis can present, as in this case, with epigastric pain, weight loss and diarrhea. The most common clinical manifestations also include jaundice, hepatomegaly and ascites. Laboratory abnormalities typically include increased serum bilirubin, elevated AST and ALT levels with AST/ALT ratio 2 or greater, elevated GGT, leukocytosis, and elevated INR. These laboratory abnormalities often resolve with cessation of alcohol use, though, more rarely, some abnormalities can persist for weeks to months after cessation, even in the absence of cirrhosis. As a result, the various manifestations of alcoholic liver disease must remain in the differential diagnosis when considering the presentation of patients with this constellation of history, symptoms, and laboratory findings. Alcoholic hepatitis is characterized by inflammation with neutrophilic infiltration of hepatocytes, usually corresponding to an elevated AST/ALT and leukocytosis. Alcoholic foamy degeneration (AFD) represents a separate pathological pathway, with neither inflammation nor fibrosis, but with significant degeneration of perivenular hepatocytes due to alcohol. AFD is characterized by transient elevation in AST/ALT but more prolonged elevation of alkaline phosphatase, without leukocytosis, mimicking obstructive biliary diseases. These two varied presentations of alcoholic liver damage are not often seen together. Importantly, alcoholic foamy degeneration is also thought to respond quickly to the cessation of alcohol use, though it is unknown whether persistence of the abnormal pathology portends a poor long-term prognosis for full recovery and resolution of symptoms.

DETERMINING THE SOURCE OF BLEEDING: A STRATEGIC DIAGNOSIS AND TREATMENT FOR OBSCURE GASTROINTESTINAL BLEEDING IN A YOUNG WOMAN Nagano Hiroyuki; Yukio Tsugihashi; Satoshi Okamori. Tenri yorozu Hospital, Tenri, Japan. (*Tracking ID #1912637*)

LEARNING OBJECTIVE 1: To recognize a small bowel tumor as a potential cause of obscure gastrointestinal bleeding in a young patient

LEARNING OBJECTIVE 2: To recognize fludeoxyglucose positron emission tomography (FDG-PET)/computed tomography (CT) as a significant tool for evaluating small bowel tumors

CASE: A 32-year-old Japanese woman presented with general fatigue and vomiting. She lost transient consciousness in the emergency room and was admitted to the Department of General Internal Medicine. Her blood pressure was 92/58 mmHg, regular pulse rate was 81 beats/min, respiratory rate was 20 breaths/min, and body temperature was 36.6 °C.

Rectal examination revealed a melena. Furthermore, her hemoglobin was 9.1 g/dL, mean cell volume was 86 fl, iron level was 23 ug/dl, and ferritin level was 79 ng/ml. Her electrocardiogram was normal. Upper and lower endoscopies confirmed bleeding in the large intestine, the source of which could not be identified. Therefore, we suspected small bowel bleeding. Chest and pelvic radiographs incidentally revealed anterior mediastinal and pelvic masses. Contrast enhanced CT also revealed the masses, however the cause of bleeding remained unidentified. FDG-PET/CT revealed abnormal accumulations on the mediastinal and pelvic masses and a duodenal lesion. Small bowel endoscopy revealed an ulcerated lesion in the distal portion of the ligament of Treitz. This biopsy revealed atypical lymphocytes. CT-guided biopsy of the mediastinal mass also revealed atypical lymphocytes. The patient was then diagnosed with malignant lymphoma. Because of the risk of perforation associated with chemotherapy, we resected the duodenal lesion and pelvic mass. Histopathological examination of the resected specimen revealed diffuse large B-cell lymphoma. The patient was referred to the Department of Hematology, where she was treated by chemotherapy. The anterior mediastinal mass has now disappeared, and the patient is now in complete remission.

DISCUSSION: This case report illustrates that small bowel tumors such as lymphomas are a potential cause of obscure gastrointestinal bleeding in young patients and that FDG-PET/CT plays a significant role in the detection of these tumors. A previous study demonstrated that in patients below 40 years of age, as in this case, a small intestinal tumor is second most common cause (23 %) of obscure gastrointestinal bleeding. In this case, upper and lower endoscopies couldn't identify the source of bleeding. Thus, we suspected a small bowel lesion including small intestinal tumor as the cause of obscure gastrointestinal bleeding. The young patient also had anterior mediastinal and pelvic masses along with obscure gastrointestinal bleeding. Therefore, we performed FDG-PET/CT in order to evaluate these masses and to survey the focus of obscure bleeding on small bowel. As a result, FDG-PET/CT revealed abnormal accumulations on the masses as well as the duodenal lesion that was not detected on contrast enhanced CT. Then, small bowel endoscopy revealed that a small bowel tumor with an ulcerated lesion was the cause of the bleeding. In conclusion, the strategic approach toward the determination of small intestinal bleeding and the masses using FDG-PET may help in the diagnosis and radical therapy.

DIAGNOSING MALIGNANT OTITIS EXTERNA - A LESSON TO IMPROVE PATIENT "HANDOFF" Anil Kumar Reddy Anumandla¹; Gaurav Kistangari¹; Avanti Reddy². ¹Cleveland Clinic, Cleveland, OH; ²Kasturba Medical College, Mangalore, India. (Tracking ID #1939269)

LEARNING OBJECTIVE 1: Recognize the unusual presentation of malignant otitis externa

LEARNING OBJECTIVE 2: Recognize the importance of inadequate handoff during transfer of patient care

CASE: An 84 year old African American male presented to our hospital with nasopharyngeal mass and dysphagia. His past medical history was significant for hypertension, seizure disorder, chronic kidney disease and deep venous thrombosis. Prior to current admission, patient was twice admitted to a local hospital for poor oral intake and acute kidney injury. During that time he underwent CT head that revealed a right nasopharyngeal mass with osseous involvement of the right clivus. Biopsy of mass was considered with a presumed diagnosis of nasopharyngeal carcinoma and patient was referred to outpatient ENT physician at our tertiary care center. At the outpatient clinic, patient reported nausea, generalized weakness and inability to eat food. He was subsequently admitted for PEG tube placement as he also had a positive barium swallow study with increased risk of aspiration. Following PEG tube placement, patient's hospital course was complicated by ileus, leucocytosis and low-grade fever. Empiric intravenous antibiotics were started for possible aspiration pneumonia. After 7 days of hospital course, the biopsy results of outside hospital were still not available and review of entire outside hospital records indicated no attempt at the biopsy; It was realized that a miscommunication during handoff made everyone assume that patient underwent biopsy at outside hospital. ENT physician was reconsulted and MRI head was done which revealed para-retropharyngeal abscess, contiguous extensive skull base osteomyelitis, and possible intracranial extension secondary to malignant otitis externa (MOE). Nasopharyngeal biopsy revealed purulence and frozen section was negative for malignancy. Post biopsy, patient was admitted to ICU as he became cyanotic and hypotensive, and was subsequently intubated for respiratory failure. Biopsy results confirmed MOE, and culture from purulent drainage grew *Pseudomonas* species and a rare yeast. Over the next 2 weeks tracheotomy was done to protect his airway. Treatment regimen was adjusted to micafungin and meropenem. Patient's condition was discharge to longterm term acute care center in a stable condition.

DISCUSSION: The diagnosis of MOE should be considered in all immunocompromised patients, especially elderly diabetics, who have severe otalgia and symptoms of cranial nerve palsy. Decreased oral intake secondary to trismus may also be present.

Iatrogenic factors such as aural irrigation may play a predisposing role. *Pseudomonas* among bacteria and *Aspergillus* or *Mucor* among fungi are common culprits. As the skull base is progressively involved, the adjacent exiting cranial nerves and their branches may be involved leading to cranial nerve deficits; sinus thrombosis, meningitis, and cerebral abscess may also complicate MOE and are late findings that portend a grave prognosis. Early nuclear and CT/MRI imaging, biopsy to rule out malignancy, and culture are essential for prompt diagnosis. Additionally, repeat biopsy and cultures are warranted to rule out an occult malignancy if the disease persists despite appropriate antibiotic therapy. Close follow-up is necessary due to its increased recurrence rates of 15 % to 20 % per year. Early recognition and early initiation of antibiotics are key to successful treatment. Ineffective patient handoffs, especially during transfer of care from other facilities, can lead to increased risk of preventable adverse events, prolonged hospitalization and reduced patient safety.

DIAGNOSING THROMBOTIC THROMBOCYTOPENIC PURPURA IN A PATIENT WITH SYSTEMIC LUPUS ERYTHEMATOSUS Alicia Stapleton¹; Daniel Ling²; Daniel Kahn². ¹UCLA, Los Angeles, CA; ²UCLA, Los Angeles, CA. (Tracking ID #1939696)

LEARNING OBJECTIVE 1: Differentiate between thrombotic thrombocytopenic purpura (TTP) and lupus flare in a patient with systemic lupus erythematosus (SLE)

CASE: A 22 year old African American female with recently diagnosed systemic lupus erythematosus (SLE) presented to the emergency department complaining of worsening bilateral lower extremity edema and fatigue. She had been healthy until 2 weeks prior when she was admitted to the hospital with similar symptoms of fatigue and swelling and was found to have acute kidney injury with creatinine 2.1. Her ultimate diagnosis of SLE was solidified by a positive ANA at 1:1280 titer, elevated dsDNA, low C3 and C4, and a renal biopsy showing diffuse proliferative glomerulonephritis with crescents consistent with lupus nephritis. She was treated with rituximab, high dose steroids, and mycophenolate with improvement in renal function. Her labs at the current presentation were notable for a creatinine of 3.3, elevated from 1.9 at prior discharge. This was attributed to a worsening of her lupus nephritis although her C3, C4, and dsDNA had all improved since the last admission. She was treated again with methylprednisolone pulse and rituximab, and she was given leuprolide in preparation for outpatient dosing of cyclophosphamide. Her creatinine stabilized but did not improve. On the day of planned discharge, her platelets decreased from 233 to 131. A heparin platelet antibody test was sent to rule out heparin induced thrombocytopenia (HIT), and discharge was delayed for further monitoring. Over the next 48 h, her platelets continued to decrease to 47, and then her hemoglobin, which had been previously stable, decreased from 7.8 to 6.5. Despite these worsening abnormalities, she remained asymptomatic and her exam was significant only for isolated anasarca, with no fever, mental status changes, bleeding or bruising. Further work up of her anemia and thrombocytopenia revealed the following: LD 588, haptoglobin undetectable, reticulocyte count 1.06, total bilirubin 3.3, direct bilirubin 1.2, fibrinogen 297, INR 1.1, aPTT 27.4, and negative antiphospholipid antibodies. A peripheral blood smear showed 6 schistocytes per high power field. Given these findings consistent with microangiopathic hemolytic anemia (MAHA) in the setting of thrombocytopenia, she was diagnosed with thrombotic thrombocytopenic purpura (TTP). Hematology was consulted and performed 7 cycles of plasma exchange. Her platelets nadired at 15 before recovering, and her hemolytic anemia resolved with therapy. ADAMTS13 returned at 55 % activity, with normal being greater than 66 % by our lab standards. Her hospital course was complicated by worsening uremia leading to the initiation of hemodialysis.

DISCUSSION: TTP is a rare but dangerous entity that can be difficult to diagnose. This is particularly true in a patient with SLE, as the primary presenting signs of TTP can also be seen in a lupus flare. As our patient's platelets decreased, TTP was low on our initial differential considering her stable hemoglobin, preserved mental status, and lack of fevers. She did have new impairment of her renal function but this was attributed to a flare of her recently diagnosed lupus nephritis. Our initial diagnostic step was to rule out HIT and to monitor. Worsening lupus flare causing immune-mediated platelet destruction was considered but thought unlikely given her ongoing immunosuppressive therapy. Only further work up revealed MAHA suggestive of TTP, prompting the urgent initiation of plasma exchange that was likely life-saving. Interestingly, her renal function did not improve despite her initial treatment for a lupus flare, suggesting that TTP was also contributing to her AKI, although no thrombotic microangiopathy was noted on her initial renal biopsy and repeat biopsy was not performed. Differentiating between TTP and lupus flare can be challenging as both can cause the pentad of hemolytic anemia, thrombocytopenia, kidney injury, fevers, and neurological symptoms, but is necessary given the divergent therapeutic pathways. TTP does not always present with this full pentad, especially in SLE

patients, and can even be diagnosed with findings of only MAHA and thrombocytopenia if clinical suspicion is present. The finding of schistocytes on peripheral blood smear is more suggestive of TTP, whereas the immune-mediated hemolysis of lupus more characteristically produces spherocytes. Additionally, clinical deterioration despite aggressive immunosuppressive therapy for a lupus flare should prompt investigation for an alternative pathological process. This case demonstrates the often occult nature of TTP and the importance of maintaining a high index of suspicion for this life-threatening syndrome.

DIAGNOSIS AND TREATMENT OF NON-TYPHI SALMONELLA INDUCED MYCOTIC ANEURYSM Jung-Eun Ha, NYU School of Medicine, New York, NY. (*Tracking ID #1928206*)

LEARNING OBJECTIVE 1: Recognize the importance of a mycotic aneurysm in the differential diagnoses of non-specific abdominal complaints and fever

LEARNING OBJECTIVE 2: Discuss the distinct therapeutic approaches for a mycotic aneurysm and recognize the poor prognosis despite appropriate treatments

CASE: A 64-year-old man with hypertension and hyperlipidemia presented with a 10 day history of epigastric pain that radiated to his back, subjective fevers, and one episode of non-bloody non-bilious diarrhea. At first evaluation he was afebrile and hemodynamically stable. A thoracic CT scan demonstrated a saccular lesion (please add the dimensions) with surrounding inflammation in the descending thoracic aorta. He then underwent an emergent thoracic endovascular aortic repair (TEVAR). Blood cultures grew pan-sensitive *Salmonella enteritidis*. Empiric antibiotic therapy with vancomycin and piperacillin/tazobactam were switched to ceftriaxone with a plan to treat for 6 weeks followed by chronic suppressive therapy in the setting of stent placement. A transesophageal echocardiogram ruled out endocarditis as the source of his aneurysm. On post-operative day 20, patient was readmitted with fever of 101.2 F, tachycardia, non-productive cough, and pleuritic chest pain radiating to left axilla. Vancomycin, piperacillin/tazobactam, and azithromycin were restarted. CT angiogram demonstrated air and debris surrounding the aortic graft concerning for the development of an abscess, of note no free air was described. Ceftriaxone was switched to ciprofloxacin. He developed a moderate-sized left pleural effusion, and thoracentesis cultures grew multidrug resistant *Klebsiella pneumoniae* and yeast, for which polymyxin B, tigecycline, and micafungin were started. An infected aortic graft was replaced by new homograft, and daptomycin was started after washout and debridement grew polymicrobes including vancomycin-resistant *E. faecium*, *Candida glabrata*, and *Candida krusei*. Post-operative course was complicated by a finding of esophageal tear on CT and barium swallow that was communicating with the mediastinal and pleural space. While awaiting diversion vs. stent, patient became hypotensive to 50s systolic with 1–2 L bloody output in left pleural tube. Despite emergent TEVAR at the site of homograft tear, on day 36 from the initial presentation, patient was pronounced dead.

DISCUSSION: Mycotic aneurysm is a rare form aortic aneurysm with high rates of morbidity and mortality. It is more common in men older than 65 years of age, and those with risk factors for atherosclerosis. Presenting symptoms are non-specific and include abdominal symptoms, back pain, and fever; delayed diagnosis and treatment can lead to aortic rupture and increased mortality. Diagnosis is confirmed by positive blood cultures as well as intraoperative cultures. Non-typhi salmonella species are the most frequent pathogens, though they have a better prognosis than other microorganisms. Several recent case reports have found that patients receiving emergent TEVAR had improved early morbidity and mortality and a comparable long term outcome when compared to patients receiving traditional open surgery. Most case reports used 6–8 weeks of third generation cephalosporin post-operatively given increased rates of ciprofloxacin-resistant salmonella. A systematic review showed that age 65 years or older, aneurysm rupture, and perioperative fever were predictors of persistent infection while preoperative antibiotics use for longer than 1 week and an adjunct intraoperative procedure were protective. The 12-month survival rate of those with sterile repeat blood cultures was 94 % while that of persistently infected group was 39 %. One case report of intraoperative, intra-aortic rifampin infusion noted a resolution of aneurysm sac at 4-month follow-up. Early diagnosis and TEVAR with adjunct procedure may improve prognosis of the rare but lethal mycotic aneurysm.

DIALYSIS DISEQUILIBRIUM SYNDROME Khaled M. Aboulezz; Ahmed Abuzaid; Mohamed El khashab; Abhishek Matta. Creighton university medical center, Omaha, NE. (*Tracking ID #1939703*)

LEARNING OBJECTIVE 1: Recognize Dialysis Disequilibrium Syndrome as a cause of brain edema and death.

LEARNING OBJECTIVE 2: Recognize risk factors for Dialysis Disequilibrium syndrome.

CASE: A 59-years-old African American male with history significant for end stage renal disease status post bilateral transplant and insulin dependent diabetes mellitus admitted with altered mental status (GCS 7) hypothermia (94.4 F), hypotension, tachypnea, kussmaul's breathing, severe dehydration and anuria. Blood tests showed elevated plasma glucose level (1000 g/dl), BUN 246 mg/dl, Creatinine 14.6 mg/dl with baseline 1.2 mg/dl, measured osmolality 437, calculated osmolality 438, and positive ketone in urine. Patient was diagnosed with diabetic ketoacidosis with acute kidney injury secondary to dehydration. Patient was intubated due to severe distress, given intravenous fluid with bicarbonate and insulin. Follow up blood work after 8 h showed BUN level 185 mg/dl. The decision was made to start the patient on hemodialysis. Patient had dialysis for 1 h. His BUN level after the dialysis was 124. Later the blood cultures disclosed gram negative rods bacteremia. Next day GCS dropped from 7 to 3. Patient was not breathing over the ventilator. CT of the head was done showed diffuse advanced global edema throughout the cerebral cortex with tonsillar herniation. Patient was given mannitol with no improvement. The patient deceased on the following day.

DISCUSSION: Our patient mostly developed dialysis disequilibrium syndrome which is a rare syndrome presented with neurologic manifestation mostly secondary to brain edema that affect dialysis patients, particularly when they are first started on hemodialysis. The pathogenesis is not clear but mostly secondary to reverse osmosis due to removing of urea or due to changing in the cerebral intracellular PH that can lead to cerebral edema. Risk factors include first dialysis treatment, markedly elevated blood urea concentration, chronic kidney disease, severe metabolic acidosis, older age, any condition that increases permeability of the blood brain barrier (such as sepsis, vasculitis, thrombotic thrombocytopenic purpura-hemolytic uremic syndrome or meningitis). Our patient had known kidney disease, sepsis. His BUN level dropped from 246 to 124 within 12 h after one dialysis session. He was intubated, that delayed recognition of his neurological status. Management of suspected DDS aims mainly to reduce the intracranial pressure of the patient. Standard maneuvers are to give mannitol or hypertonic saline to raise the blood osmolality and to hyperventilate the patient; however, these measures may be futile. The corner stone in the management is the prevention. The most important preventive measure is to limit the reduction in BUN per treatment so that there is a gradual reduction that is distributed over several days. Slow urea removal can be achieved by low blood flow rate of 150 to 250 mL/min with a small surface area dialyzer (0.9 to 1.2 m²), patients who have marked fluid overload can be treated with ultrafiltration. Patients with extremely elevated BUN or neurologic symptoms, dialysis should be initiated as an inpatient. Conclusion: Dialysis disequilibrium syndrome is a disease that can result from rapid drop in BUN in patient on dialysis especially during the first session, resulting in neurological manifestation range from nausea to herniation and death. The main cornerstone in the management is prevention by slow urea removal and early detection.

DIFFUSE CEREBRITIS IN ALCOHOL WITHDRAWAL AND MENINGITIS: NO ROOM FOR DIAGNOSTIC DELAY Poojita Shivamurthy; Sparsha Kukunoor. University of Connecticut Health Center, Farmington, CT. (*Tracking ID #1933996*)

LEARNING OBJECTIVE 1: Suspect meningitis early in patients with altered mental status in setting of alcohol withdrawal to prevent fatal complications.

LEARNING OBJECTIVE 2: Recognize infrequent complications of Pneumococcal meningitis including diffuse cerebritis and acute demyelinating encephalomyelitis (ADEM).

CASE: Fifty four year old male with alcohol abuse was brought to the hospital by friends for poor intake and not being himself for 2 days. His medical history was significant for heavy alcohol abuse. He drank a gallon of vodka and snorted heroin daily. He took no medications, lived alone and was unemployed. Limited review of systems was positive for headache, negative for fall, fever, cough and diarrhea. At arrival, he was afebrile, tachycardic to 120 beats per minute with blood pressure 160/90 mmHg and normal respiration. He was disheveled, agitated with an unsteady gait with poor oral hygiene. He had bilateral rhonchi on lung exam, normal intensity heart sounds, soft non tender abdomen without organomegaly. Neurological exam was non focal. Lab data showed hyponatremia (128 meq/L), hypochloremia (86 meq/L) with creatinine. His neutrophil count was 6400 per microL. Hemoglobin of 10 g/dL with platelet count of 282,000 per microL. Alcohol level was 33 mg/dL, urine positive for opiates and cannabis. Head CT was suggestive of mild nonobstructive hydrocephalus. Chest Xray showed patchy left lower lobe consolidation for which Vancomycin was given in the ER. He was diagnosed with alcohol withdrawal, received Ativan following which he got intubated for airway protection. In ICU, he was sedated with propofol. Blood cultures grew Streptococcal pneumonia which was thought to be secondary to pneumonia. To investigate quick deterioration in mental status, lumbar

puncture was done in the ICU. CSF was turbid with WBC 1685 per microL, elevated protein at 625 mg/dl, and a strikingly low CSF glucose of 2 mg/dl growing streptococcal pneumoniae. He was immediately started on high dose of ceftriaxone, and dexamethasone but more than 15 h had elapsed prior to this. Transesophageal echocardiogram did not show vegetations. He remained hemodynamically stable. Following day, during sedation holiday, patient was unresponsive with GCS of 3, flaccid quadriplegia and absent deep tendon reflexes. Immediate head CT showed diffuse supratentorial white matter hypoattenuation and loss of gray-white differentiation in bilateral parietal lobes and cerebellum suggestive of extensive multifocal acute infarcts with superimposed cerebritis. There was a small suspicion ADEM based on intensity of demyelination. Hence, patient was given high dose prednisone (1 g daily for 5 days) while antibiotics were continued. Repeat MRA showed slight improvement in degree of restricted diffusion in the white matter but progression of cerebritis. Due to poor prognosis, family wished to focus on comfort. Patient expired 4 days after.

DISCUSSION: It is crucial to broaden our differential for altered mental status in alcohol withdrawal. Unrecognized sepsis or meningitis is detrimental. There was a delay in recognizing meningitis and hence in starting antibiotics and steroids (ideally within 4 h). This gives us opportunity to review literature on cerebritis and ADEM in meningitis. Cerebritis is a result of cerebral vascular involvement from infection or inflammation which causes altered mental status or focal deficits if infarcts occur. High clinical suspicion, contrast MRI are the diagnostic methods. Altered mental status in pneumococcal meningitis is an independent predictor of in-hospital mortality and neurological deficits¹. It could be due to persistence of biologically active agents in killed bacteria which incite host inflammatory response. While early diagnosis of meningitis may prevent these complications, it is unknown if early diagnosis of cerebritis in timely treated meningitis has better prognosis. A case report with cerebritis from Klebsiella pneumonia in an alcoholic cites an animal study where alcoholic hosts were more susceptible due to lack of cytokine IL-7 response.² Post infectious ADEM is a rare differential for cerebritis when there is intense demyelination.³ It occurs within few weeks of an infective process. T2-weighted images, FLAIR sequences, and contrast-enhanced MRI with gadolinium are preferred tests. High dose steroids is the treatment of choice. Time frame and no response to steroids goes against ADEM in our patient. References: 1. Pfister HW, Feiden W, Einhaupl KM. DIFFUSE MESENTERIC VENOUS THROMBOSIS RESULTING IN BOWEL ISCHEMIA AND OBSTRUCTION WITH NORMAL LACTATE LEVELS

Yevgeniy Mikityanskiy: Gary Carpenter; Farah Daccueil; Evan Schloss; Nicholas Barbari; James Gardner. Winthrop University Hospital, Mineola, NY. (*Tracking ID #1937639*)

LEARNING OBJECTIVE 1: To reinforce the importance of a trusting physical exam findings, maintaining a broad differential diagnosis and constantly reevaluating the approach to treatment if the patient's condition is not improving despite appropriate therapy.

LEARNING OBJECTIVE 2: To emphasize that sensitive laboratory studies may still be normal in atypical presentations of certain disease processes.

CASE: A 36 year-old male with no past medical or surgical history presented with 2 weeks of abdominal pain and constipation. He was initially evaluated at another emergency department with an abdominal CT scan and ultrasound, both of which were negative. The patient traveled to Florida where the pain worsened again and became accompanied by nausea and vomiting. On arrival to our hospital, the patient was hypertensive with an abdominal exam positive for hypoactive bowel sounds, voluntary guarding, diffuse tenderness to palpation, but no rebound or rigidity. Laboratory work up revealed leukocytosis, elevated INR, ESR and CRP, but normal liver related tests as well as a normal lactate level. Abdominal x-ray showed relative obstruction of emptying of all contrast from the stomach and duodenum. CT of the abdomen revealed duodenal wall thickening, marked wall thickening and edema of several jejunal loops in the left upper quadrant with associated mesenteric edema. The findings were consistent with enteritis. The patient was treated aggressively with intravenous fluids, broad spectrum antibiotics and pain control. However, his condition worsened daily with increasing leukocytosis, worsening abdominal pain despite high doses of opioids as well as profound tachycardia. Serum lactate measurements remained normal. The patient developed feculent vomiting, abdominal rigidity and rebound tenderness. A nasogastric tube was inserted for small bowel obstruction, which was confirmed by abdominal x-ray. The initial abdominal CT was reevaluated as showing

extensive thrombus in the portal vein, superior mesenteric vein and splenic vein. Stat abdominal MR showed ischemia and necrosis involving proximal jejunal loops with presumed secondary thrombosis of several mesenteric veins. Emergent exploratory laparotomy with 60 cm jejunal resection revealed loops of jejunum with a sharp demarcation between necrotic and healthy bowel without any obvious anatomical etiology. Post-operatively, full dose low molecular weight heparin was initiated and the patient showed significant clinical improvement. Abdominal CT angiography showed patent mesenteric arterial system. Hypercoagulable workup revealed heterozygosity for factor V leiden gene mutation and prothrombin G20210A mutation suggesting that mesenteric venous thrombosis was, in fact, the primary event.

DISCUSSION: Mesenteric ischemia is typically arterial in etiology in patients with known risk factors. It is described as pain out of proportion to physical exam findings and elevated serum lactate is a rather sensitive marker used to aid in making the diagnosis. The pathophysiology of intestinal ischemia caused by venous thrombosis involves increased resistance in mesenteric venous blood flow causing profound bowel wall edema, fluid efflux into bowel lumen resulting in systemic hypotension, increase in blood viscosity leading to decreased arterial flow, submucosal hemorrhage and ultimately bowel infarction. This case of hereditary hypercoagulability induced mesenteric venous thrombosis with subsequent bowel ischemia and necrosis is unusual since most causes of bowel ischemia are indeed arterial in origin. Additionally, persistently normal lactate levels in the setting of severe bowel necrosis proved to be an uncommon as well as misleading phenomenon. This case also serves to reinforce the importance of trusting the physical exam, even if it does not perfectly correlate with pertinent laboratory and imaging findings, as well as maintaining a broad differential diagnosis if the patient's condition is not improving despite seemingly appropriate medical treatment.

DIRE DIARRHEA: IPILIMUMAB INDUCED COLITIS AND ITS MANAGEMENT

Youran Gao; Saumya Sharma; Rubina Boparai. Northshore-LIJ, Manhasset, NY. (*Tracking ID #1899684*)

LEARNING OBJECTIVE 1: Increase early detection of colitis in patients who present with diarrhea and abdominal while on ipilimumab for melanoma treatment.

LEARNING OBJECTIVE 2: Recognize the treatment options for ipilimumab induced colitis.

CASE: Case 1: A 49-year-old woman with metastatic melanoma developed abdominal pain 1 day after initial dose of ipilimumab at 3 mg/kg. After second dose she also developed small volume watery diarrhea occurring 3–4 times daily. She was started on oral prednisone 40 mg taper for 1 week. Within the week, patient's diarrhea worsened to 5–6 per day, and she was admitted to the hospital. A colonoscopy was performed which showed pancolitis with diffuse erythema and edema. Methylprednisolone 60 mg IV q8 h was started and patient's symptoms improved within 24 h. Patient was discharged home on oral prednisone 60 mg taper with complete resolution of symptoms within 1 week. Case 2: A 86-year-old man with metastatic melanoma presented with 3 day history of non-bloody diarrhea without abdominal pain. Two weeks prior, patient received second infusion of Ipilimumab at 3 mg/kg for the treatment of metastatic melanoma. CT scan of abdomen showed diffuse colonic wall thickening with pericolonic fat stranding suggesting pancolitis. Clostridium difficile testing was found to be negative and treatment with high dose IV steroids was started. Response to steroid use was suboptimal and patient continued to have diarrhea. Initiation of Infliximab as an alternate treatment was considered however not initiated due to patient's poor cardiac function (EF 20%). IV steroid treatment was continued and patient began to show improvement. He was discharged with slow oral prednisone taper with complete resolution of diarrhea within 2 weeks.

DISCUSSION: Ipilimumab, a monoclonal antibody to cytotoxic T-Lymphocyte antigen 4 (CTLA-4), is used for the treatment of metastatic melanoma. Inhibition of CTLA-4 results in activation of T cells which proliferate and infiltrate into tumors causing tumor cell death. However, this same mechanism also leads to increased immune activity against normal cells which is the underlying cause of side-effects associated with ipilimumab. The most commonly seen adverse event is colitis but skin, liver, and endocrine organs can also be affected. Steroids are usually used first but Infliximab can be used as second line. As in case 2, many patients may have contraindications to infliximab therapy. Both of these patients had colitis after 2 treatments of ipilimumab and both were successfully treated with high dose IV steroids. Case 1 had a faster and more sustained response to steroids mostly because of her age and lack of other comorbidities. In both instances, further treatment with ipilimumab was aborted because the risk of complications from recurrent colitis outweighed the benefits.

DISSEMINATED HISTOPLASMOSIS PRESENTING WITH PANCYTOPENIA IN AN AIDS PATIENT

Ribka Ayana^{1,2}; Katherine C. Chretien^{1,2}; Suzanne Sweidan¹. ¹George Washington University Hospital, Washington, DC, DC; ²DC VA Medical Center, Washington, DC, DC. (*Tracking ID #1939247*)

LEARNING OBJECTIVE 1: Recognize clinical features of disseminated histoplasmosis

LEARNING OBJECTIVE 2: Adopt a cost-conscious approach to diagnosis of disseminated histoplasmosis

CASE: A 38 year-old man presented with 5 days history of fevers and shortness of breath. He also noted 30 lb weight loss, malaise, headache, gingival bleeding, and dark urine. He was diagnosed with HIV 10 years prior, but he was treatment naïve, followed by holistic doctors who treated him with various unknown herbal medications. The patient was chronically-ill appearing. He had scleral icterus and multiple, small, shallow, ulcers with a clean base. Lung exam revealed diminished breath sounds diffusely and crackles at the bases. Complete blood count revealed pancytopenia with white blood cell count of 1,850, hemoglobin of 5.4 g/dL, platelet count of 18,000 and a CD4 count of 0. His hepatic panel was notable for an albumin of 1.8, total bilirubin of 2.7, aspartate aminotransferase of 479, alanine aminotransferase of 104 and alkaline phosphatase of 141. Ferritin level was greater than 10,000 ng/mL. Lactate dehydrogenase was 7,108 with haptoglobin of less than 20 suggesting a hemolytic process. A thoracic CT scan revealed scattered tree bud opacity and bilateral pleural effusions, splenomegaly, and bulky necrotic left axillary lymphadenopathy. On admission, he was empirically started on moxifloxacin to cover for possible community-acquired pneumonia and sulfamethoxazole/trimethoprim for possible pneumocystis pneumonia. Fluconazole was added for oral candidiasis. Further diagnostic studies were negative including hepatitis panel, serum RPR, stool AFB, quanteferon, serum cryptococcal antigen, and head CT scan. On the fourth day of hospitalization, he was transferred to the intensive care unit (ICU) with septic shock and disseminated intravascular coagulation. Clarithromycin, ethambutol and rifabutin were begun for empiric mycobacterium avium-intracellulare (MAI) infection treatment. The next day, a bone marrow biopsy was preformed and the aspirate smear as well as the core biopsy revealed histiocytes containing numerous intracellular yeast forms morphologically consistent with Histoplasma. Following the diagnosis of disseminated histoplasmosis, Ambisome was started at a dose of 5 mg/kg daily.

DISCUSSION: Although opportunistic infections are not seen as commonly in the post antiretroviral era, internists need to be adept at recognizing and diagnosing these infections as timely diagnosis and initiation of early, appropriate, therapy is critical for good patient outcome. It has been well-established that patients with AIDS have increased incidence of both AIDS defining and non-AIDS defining malignancies. Thus, when hematologic abnormalities are seen, concern for malignancy is warranted. Nonetheless, it is also important to consider infiltrative infectious processes when AIDS patients present with cytopenia. Disseminated histoplasmosis is an uncommon, potentially fatal, but treatable infection seen in immunocompromised patients such as those with advanced AIDS and CD4 lymphocyte count less than 100 cells/microL. While disseminated histoplasmosis is a well-recognized complication of AIDS, fortunately, it is fairly uncommon in the post antiretroviral era, which can lead to potential delayed or missed diagnosis. This patient presented with many of the clinical and laboratory features seen in disseminated histoplasmosis including fever, fatigue, night sweats, splenomegaly, cytopenia, elevated ferritin and liver enzymes. Failure to recognize the diagnosis in this patient led to unnecessary studies and delay in initiation of the appropriate therapy. In AIDS patients with disseminated disease, histoplasma antigen detection is the most sensitive and specific test. In this case, a urine histoplasma antigen test could have led to an earlier diagnosis and prevented complications as well as more costly, and more invasive studies.

DISSEMINATED MYCOBACTERIUM AVIUM COMPLEX INFECTION AS A CAUSE OF TREATABLE DEMENTIA *Hirotaka Kato; Matthew Harrington. Beth Israel Medical Center, New York, NY. (Tracking ID #1935439)*

LEARNING OBJECTIVE 1: Recognize disseminated mycobacterium avium complex infection as an etiology of reversible dementia in AIDS patients.

LEARNING OBJECTIVE 2: Recognize the risk of early diagnostic closure in AIDS patients given concomitant infections can exist.

CASE: A 58 year-old male with recently diagnosed HIV presented with altered mental status in setting of 6 months progressive cognitive decline, visual hallucinations and paranoia. Patient reported subjective fevers, night sweats, weight loss, and diffuse pruritic nodular rash. On presentation, the patient was somnolent, afebrile. Neurologic exam revealed emotional lability, absent focal deficits or meningeal signs. The following laboratory tests were normal, including electrolytes, TSH, B12, folate, RPR/FTA-ABS, urinalysis, urine toxicology, and CSF studies. Toxoplasma, cryptococcus, and JC Virus serologies were also negative. HIV vial load was 1.2 million copies/mL, CD4 count was 2 cells/mL. MRI revealed diffuse white matter changes. Blood cultures detected *Staphylococcus aureus* (MSSA) in 1 of 4 initial cultures and 2 of 4 repeat cultures. The patient was treated with cefazolin for 6 weeks for presumed Infectious Endocarditis due to this persistent MSSA

bacteremia. Opportunistic infection prophylaxis initiated with azithromycin and trimethoprim/sulfamethoxazole, however, antiretroviral therapy was deferred due to the risk of immune reconstitution syndrome. His mental status remained labile with aggressiveness, which was considered as HIV-associated dementia. Patient was discharged on day 10. The patient presented 2 weeks later with fever and rigors. Infectious workup was unrevealing. AFB blood cultures from the initial hospitalization detected *mycobacterium avium* complex. Within 1 week after clarithromycin, ethambutol and rifampicin were initiated, the patient defervesced and mental status resolved to baseline.

DISCUSSION: Symptoms of disseminated *mycobacterium avium* complex infection (MAI) are non-specific, including fever, diarrhea, and weight loss, which precede the onset of fever. Since it takes about 10 days to detect *mycobacterium* from blood culture, early diagnosis and treatment are challenging. To our knowledge, there exists no case report documenting disseminated MAI presenting as progressive cognitive impairment. Furthermore, concomitant bacteremia with disseminated MAI has not been described in the literature. This patient had fever, night sweats, which were consistent with symptoms of MAI, however, the presence of MSSA bacteremia misled to early diagnostic closure in the first hospitalization. We initially considered HIV-associated dementia as the cause of his early dementia and planned to initiate HAART later due to the concern of immune reconstitution syndrome, however, his significant cognitive improvement after the initiation of disseminated MAI treatment strongly suggests disseminated MAI as the cause of his progressive cognitive decline. Physicians should be aware of disseminated MAI as an etiology of neurocognitive decline or altered mental status in AIDS patients. Also, acid-fast bacilli culture must be considered for any patient with AIDS or unknown CD4 count presenting with non-specific symptoms, even without fever.

DISSEMINATED PYOGENIC INFECTION CAUSED BY STREPTOCOCCUS ANGINOSUS THROUGH HEMATOGENOUS SPREAD VIA INFECTIOUS ENDOCARDITIS *Rie Ueno¹; Ayumi Maeda²; Misako Nagasaka¹; Wan L. Lam¹; Dennis Karter¹; David C. Perlman¹. ¹Beth Israel Medical Center, New York, New York, NY; ²Massachusetts General Hospital, Boston, MA. (Tracking ID #1934424)*

LEARNING OBJECTIVE 1: Identify *Streptococcus anginosus* as one of the causes of infectious endocarditis

LEARNING OBJECTIVE 2: Recognize the importance of early detection of brain abscess during *Streptococcus anginosus* bacteraemia

CASE: A 57 year-old female with a history of a perianal abscess presented with fevers and chills for 7 days. Two weeks prior the abscess had drained spontaneously. On admission, temperature 100.9 °F, BP 104/70, HR 112/min, and RR 15/min. Physical exam demonstrated mild right upper quadrant tenderness and a 1–2 mm well healed scar in 6 o'clock position of her anus. Labs showed WBC 15.7/mL with 88 % PMNs, ALP 202 U/mL, T bil 1.5 mg/dL, ALT 70 U/L, AST 145 U/L. Abdominal CT scan showed a 11.4×9×14 cm lobulated collection in the right hepatic lobe with satellite abscess measuring 2.4×2.2×1.8 cm in the left lobe. The patient received piperacillin/tazobactam 3.375 g IV q6 and underwent percutaneous drainage of the larger abscess. Cultures of the aspirate and 1 out of 2 sets of blood cultures grew *Streptococcus anginosus*. Antibiotics were changed to ceftriaxone 2 g q24 and metronidazole IV 0.5 g q8. Transthoracic echocardiogram was negative for vegetation and subsequent blood culture was negative. She was discharged on the same antibiotic regimen but presented 1 week later with memory deficits. Head CT and brain MRI showed more than 10 ring-enhancing brain lesions measuring 0.3–1.7 cm in the bilateral cerebral and cerebellar hemispheres, most prominently adjacent to the left ventricle with associated edema. Transesophageal echocardiogram (TEE) showed 0.7 cm vegetation on the aortic valve with a trace aortic regurgitation. Ceftriaxone was increased to 2 g q12. Repeat TEE 1 week later showed disappearance of the vegetation. Her symptoms improved and she was discharged with ceftriaxone IV 2 g q12. Head and Abdominal CT scans at 4 weeks of therapy showed interval resolution of the brain lesions and the liver abscesses.

DISCUSSION: The *Streptococcus anginosus* group (SAG), also known as the *Streptococcus milleri* group is a subgroup of viridans streptococci that consists of three distinct streptococcal species: *S. anginosus*, *S. intermedius*, and *S. constellatus*. Compared to other viridans streptococci, members of the SAG are more often associated with abscess formation, including liver and brain abscess through their cell surface adhesions and pyogenic exotoxins but less often associated with infectious endocarditis. When endocarditis does occur, it is more common in patients with damaged or prosthetic heart valves than patients with normal native valves. A 2012 literature review identified 12 cases of disseminated pyogenic infection affecting multiple (2 or more) organs, caused by SAG, but none was accompanied with endocarditis. Our case describes a rare instance of liver and brain abscesses in the setting of infectious endocarditis by SAG. It is important to

recognize SAG as one of the causes of native valve infectious endocarditis and to search for signs of dissemination to other organs. Brain abscess should be considered in any patient with SAG bacteremia who presents with cognitive deficits. Also our case suggests the importance of performing TEE to evaluate for endocarditis for patients with SAG bacteremia.

DISSEMINATED TOXOCARIASIS IN AN IMMUNOCOMPETENT HOST

Paras Karmacharya¹; Madan R. Aryal¹; Ranjan Pathak¹; Smith Giri⁴; Amrit Pokharel³; Pragya Shrestha²; Supriya Shrestha Tamrakar³; Richard Alweis¹. ¹Reading Health System, West Reading, PA; ²Nanjing Medical University, Nanjing, China; ³Guangxi Medical University, Guangxi, China; ⁴University of Tennessee Health Science Center, Tennessee, TN; ⁵Tribhuvan University Teaching Hospital, Kathmandu, Nepal. (*Tracking ID #1935244*)

LEARNING OBJECTIVE 1: Consider toxocariasis as a differential diagnosis in patients with persistent hypereosinophilia. Look for a history of exposure to dogs and cats in patients with multiple non-cavitating pulmonary and hepatic infiltrates and perform toxocara serology if present.

LEARNING OBJECTIVE 2: Treat promptly with albendazole or mebendazole with concomitant corticosteroid.

CASE: A 36 year-old-male presented with low grade fever, fatigue, and intermittent right upper quadrant abdominal pain for 1 week. Associated symptoms included nausea with 5 episodes of non-bilious vomiting and nonproductive cough. He lived in an apartment with 6 dogs and a kitten. On physical examination, he was afebrile with mild right upper quadrant tenderness. Labs included a white cell count 17,400/mm³ (eosinophils 18 %, absolute eosinophil count 3,220), and normal liver function tests. Serum immunoglobulin (Ig) E levels were 5564 U/ml; IgA, G and M as well as complement levels (CH50) were within normal limits. Flow cytometry did not reveal abnormal cell population. Additional tests, including antinuclear antibody, anti-neutrophil cytoplasmic antibody, stool examination for ova and parasites, serologies for HIV, hepatitis B and C, Aspergillus fumigatus, Trichinella spiralis, Histoplasma capsulatum, Toxoplasma gondii, Strongyloides stercoralis and quantiferon test were all negative. His serum toxocara Ig M antibody levels on ELISA was 3.19 (normal <1). Chest radiograph revealed bilateral scattered small ill-defined nodules bilaterally. Contrast enhanced CT scan of the chest and abdomen revealed ill-defined pulmonary nodules and multiple hypodense lesions in the liver. CT scan of the brain was unremarkable. Gram stain, acid fast stain and bacterial/fungal cultures of bronchial washings and endobronchial biopsy were negative. Urine and blood cultures were negative. He was treated with mebendazole 200 mg twice daily for 5 days for disseminated toxocariasis. Concomitant prednisone was started at 1 mg/kg/day and tapered over the next 2 months.

DISCUSSION: Toxocariasis is a human infiltrative larval infection caused by the dog ascarid, *Toxocara canis* and the cat ascarid, *Toxocara cati*). While it is more common in the tropical regions of the world; it is estimated that human seroprevalence is 13.9 % in the United States (2) and that about 5 % of dogs and puppies in North America are infected (3). It commonly affects the pediatric and immunocompromised population; and rare in the immunocompetent. Most human infections are asymptomatic. Two of the well-recognized syndromes especially in children are visceral larva migrans and ocular larva migrans. Diagnosis is established on the basis of marked eosinophilia and presence of specific serum toxocara antibodies in the right clinical setting. Serum eosinophil levels may be used to assess therapeutic response. Mild forms of toxocariasis are self-limited and do not require anti-helminthic therapy; severe or persistent infections, such as in our case, can be treated with mebendazole and albendazole (4). Concomitant corticosteroids limit the inflammatory response. References: 1. Nicoletti A. Toxocariasis. *Handb Clin Neurol*. 2013;114:217-28. 2. Won KY, Kruszon-Moran D, Schantz PM, Jones JL. DO NOT LET THE MOMENTUM TAKE YOU Reza Sedighi Manesh; Jeff Kohlweis; Jeffrey Dixson. UCSF, San Francisco, CA. (*Tracking ID #1940211*)

LEARNING OBJECTIVE 1: Apply Bayes' theorem to improve diagnostic accuracy

LEARNING OBJECTIVE 2: Recognize diagnostic momentum to reduce diagnostic error

CASE: 67 y/o Japanese American who has been out of care for 15 years is brought to the emergency department by his brother with painless jaundice for

3 weeks. For 2-3 weeks prior to presentation, pt noted yellow eyes and skin, white stool, fatigue, and severe pruritis that was interfering with sleep. He denied abdominal pain, fevers, chills, diarrhea, nausea or vomiting but did note 15-20 lb unintentional weight loss over the last 1-2 months. He has had a good appetite without dysphagia or odynophagia, melena, or BRBPR. Past medical history was notable only for a remote stab wound in his LUQ from a disgruntled mistress for which he underwent laparotomy without bowel resection at another institution. He takes no medications and has no allergies. By social history he is a Vietnam vet, lives with his ex-wife and owns a video store. He previously drank 10-12 beers daily, but has cut back to 1-2 daily. He has a 50 pack year smoking history and used marijuana in the service, but otherwise denies any illicit drug use. Family history was negative for malignancy or liver disease. Exam was notable for normal vital signs, marked jaundice, a large surgical scar on his abdomen, and multiple excoriations over his abdomen consistent with his history of pruritis. He had no stigmata of chronic liver disease, no appreciable organomegaly, and no asterixis, but did have a possible fluid wave detected. Labs were notable for a predominantly direct hyperbilirubinemia with intact synthetic function. AFP and viral hepatitis serologies returned negative. CT abdomen pelvis with contrast showed marked intrahepatic and extrahepatic biliary dilation. An ampullary lesion could not be entirely excluded. EUS revealed a 2.3×2.8 cm mass in the uncinate process of the pancreas without vascular invasion, which was sampled by FNA. ERCP was performed and revealed a single, localized, 1 cm stenosis of the common bile duct that was successfully stented. FNA biopsy results returned "abundant benign pancreatic elements". He was seen in general surgery pre-op clinic where all imaging, pathology, and laboratory results were thoroughly reviewed. A pylorus-preserving Whipple resection was performed. The surgical pathology report returned and showed duct-centered lymphoplasmacytic inflammation, ductitis, fibrosis, and phlebitis with more than 100 IgG4 plasma cells per high power field, consistent with autoimmune pancreatitis type I, or IgG4-related sclerosing pancreatitis and cholangitis.

DISCUSSION: Diagnostic momentum is the conveyance of an initial working diagnosis from one team to another without adequate consideration of alternative possibilities. In this case the diagnostic momentum was initiated by the medicine service and subsequently accepted by the consulting services. The diagnosis of pancreatic adenocarcinoma, resulting in a potentially morbid procedure (i.e., pancreaticoduodenectomy), should have been seriously questioned with the benign pathology of EUS-guided biopsy. In medicine Bayes' theorem, the act of refining the probability of a specific diagnosis with new information, can both improve diagnostic accuracy and reduce diagnostic errors due to diagnostic momentum. A method to determine how a single test or series of tests influences the posttest probability of a diagnosis, one can follow 4 steps introduced by Friedland et al. (REF 1). (1): Develop a differential diagnosis; (2): Determine the pre-test probability (i.e., in term of percentages from 0 to 100) of a particular diagnosis. The pretest probability is determined by personal experience and published data (i.e., use prevalence data for clinical symptoms and signs). (3) Convert diagnostic test information into likelihood ratios (LR) using sensitivity and specificity. If a test is positive, then the positive LR should be calculated. If the test is negative, then a negative LR should be calculated. (4) Using a nomogram or simple math to combine pretest probability and likelihood ratios to arrive at the final posttest probability of disease. In this case the tests completed to evaluate for pancreatic cancer (MRCP, CT-abd, EUS-guided biopsy, CA19-9) resulted in the posttest probability of pancreatic cancer decreasing from 50 to 11 %. If the clinicians had applied Bayes' theorem, it is conceivable they would have paused and considered alternative diagnoses (e.g., type 1 autoimmune pancreatitis) prior to performing a pancreaticoduodenectomy.

DON'T BATHE IN THE CREEK Uchechukwu Obih; Thomas Montgomery. Carolinas Medical Center, Charlotte, NC. (*Tracking ID #1926361*)

LEARNING OBJECTIVE 1: Recognize the importance of obtaining a thorough social history

LEARNING OBJECTIVE 2: Identify one cause of water-borne illness

CASE: The patient is a 59 year old man who presents to the emergency department with complaints of chest pain, dyspnea, and chills. He also presents with a new swelling above his right eye. His past medical history is notable only for hypertension. His exam shows normal vital signs, an area of erythematous, fluctuant swelling above his right eye. Laboratory data is notable for an elevated white blood cell count of 17.6 g/dL and creatinine of 1.31 mg/dL. CT angiography of the chest reveals bibasilar consolidation, extensive bilateral hilar and mediastinal lymphadenopathy, and bilateral lung nodules. The patient leaves against medical advice only to return the next day with sepsis, with hypotension and tachypnea, and an elevated lactic acid of 5 mmol/L. He is placed on broad spectrum antibiotics but continues to

decompensate. He develops multi-organ system failure affecting the kidneys, septic emboli to the liver, and septic emboli to the lungs, requiring ventilator support and pressors. Incision and drainage of his right eye abscess reveals Yersinia enterocolitica. Blood cultures also grow Yersinia enterocolitica. His antibiotics are switched to Ceftriaxone. Further exploration of the patient's social history reveals that he lives downstream from a pig farm in rural North Carolina, nearby a creek in which he frequently bathed. He is treated with 3 weeks of Ceftriaxone 2 g daily. He requires tracheostomy for prolonged ventilatory requirements and hemodialysis is initiated secondary to renal failure.

DISCUSSION: Obtaining a thorough social history of environmental and dietary exposure to pigs is essential in the diagnosis of Yersinia enterocolitica given the nature of this bacterium. Yersinia enterocolitica, is a gram-negative coccobacilli frequently colonized in the oropharyngeal lymphoid tissues of pigs. It is transferred by consumption of undercooked pork and, on rare occasion, through untreated water. Incidence of Yersinia in North America is approximately 1000 cases per year, of which incidence is highest in children, often manifesting as a diarrheal illness. Infection occurs by bacterial attachment to gut epithelial walls or by the release of pore-forming toxins. A method of bacterial virulence also includes the release of proteins to avoid host cell mediated immune response. Very rarely does Yersinia cause septicemia, making this case exceptional. Yersinia growth can be overlooked given its colorless appearance on routine culture mediums. Diagnosis is obtained from lymphoid tissue, stool, or blood cultures. Treatment for septic patients includes ceftriaxone 2 g daily.

DON'T GO BREAKIN' MY HEART: ACUTE STREPTOCOCCAL INFECTION CAUSING MYOPERICARDITIS Sara Jane Cromer; Priti Dangayach; Courtney N. Miller-Chism. Baylor College of Medicine, Houston, TX. (*Tracking ID #1927210*)

LEARNING OBJECTIVE 1: Diagnose acute streptococcal infection in the setting of a negative rapid strep test

LEARNING OBJECTIVE 2: Recognize that streptococcal infection can be complicated by myopericarditis which may mimic acute coronary syndrome (ACS)

CASE: A 20-year old African-American male with past medical history of hypertension and asthma presented with severe chest pain described as "the grim reaper sticking his scythe in my chest" in the setting of a several day history of sore throat, fever, chills, myalgias, and back pain. He denied a cough. His temperature was 100 °F, and he was hypertensive (160/93), tachycardic (120 beats/min), and tachypneic (24 breaths/min) with an O₂ saturation of 99 % on room air. On exam, he was diaphoretic and had dry mucous membranes, tender anterior cervical lymphadenopathy, and erythema of the oropharynx. Initial labs were remarkable for white blood cell count of 24,600 cells/µL, with ESR of 77 mm/h and CRP of 30.2 mg/dL. His troponin on presentation was 0.487 ng/mL. Monospot, HIV, and rapid strep screening tests were all negative. Imaging included a normal chest X-ray. His initial EKG was normal. On hospital day #2, he again complained of severe chest pain, and a repeat EKG showed ST elevation in leads I, II, aVL, and V4-V6. His troponin peaked at 2.69 ng/mL, with total CK of 2,641 u/L and CKMB of 2.2 ng/mL. A transthoracic echocardiogram showed a normal ejection fraction and no wall motion abnormalities. A cardiac catheterization was performed, which revealed no obstructive culprit lesions. Treatment for myopericarditis was initiated with high-dose ibuprofen and the patient improved clinically, with resolution of chest pain and cardiac enzyme elevation, and normalization of his EKG. A throat culture returned β-hemolytic Group A Streptococcus on hospital day #4, and he was discharged in stable condition to complete a course of penicillin.

DISCUSSION: Group A Streptococcus is a common cause of bacterial pharyngitis. The Centor Score for predicting streptococcal pharyngitis based on clinical symptoms can aid in decision making. When the clinical suspicion is high for streptococcal infection, a throat culture (sensitivity 90–95 %) or PCR-based test should be performed as rapid antigen detection tests for streptococcal organisms have limited sensitivity (70–90 %, depending on technique). Throat culture is the gold standard for diagnosing acute streptococcal pharyngitis. Acute non-rheumatic streptococcal myocarditis has been reported to mimic ACS in young patients presenting with chest pain that have troponinemia and ST elevation. Descriptive studies have demonstrated that over 95 % of cases of myopericarditis in the setting of streptococcal pharyngitis or tonsillitis occur in young males (average age 28.6), and almost all present with chest pain, diffuse ST segment elevation, and elevated CK, CKMB, and troponin. Many of these patients (up to 67 % in one study) underwent cardiac catheterization despite their young age and very few risk factors. In the setting of an acute infection in a young patient, it is important to recognize myopericarditis in order to avoid

unnecessary invasive testing. While ACS should always be on the differential diagnosis in a patient presenting with chest pain, it is important to recognize myopericarditis as a potential cause of chest pain in a young person with acute streptococcal infection.

DOWN IN THE DUMPS: SELECTIVE SEROTONIN REUPTAKE INHIBITORS AS A CAUSE OF DIARRHEA Talia Kahn; Ryan Laponis. UCSF, San Francisco, CA. (*Tracking ID #1936899*)

LEARNING OBJECTIVE 1: Recognize selective serotonin reuptake inhibitors as a cause of chronic, non-inflammatory diarrhea

CASE: A 64 year-old man with a history of Crohn's disease and severe major depression presented with 6 months of chronic, watery, non-bloody diarrhea. He described four to six watery bowel movements per day. He denied bloating, abdominal pain, fevers, chills, night sweats, weight loss, bowel movements at night, recent travel, camping, antibiotic use, or association with foods such as dairy or grains. Medications included adalimumab, aripiprazole, mirtazapine, and sertraline. His vitals as well as his abdominal, skin and rectal exams were unremarkable. A basic metabolic panel, TSH, liver function, and tissue transglutaminase were normal. Additionally, bacterial culture, clostridium difficile, and ova and parasite, including specific testing for cryptosporidium and cyclospora, exams were negative. Furthermore, elimination of lactose from his diet resulted in no improvement. Colonoscopy revealed minimal to quiescent colitis in the cecum and colon. Given this, a plan was made to check fecal fat and white blood cells, stool potassium and sodium, trial him on treatment for bacterial overgrowth, and possibly examine the small bowel by MR enterography. He returned, however, to clinic indicating that his psychiatrist had changed his sertraline to bedtime dosing, leading to resolution of his symptoms.

DISCUSSION: Our patient's known diagnosis of Crohn's disease and concomitant immunosuppression led to an extensive work-up of his chronic diarrhea and we overlooked a common cause of chronic, non-inflammatory diarrhea: medications. Over 700 drugs can cause diarrhea and this side effect can appear long after the initiation of the drug, leading to a delay in recognition. With respect to selective serotonin reuptake inhibitors (SSRIs), studies have shown that serotonin initiates peristaltic and secretory reflexes in the gut and potentiation of serotonergic signaling by inhibition of the serotonin reuptake transporter contributes to increased stool water and motility. Since SSRIs prolong the availability of physiologically released serotonin in both the central nervous system and gut, these medications can lead to the watery diarrhea described by this patient. Given that inflammatory bowel disease is often co-morbid with depression, SSRIs should not be overlooked in these patients as a cause of chronic, watery diarrhea even months after drug initiation.

DRESSED IN DISGUISE Jeffrey M. Kroopnick^{1,2}; Rosemarie Conigliaro^{1,2}.

¹Montefiore Medical Center, Bronx, NY; ²Albert Einstein College of Medicine, Bronx, NY. (*Tracking ID #1936772*)

LEARNING OBJECTIVE 1: Recognize the clinical and laboratory presentation of Drug Reaction with Eosinophilia and Systemic Symptoms (DRESS Syndrome)

LEARNING OBJECTIVE 2: Identify factors that may play a role in the pathogenesis of DRESS

CASE: A 27-year old woman presents with one-day duration of rash and fever. She described the rash as red, pruritic, and burning. She also noted a flushing sensation and tingling throughout her body. Exam revealed fever of 102.5 °F; a non-vesicular erythematous rash with coalescing macules and papules on the face, neck, chest, abdomen, groin, and legs; a quarter-sized scar on her right lateral calf was also noted. She had facial swelling and cervical lymphadenopathy. Aspartate aminotransferase (AST) was 382 U/L and Alanine aminotransferase (ALT) 738 U/L; white blood cell count peaked at 26.7 k/uL with a maximum of 20 % eosinophilia and 12 % atypical lymphocytes. Skin biopsy revealed spongiosis and lichenoid dermatitis with eosinophils consistent with a drug eruption. Medication reconciliation disclosed that she had been receiving vancomycin infusions for two and a half weeks for a methicillin-resistant Staphylococcus aureus (MRSA) brain abscess and pulmonic valve vegetation diagnosed during a recent hospitalization. Her constellation of symptoms and laboratory findings were concerning for Drug Reaction with Eosinophilia and Systemic Symptoms (DRESS) with vancomycin as the likely culprit. Once this medication was discontinued, her rash improved, AST decreased to 60, ALT to 318, eosinophilia resolved (0 %), and atypical lymphocytes declined to 4 % post-discharge.

DISCUSSION: Rashes from medications are quite common; these may be benign, but sometimes more serious. DRESS has been estimated to occur in 1 in 1,000 to 1 in 10,000 drug exposures and carries a 10 % mortality rate, primarily from visceral organ involvement. It is typically characterized by a skin rash consisting of erythematous coalescing macules and papules without scale or vesicles, fever, eosinophilia or atypical

lymphocytes, lymphadenopathy, and internal organ involvement, usually the liver and less frequently, kidneys, lungs, and central nervous system. The RegiSCAR (European registry of Severe Cutaneous Adverse Reaction) is a scoring system to analyze cases of DRESS as 'no,' 'possible,' 'probable,' or 'definite' by assessing for these characteristics, in addition to time of resolution and ruling out other causes, such as infection, viral hepatitis, and vasculitic/rheumatologic etiologies. Our patient garnered 6 points, characterizing her as a 'definite' case. The most common offending agents in DRESS are anti-epileptic drugs such as phenytoin, carbamazepine, lamotrigine, and phenobarbital, and the xanthine oxidase inhibitor, allopurinol. While some antibiotics have been implicated in DRESS, there are only a few reported cases of vancomycin as the guilty agent. Interestingly, recent evidence suggests that viral replication, namely Human Herpes Virus (HHV)-6, and other herpes viruses may play a role in the pathogenesis of DRESS. It has been theorized that some of the inciting medications may elicit viral reactivation and a subsequent immune response. Unfortunately, there are no distinct clinical or laboratory entities to indicate when DRESS is life-threatening. Treatment typically consists of discontinuation of the implicated drug in addition to supportive care with topical steroids, emollients, anti-pyretics, adequate caloric intake, and correction of electrolyte and fluid abnormalities. In more extreme cases, systemic steroids may be necessary. DRESS is an important, and potentially fatal condition, that all physicians should recognize.

DUKE IT OUT: FINDING THE RIGHT DIAGNOSIS Farah Kaikow; Philip J. Putnam. Tulane University Health Sciences Center, New Orleans, LA. (*Tracking ID #1925935*)

LEARNING OBJECTIVE 1: Diagnose bacterial endocarditis in the absence of echocardiographic evidence of endocardial involvement.

CASE: A 42-year-old man presented with a two-day history of right hand pain and swelling, which began the day prior while injecting heroin into his hand. He had been awoken from sleep that morning by a sharp, left-sided chest pain that worsened with deep inspiration and was associated with shortness of breath. Temperature was 104.4 °F, heart rate was 122 beats per minute, blood pressure was 169/109, respirations were 22 breaths per minute, and oxygen saturation was 84 % on room air. Past medical history was significant for opiate abuse, hypertension, Type 2 diabetes, and previous trauma to the right hand with residual orthopedic hardware. The patient's hand was warm, swollen, and tender to palpation along the dorsum. Peripheral white blood cell count was significantly elevated and a plain radiograph of the hand showed soft tissue swelling with foreign bodies and no evidence of osteomyelitis. A chest x-ray was normal; CT PE protocol revealed multiple nodules in each lung, concerning for cavitation. A transthoracic echocardiogram was negative, but given the high suspicion for endocarditis, a transesophageal echocardiogram was performed, and was also negative. All three sets of blood cultures, drawn on admission, quickly resulted as gram-positive cocci in clusters, ultimately identified as Methicillin-Resistant Staphylococcus aureus. Despite the lack of visual evidence of endocardial involvement, the patient was diagnosed with acute bacterial endocarditis based on the Modified Duke Criteria.

DISCUSSION: Bacterial endocarditis is a life-threatening condition frequently treated by general internists. The estimated annual incidence is between three to nine cases per 100,000 people, with twice as many men as women effected. Patients classified as 'high-risk' include intravenous drug users and individuals with prosthetic valves or a prior history of valvular disease, and have a much higher infection rate. The diagnosis of bacterial endocarditis is made based on the Modified Duke Criteria, which have a greater than 80 % sensitivity, specificity, and negative predictive value. In 90 % of cases, vegetations are seen on transthoracic or transesophageal echocardiogram, which is one of the two major Duke Criteria. The other major criterion is bacteremia by an organism commonly known to cause endocarditis; if both major criteria are met the diagnosis of definitive bacterial endocarditis is made. In the other 10 % of cases, diagnosis must include at least three minor criteria, such as a predisposing condition, fever, vascular or immune phenomena, or positive blood cultures with an organism not commonly known to cause endocarditis. Definitive endocarditis can be diagnosed in a patient with one major and three minor criteria, or with no major but all five minor criteria. In this case, the patient met one major and three minor criteria: Staphylococcus aureus bacteremia, a predisposing condition (intravenous drug use), fever, and a vascular phenomenon (septic pulmonary emboli as seen on chest CT). With intravenous drug use on the rise, general internists should be familiar with the Modified Duke Criteria for diagnosing endocarditis, particularly when echocardiography does not correlate with clinical presentation.

DYNAMIC EARLY REPOLARIZATION PATTERN AND VENTRICULAR FIBRILLATION: CASE REPORT AND A BRIEF LITERATURE REVIEW Vimalkumar Veerappan Kandasamy¹; Satish Chandraprasadam²; Aryan Mooss².

¹Creighton University, Omaha, NE; ²Creighton University, Omaha, NE. (*Tracking ID #1939222*)

LEARNING OBJECTIVE 1: To recognize the dynamic nature and association of early repolarization (ER) pattern with idiopathic ventricular fibrillation.

LEARNING OBJECTIVE 2: To identify electrocardiographic characteristics that differentiate the benign ER pattern from the malignant variant.

CASE: A 43 year old Caucasian male was admitted following a witnessed out of hospital sudden cardiac arrest (SCA) without any preceding symptoms. Cardiopulmonary resuscitation was initiated within minutes of arrest. Initial presenting rhythm was ventricular fibrillation (VF) and 2 unsynchronized shocks successfully converted him to sinus rhythm. Upon return of spontaneous circulation, electrocardiogram (EKG) showed sinus tachycardia without signs of ischemia. Computed tomography of head showed no acute abnormalities. Since he was minimally responsive, he was intubated and hypothermia was initiated per hospital protocol. Cardiac examination was unremarkable. Troponin I peaked at 0.33 ng/ml 8 h after admission. Echocardiogram showed normal left ventricular systolic function without regional wall motion abnormalities. Upon re-warming, he had an excellent neurological outcome. Coronary angiogram (CAG) showed 99 % stenosis in the distal first diagonal artery and 75 % discrete stenosis in the proximal left anterior descending artery. He received drug eluting stent to both lesions given their hemodynamic significance by fractional flow reserve. Follow up EKGs showed 1 mm J-point elevation in the inferolateral leads with concave upwards ST segment elevation and notching at the end of QRS complex suggestive of early repolarization pattern. Cardiac magnetic resonance (CMR) demonstrated minor right ventricle (RV) wall motion abnormality but no evidence of fibro fatty infiltration of RV myocardium. It was inconclusive if the cardiac arrest was secondary to ischemia despite the presence of obstructive lesions noted in CAG. Absence of symptoms prior to SCA, lack of biomarker and echocardiographic/CMR evidence of myocardial infarction and/or structural abnormalities suggested the possibility of underlying electrical instability (ER pattern) initiating VF. After multi-disciplinary team discussion, an implantable cardioverter defibrillator (ICD) was placed for secondary prevention. He was doing well without any ICD therapy at 6 month follow up.

DISCUSSION: Early repolarization (ER) pattern consists of 2 EKG components: prominent J-point elevation ≥ 0.1 mV in adjacent leads with a slurred or notched QRS morphology and ST segment elevation. Prevalence of ER ranges from 5 to 13 %. Historically, ER pattern has been considered a marker of good health because it is more prevalent in athletes, younger persons, and at slower heart rates. On the contrary, its potential to cause serious ventricular arrhythmias was not recognized until recently. ER pattern when associated with symptomatic arrhythmias is known as ER syndrome. Haissaguerre et al. showed an increased prevalence of early repolarization among patients with a history of idiopathic ventricular fibrillation. Tikkanen et al. studied two populations of healthy adults and concluded that association between ER and increased risk of death from arrhythmia was found in persons with the horizontal ST segment pattern whereas risk for adults with rapidly up-sloping ST segment was similar to that of persons without ER. This association was also reported by Wu et al. in a large meta-analysis of 9 studies involving 141,095 subjects. However, there was no significant difference in risk of all cause or cardiac death in this study. The inferior or global distribution and higher J-point amplitude are known to be associated with increased arrhythmic risk both in general population and patients with idiopathic VF. In addition, horizontal ST segment elevation has also been identified as a high risk variable. In conclusion, early repolarization (ER) pattern is a common and benign electrocardiographic finding. As demonstrated in this case, ER pattern is dynamic and can vary in the same patient with change in body position, activity or over time. In select populations, the presence of certain subtypes of ER pattern may portend higher risk of death from arrhythmia. However no cause and effect relationship has been proven so far.

EARLY IMMUNE MODULATING THERAPY FOR PSEUDOTUMORAL ANOGENITAL HERPES IN HIV INFECTION Stacey Schott¹; Veronique Nussenblatt¹; Siham Mahgoub²; Khalil Ghanem¹. ¹Johns Hopkins University School of Medicine, Johns Hopkins Bayview Medical Center, Baltimore, MD; ²Whitman Walker Health, Washington, DC. (*Tracking ID #1938713*)

LEARNING OBJECTIVE 1: Recognize pseudotumoral forms of anogenital HSV2 in HIV infected individuals

LEARNING OBJECTIVE 2: Consider the use of early immune modulating therapy for anogenital HSV

CASE: A 41 year old man with HIV/AIDS since 2004, CD4 count of 35 cells/mm³ and undetectable viral load presented with a 2 month history of progressively ulcerated penile lesions despite multiple courses of valacyclovir. Two months after re-initiating HAART, a painless, small, round, fluid-filled pimple-like lesion spontaneously appeared on the dorsum of his penis, shortly followed by a similarly appearing second lesion on the ventral side. Analogous to two previous episodes of suspected

HSV outbreak in the previous year that completely resolved with 2 weeks of standard valacyclovir treatment, the lesions were thought to be recurrent HSV and were again treated with valacyclovir 1000 mg twice daily for 14 days. While on valacyclovir, the lesions became ulcerated and the medication was increased to 1000 mg three times daily. Despite 1 month of treatment, the lesions continued to grow and ulcerate, becoming painful, sore and bloody. The patient denied fever, chills or other systemic symptoms. A trial of famciclovir and doxycycline for suspected superinfection was ineffective. Laboratory testing included: positive HSVI and II IgG serologies; negative RPR, FTA-Abs, Quantiferon, chlamydia and gonorrhea. Acyclovir (ACV) resistance was thought to be unlikely given the patient's lack of prolonged valacyclovir exposure or history of suppressive valacyclovir, but viral culture verified acyclovir resistant, foscarnet sensitive HSV2. Biopsy of the ulcer was performed to rule out other etiologies including malignancy. While awaiting biopsy results, topical imiquimod 5 % cream was initiated three times per week for suspicion of pseudotumoral HSV2 and lesions dramatically healed after 1 month of use. Biopsy then confirmed HSV infection and demonstrated multinucleated cells with dense and predominately lymphocytic infiltrate.

DISCUSSION: HSV 2 is the primary agent of genital ulcerations and in HIV infected individuals herpetic lesions may be more extensive or last for longer periods. First line treatment for primary and recurrent genital ulcerations is acyclovir (or nucleoside analogues). However, atypical hypertrophic, ulcerative, or pseudotumoral forms of HSV exist and are usually suspected to contain drug resistant viral subtypes because they show poor response to acyclovir. It may be difficult to initially identify pseudotumoral forms as they appear to mimic epidermoid carcinoma, chancroid or lymphoma. The differential may also include HSV IRIS and atypical syphilis. A recent histopathologic, virologic and immunologic analysis elucidated that pseudotumoral lesions harbored ACV sensitive strains and ulcerative lesions harbored ACV resistant strains but patients with either of these types continued to fail anti-herpetic medications. The discovery of a predominance of polyclonal lymphoplasmacytic B cells in lesional infiltrates revealed a pseudolymphoma nature to the disease. Therefore, treatment with imiquimod, a toll-like receptor 7 agonist that boosts innate and adaptive antiviral immunity; or thalidomide, an anti-angiogenic, anti-proliferative immune modulator, may help overcome deficiencies in anti-herpetic immunity that persist in HAART treated patients to provide more consistent and lasting efficacy against the disease. In HIV infected individuals with suspected HSV2 refractory to antiherpetic drugs, early initiation of immune modulating therapy should be considered and may offer an effective, less toxic (than foscarnet) and more easily administered treatment choice for acyclovir resistant HSV infection.

EKG CHANGES IN A PATIENT WITH ACALCULOUS CHOLECYSTITIS: A RED HERRING Harish Madala; Tessa Antalan; Sandeep Padala; Vamsi Korrapati; Kavitha Kesari; Susan J. Smith. McLaren Regional Medical Center, Flint, MI. (Tracking ID #1922038)

LEARNING OBJECTIVE 1: Acute Cholecystitis can present with EKG changes suggestive of Myocardial Ischemia, usually as ST depression but very rarely ST elevation as well.

LEARNING OBJECTIVE 2: Importance of using clinical judgement when dealing with ambiguous clinical presentation to avoid anchoring bias.

CASE: A 53 year-old Caucasian male with a past medical history of diabetes, dyslipidemia, extensive smoking and family history of cardiac disease, presented with acute-onset midsternal pressure-like chest pain that had awakened him from sleep. There was also associated vague right upper quadrant abdominal pain and nausea. Physical examination was normal, except right upper quadrant abdominal tenderness. The white blood cell count was 13,600 per microliter. Initial EKG revealed diffuse ST segment elevation in leads I, II, III and V3-V6, along with peaked T waves in V3 and V4; two sets of troponins were negative. He was given intravenous nitroglycerin which provided moderate pain relief. An emergent cardiac catheterization was negative for focal obstructive coronary artery disease. Simultaneously he was started on intravenous antibiotics for suspected cholecystitis, which was confirmed by pericholecystic fluid seen on gallbladder ultrasound as well as by HIDA scan. The patient underwent laparoscopic cholecystectomy 2 days later, and was found to have acute on chronic gangrenous acalculous cholecystitis. Post-operatively, follow-up EKG's revealed near normalization of the ST segment changes.

DISCUSSION: Acute cholecystitis is usually recognized by a triad of fever, leukocytosis and right upper quadrant pain. The two main types are calculous and acalculous cholecystitis. There have been multiple references to acute cholecystitis presenting with EKG changes such as T wave inversions or ST segment depressions, but there have only been a handful of instances where ST-segment elevation was present. The exact pathophysiology of the EKG changes in acute cholecystitis is unclear. Based on animal experiments, a possible relationship of gallbladder distension to increased heart rate, blood

pressure and plasma renin levels has been postulated to cause transient changes in the coronary vasculature. In our literature review, we found 8 previous case reports of ST-segment elevation in patients with cholecystitis. Of these 8 cases, there was only one reference to acalculous cholecystitis while the rest were associated with gallstones. Our case reiterates the importance of exercising appropriate clinical judgment in the face of ambiguous findings. Having knowledge of this "red herring" in patients with cholecystitis could prevent unnecessary diagnostic testing and ensure timely administration of antibiotics as well as prompt surgery, if indicated.

ELECTROCARDIOGRAM CHANGES IN COMMON VARIABLE IMMUNODEFICIENCY RELATED ADRENAL INSUFFICIENCY Nili Parekh¹; Jagannath Mod²; Brijal P. Patel¹; Ryland P. Byrd^{2,1}; Thomas M. Roy^{2,1}. ¹ETSU, Johnson City, TN; ²ETSU, Johnson city, TN. (Tracking ID #1925143)

LEARNING OBJECTIVE 1: We present an adult patient with known history of common variable immune deficiency (CVID) who was identified to have adrenal insufficiency-associated QTc interval prolongation and t-wave inversion. Treatment with hydrocortisone resolved these endocrinopathy-associated myocardial electrical abnormalities.

LEARNING OBJECTIVE 2: Consideration of adrenal insufficiency early in hospitalization lead to prompt diagnosis and treatment which prevented catastrophic consequences of ventricular arrhythmia or death in this patient.

CASE: A 70 year-old male with atherosclerotic coronary artery disease and CVID was admitted for hypotension refractory to fluid challenges. He reported fatigue, loss of appetite and an unintentional weight loss of 40 lb of several months duration. His blood pressure was 82/42 mmHg. His hemoglobin was 11.9 g/dL and had an eosinophilia of 13.9 %. He was hyponatremic with normokalemia. The electrocardiogram (ECG) showed a QTc prolongation of 600 ms with nonspecific anterolateral T wave changes. Thorough history was taken and records were studied to rule out any prior use of glucocorticoids or other medications which could be the cause of adrenal insufficiency or QT interval prolongation before this hospitalization. Adrenal insufficiency was confirmed by low morning cortisol levels of 1.3 ug/dL which were drawn on morning after admission. Blood ACTH level was collected. Intravenous hydrocortisone was started immediately. Improvement in patient's symptoms, blood pressure and EKG occurred with hydrocortisone supplementation. Serial ECGs showed gradual return to normal by the fifth day of treatment. He was later diagnosed with low serum ACTH and a partially empty sella on magnetic imaging studies.

DISCUSSION: We found one pediatric case report suggesting autoimmune lymphocytic hypophysitis in a patient with CVID. Panhypopituitarism begins with involvement of adrenocorticotrophic (ACTH) and growth hormone at earlier stages in CVID patients. In 1950s, ECG abnormalities in adrenal insufficiency were described. Studies of rat heart muscle show that glucocorticoid is essential for the calcium transport in sarcoplasmic reticulum and microsomal phosphorylase activity. There are other reports in literature also suggesting adrenal insufficiency-related reversible cardiomyopathy and T wave changes but it is rare that such a finding is present in an adult patient with CVID. To our knowledge, this is the first case report of CVID, adrenal insufficiency and QTc abnormality in adult patient. Consideration of adrenal insufficiency early in hospitalization lead to prompt diagnosis and treatment which prevented catastrophic consequences of ventricular arrhythmia or death.

EMPTY SELLA SYNDROME PRESENTING AS EPISODIC HYPOGLYCEMIA Eric R. Simon; Pinky Jha. Medical College of Wisconsin, Wauwatosa, WI. (Tracking ID #1938665)

LEARNING OBJECTIVE 1: Recognize empty sella syndrome as a cause of hypoglycemia

LEARNING OBJECTIVE 2: Diagnose and treat secondary adrenal insufficiency due to empty sella syndrome

CASE: A 38-year-old female with a past medical history of Crohn's disease and hypothyroidism presented to the emergency room with dizziness after she skipped a meal due to nausea. On arrival, her finger stick blood glucose level was 41 mg/dL and it was corrected to 247 mg/dL with IV glucose. Over the past 18 months, she has had five previous known episodes of hypoglycemia that would always occur after she skipped a meal. She had no other associated symptoms. Her last Crohn's flare, and oral steroid use, was in 2009. Her hypothyroidism was diagnosed 6 years ago and she was prescribed levothyroxine, however she only took it for 6 months before stopping. Her only home medication was acetaminophen as needed. Family history is positive for diabetes mellitus type 2 in her father. She does not smoke or drink. Physical exam was unremarkable. Laboratory findings included an elevated TSH of 9.38 uIU/mL, a low free T4 of 0.54 ng/dL, a normal hemoglobin A1C, a normal c-peptide level, and a

normal pro-insulin level. During the hospital course, she continued to have multiple episodes of hypoglycemia that ranged between 40 and 60 mg/dL that would respond to oral glucose. Endocrinology was consulted and a cosyntropin (synthetic ACTH) stimulation test was performed, which showed low cortisol levels of 0.1 ug/dL, 0.2 ug/dL, and 0.3 ug/dL at 0, 30, and 60 min respectively. An ACTH level that was drawn 4 h after the cosyntropin stimulation test was <1.0 pg/mL. An MRI of the sella was then performed to evaluate for possible causes of secondary adrenal insufficiency and it showed a partially empty sella with a thin sliver of pituitary tissue at the floor of the sella. Subsequent additional laboratory work showed normal levels of FSH and LH along with an elevated prolactin and a low somatomedin C. She was started on hydrocortisone for her adrenal insufficiency and levothyroxine for her hypothyroidism. Her hypoglycemic episodes resolved after the initiation of steroid therapy.

DISCUSSION: Empty sella syndrome is a condition in which the sella turcica, which normally houses the pituitary gland, appears to be empty on imaging. This syndrome has been reported in 6–20 % of people, most commonly in multiparous women with obesity and hypertension. Empty sella syndrome can be asymptomatic or the patient may have various types of endocrine dysfunction. The most common endocrine abnormality is hyperprolactinemia and the most common hormone deficiency is growth hormone deficiency (measured by somatomedin C), both of which were seen in our patient. When the pituitary gland fails to produce ACTH, which normally stimulates the adrenal glands to produce cortisol, secondary adrenal insufficiency occurs. This can result in hypoglycemia because cortisol normally acts to increase blood sugar by increasing gluconeogenesis within the liver as well as blocking the uptake of glucose into cells throughout the body. Adrenal insufficiency can be diagnosed by the cosyntropin stimulation test, where an infusion of cosyntropin is given to the patient and plasma cortisol levels are measured over time. In primary adrenal insufficiency, cortisol levels will fail to increase in response to cosyntropin due to atrophy of the adrenal glands, and plasma ACTH levels will be high. In secondary adrenal insufficiency, cortisol levels will also fail to increase in response to cosyntropin because the adrenal glands are not used to being stimulated, but they will begin to respond and produce cortisol within 4–5 days. However in secondary adrenal insufficiency, plasma ACTH levels will be low, as was seen in our patient. Similarly, when the pituitary gland fails to produce TSH, secondary hypothyroidism occurs. The lab values for our patient, namely an elevated TSH and a low free T4, initially look like primary hypothyroidism. However with such a low free T4, one would expect the TSH to be even higher than it is, so there may be an element of secondary hypothyroidism as well. Treatment of empty sella syndrome is replacement of the deficient hormones, which included hydrocortisone and levothyroxine for our patient. Of note, with secondary adrenal insufficiency, the renin-aldosterone system is intact so mineralocorticoid treatment is not necessary.

EOSINOPHILIA IN THE CSF IN A PATIENT WITH ALTERED MENTAL STATUS

Vikas Khullar¹; Lucas A. Burke¹; James Wynne^{2,1}; Peruvemba S. Sriram^{2,1}.
¹University of Florida -College of Medicine, Gainesville, FL; ²University of Florida -College of Medicine, Gainesville, FL. (Tracking ID #1938188)

LEARNING OBJECTIVE 1: Recognize the differential diagnosis of eosinophilia in the CSF.

LEARNING OBJECTIVE 2: Assess and understand the treatment options for patients with eosinophilic meningitis.

CASE: A 58 year-old-man with no past medical history presented to the emergency department complaining of headaches, blurred vision, nausea, vomiting and poor balance of 1 week duration. Physical exam was unremarkable except for mild imbalance. Laboratory workup was significant for leukocytosis of 15,000 cells/uL with 8 % eosinophils with normal blood chemistry and liver function tests. Urine toxicology screen was positive only for marijuana. Chest radiograph and urinalysis were unremarkable. Computed tomography of the head did not show any abnormalities and patient was admitted for further evaluation. The day after admission, patient's neurological status deteriorated with acute onset confusion and agitation requiring sedative medication. Given acute decline, neurology was consulted and recommended lumbar puncture (LP); however, it was unsuccessful given patient's severe agitation. Empiric treatment for infectious meningitis was initiated, including ampicillin, vancomycin, ceftriaxone and acyclovir. However, patient's mental status continued to decline requiring intensive care unit admission and tracheal intubation. Patient subsequently underwent a LP and magnetic resonance imaging (MRI) for further evaluation. LP showed an opening pressure of 42 mmHg, clear cerebrospinal fluid (CSF) with 48 WBC #/cm² with 14 % lymphocytes, 53 % eosinophils and 7 % basophils. CSF protein was 178 mg/dL [N=15–45 mg/dL] and glucose of 58 mg/dL [N=40–70 mg/dL]. CSF gram stain, india ink and cultures were negative. CSF VDRL, Cryptococcus Antigen, Coccidioides Antibody, HSV 1 and 2 DNA were also negative. Serum HIV antibody and antigen were both negative. MRI showed diffuse

leptomeningeal enhancement most consistent with acute meningitis. Electroencephalogram was also ordered and was negative for seizure activity. Based on these investigations, a diagnosis of eosinophilic meningitis was established. Infectious diseases was consulted and recommended treatment with high dose steroids (1 mg/kg/day) for suspected parasitic meningitis and recommended no anti-helminthic medications due to concerns for causing increased inflammation. Hematology was also consulted to review CSF and concluded that the cells appeared mature in nature without blastoid features concerning for leukemia. With this intervention, patient's mental status began to improve and he was successfully extubated. Once the patient returned to baseline mental status, he reported recently working in a wooded construction area about 2 weeks prior to presentation with sighting of multiple raccoons in the area. A presumptive diagnosis of parasitic meningitis likely secondary to Baylisascaris procyonis given possible raccoon exposure was made and patient was discharged on a slow taper of prednisone.

DISCUSSION: This case demonstrates an unusual cause of meningitis and highlights the importance of cell differential in the CSF for the diagnosis and identification of certain pathologies. Eosinophilic meningitis is defined as the presence of 10 or more eosinophils/uL or eosinophilia of at least 10 % of the total CSF leukocyte count. The presence of eosinophilia in the CSF is associated with a limited number of diseases, with invasion of the central nervous system by helminthic parasites (such as Angiostrongylus cantonensis, Gnathostoma spinigerum, Baylisascaris procyonis and other helminths) being the most common. Other infectious causes include other parasites such as neurocysticercosis, cerebral toxocariasis and fungal infections with most common being coccidioides immitis. The diagnosis of a specific organism is made based on history of possible exposure, the clinical presentation and CSF eosinophilia. Serologic testing for its diagnosis is only available in endemic areas. Non-infectious causes of eosinophilia in the CSF include malignancy (Hodgkin's and Non-Hodgkin's, eosinophilic leukemia), medications (such as NSAIDs, ciprofloxacin, IV vancomycin, IV gentamycin), and presence of ventriculoperitoneal shunts. Treatment of eosinophilic meningitis secondary to helminthic parasites is mainly supportive as anti-helminthics have not been shown to be effective and often worsen symptoms by increasing inflammation due to antigens released by the dying parasites. Repeated lumbar punctures and analgesics can provide relief in patients with persistent headaches due to increased intracranial pressure. Corticosteroids have been used and shown to reduce focal neurological deficits. Most patients with helminthic parasites invasion require no specific treatment and recover completely in 3 to 6 weeks.

EOSINOPHILIC GASTRITIS Pearl Yu¹; Vivian Shing². ¹UCSD, La Jolla, CA; ²Canyon Crest Academy, San Diego, CA. (Tracking ID #1931860)

LEARNING OBJECTIVE 1: Recognize Eosinophilic Gastritis as a treatable disease that presents as nonspecific symptoms of dyspepsia, dysphagia and stomach bloating.

LEARNING OBJECTIVE 2: Understand the diagnosis and treatment of Eosinophilic Gastritis

CASE: A 62 yo female with history of osteopenia, factor 7 deficiency presents with stomach discomfort and indigestion after her colonoscopy procedure 3 months prior. She is not currently on medications nor dietary supplements except vit D. Patient describes symptoms of intermittent dysphagia, belching and stomach bloating. Her labs show normal CBC, comprehensive chemistry. Her Helicobacter pylori antibody and stool antigen test are both negative. An upper endoscopy is performed that shows a small healing gastric antrum ulcer otherwise negative. Random gastric biopsies show reactive gastropathy, erosions and an increased eosinophils greater than 30 HPF per HPF over 5 HPF. No evidence of Helicobacter pylori on routine stain. Esophageal and duodenal biopsies are all negative. Patient also has a RAST test which shows that she is mildly allergic to tomatoes, soy, peanuts and milk. Patient is put on proton pump inhibitors for 2 weeks without response and then is started on diet eliminations including seafood, soy, wheat, corn, egg, milk, peanut for 6 weeks trial. Patient reports life style of large amount of fish and soy consumption.

DISCUSSION: Eosinophilic Gastritis (EG) is a rare disease with limited case reports and there have been no prospective randomized therapeutic trials. The diagnosis is typically confirmed by endoscopic biopsies which reveal >20–25 eosinophils per HPF. Typical endoscopic findings include gastropathy with erythema and erosions. Lab findings may or may not show peripheral eosinophilia (20 % of the patients have normal absolute eosinophil count.). Treatment is empiric and based upon the severity of the clinical manifestations. Although food hypersensitivity plays an important role in EG pathogenesis, no food allergy test (skin, patch or allergen specific IgE) has been shown to effectively identify the culprit. A prospective trial in adults with EG has demonstrated clinical remission with a 6 week course of dietary elimination. The six-food elimination diets employed in EG include soy, wheat, corn, egg, milk, peanut and seafood for 6 weeks. If the dietary changes are successful at reducing symptoms,

foods can be added back slowly in a systematic fashion from the least allergenic to most allergenic. If dietary measures do not result in decrease symptoms and tissue eosinophilia, a trial of prednisone (20 to 40 mg/day) for 2 weeks followed by a rapid taper is the next treatment option. Other approaches include oral cromolyn, Ketotifen, montelukast. Untreated patients with EG may rarely remit spontaneously or progress to severe obstruction, malabsorption, malnutrition. Presentations and course is variable, and most may experience recurrence. Some patient may require long term maintenance therapy.

ERYTHEMA NODOSUM CAUSED BY CHLAMYDIAL INFECTION Yuki Otani; Christine Kwan. Teine Keijinkai Hospital, Sapporo, Japan. (*Tracking ID #1924164*)

LEARNING OBJECTIVE 1: Recognize the importance of taking a sexual history even in patients with a nodular rash.

LEARNING OBJECTIVE 2: Assess the possibility of sexually transmitted diseases (STD) with erythema nodosum.

CASE: A 29 years old Asian woman presents with 2 days' worsening rash on her bilateral lower legs; the lesions are round, red, raised, tender, non-itchy, and have no discharge. She also reports headache, dry cough, fever up to 39°, and chills despite non-steroidal anti-inflammatory drug use. She has no other constitutional, lung, abdominal, urinary, or musculoskeletal symptoms, in addition to no neck mass, new topical exposures, trauma, sick contacts, travel/hiking, or new pets; all other review of systems are negative. Her past medical history includes endometriosis and resected right ovarian chocolate cyst; she takes a gonadotropin-releasing hormone agonist (buserelin) and has no drug/food allergy. She does not use tobacco, alcohol, or recreational drugs. Her family history is not significant. Her physical exam shows temperature = 37.8C, heart rate = 92, blood pressure = 92/53, respiratory rate = 30, and O₂ saturation = 99 % room air. She appears tired but alert/oriented ×3. Head/neck exam reveals bilateral posterior cervical lymphadenopathy, 1 on each side at 2–3 cm, which is mobile, rubbery, and tender on the right. Skin exam shows ~15 erythematous, tender, 0.5 cm nodules on her bilateral palms, anterior shins, and dorsum of her right foot. The rest of her exam shows no irregularities. Labs show no abnormalities in the CBC or chemistry, except for slightly elevated C-reactive protein. Rapid Strep Test is negative; throat cultures show only normal oral flora. Anti-nuclear antibody is elevated at 160× titer in a homogenous pattern, but anti-nuclear cytoplasmic antibody is negative. Transthoracic echocardiogram does not reveal any vegetations. Skin biopsy shows neutrophilic septal panniculitis without vasculitis consistent with erythema nodosum, but slit-lamp exam reveals no evidence of uveitis. On further questioning, she reports being sexually active with only her husband but no condom use even though she has had untreated chlamydia 2 years ago. Her husband also has had multiple sexual partners until last year. Her last menstrual period is yesterday. Chlamydia PCR is positive on throat swab and urine; gonorrhea, syphilis, and HIV are negative. She is thus treated with both minocycline and ceftriaxone; her erythema nodosum subsides within 10 days.

DISCUSSION: Erythema nodosum, the most frequent clinico-pathological variant of the panniculitides, has the highest incidence in 20–40 years old, like the above patient. The inflamed, tender, and nodular lesions, usually located on the bilateral anterior aspects of the legs, are associated with a wide variety of diseases although the two most common causes are streptococcal infection and medications; 60 %, however, is idiopathic. On the other hand, chlamydial infection is one of the most common STD's, especially in those under 25 years. Because it usually remains asymptomatic, it can be unknowingly transmitted to sexual partners. Complications include pelvic inflammatory disease, ectopic pregnancy, and infertility. Erythema nodosum, however, is rarely caused by chlamydial infection; only 10 case reports have shown this association. Given its asymptomatic nature, however, one should still recognize that erythema nodosum may be caused by chlamydia and take the appropriate sexual history.

ERYTHRODERMA...THE OTHER DERMATOLOGICAL EMERGENCY Mike Butterfield; Rachel Sandler; Kate Hust. Tulane University Health Sciences Center, New Orleans, LA. (*Tracking ID #1925918*)

LEARNING OBJECTIVE 1: Generate a differential diagnosis for erythroderma and understand its life-threatening complications

LEARNING OBJECTIVE 2: Recognize the erythrodermic subtype of psoriasis and its management

CASE: A 61-year-old man presented with a rash beginning 5 months prior to arrival as well as chills and an unintentional 40-lb weight loss. The rash began on the extensor surfaces of both arms and subsequently encompassed his entire body,

causing severe pruritus. An outside dermatologist diagnosed the patient with psoriasis. Courses of topical and oral steroids failed to change the patient's symptoms, but etanercept achieved moderate relief. The patient ran out of etanercept 2 weeks prior to presentation, and his symptoms again flared. Physical examination was notable for cachexia, alopecia, and global erythroderma sparing only his face and genitals. He had 2+ non-pitting edema of the lower legs with lichenified skin changes, thickening of the palms and soles (keratoderma), and hypertrophic finger and toenails (onychauxis). Non-tender supraclavicular, axillary, and inguinal lymphadenopathy was present. Initial laboratory workup revealed negative HIV serology and normocytic anemia. Lower-extremity ultrasound detected 3–4 cm inguinal lymph nodes bilaterally. Skin biopsy demonstrated psoriaform dermatitis, and flow cytometry of an excised right inguinal node later revealed an elevated CD4:CD8 ratio. T-cell receptor rearrangements were not present in the biopsy specimen or peripheral blood.

DISCUSSION: Erythroderma is a rare inflammatory skin condition defined by involvement of more than 90 % of body surface area. Patients display a "lobster-like" appearance with erythematous, warm, scaly skin that can be quite painful and pruritic. Generalized lymphadenopathy and skin lichenification may also be present. Erythroderma is a dermatologic emergency as widespread damage to the dermis compromises its role as an immunologic barrier, placing patients at risk for infection (particularly by staphylococcus, pseudomonas, and herpes) and sepsis. Heightened insensible losses may cause dehydration and electrolyte disturbances while cutaneous vasodilation may induce high-output heart failure. Erythroderma often represents the exacerbation of a pre-existing skin condition (eczema, psoriasis, contact dermatitis). Flares may be triggered by events such as stress or sudden cessation of medications. Alternatively, erythroderma may be a manifestation of underlying systemic disease such as lymphoma (including the Sézary Syndrome), paraneoplastic syndromes, lupus, graft-versus-host-disease, or hypereosinophilic syndrome. Though erythroderma only complicates 1–2 % of all cases of psoriasis, its presence must be promptly recognized. The onset of psoriasis in mid-to-late adulthood generally portends a milder natural history compared with those presenting at an earlier age; however, the proportion of erythrodermic cases appears to increase with age, approaching 5 % of new cases in those over 60. Rapid symptom control is often needed in the acute setting, but the evidence for treatment of erythrodermic psoriasis is limited. In addition to supportive measures such as topical steroids, moisturizers, and oatmeal baths, the National Psoriasis Foundation currently recommends cyclosporine or infliximab as first-line treatment, due to their quick onset of action.

ESRD + DIABETES = CRAZY LEGS? Sagar Y. Patel; Justin B. Miller; Thomas Montgomery. Carolinas Medical Center, Charlotte, NC. (*Tracking ID #1925056*)

LEARNING OBJECTIVE 1: Discuss the diagnosis, prognosis, and treatment of diabetic uremic syndrome

LEARNING OBJECTIVE 2: Recognize the vast differential for hyperkinetic movements

CASE: A 60-year-old African American man with end-stage renal disease on hemodialysis complicated by anemia and secondary hyperparathyroidism, diabetes mellitus complicated by nephropathy, neuropathy, retinopathy, and previous episodes of hyperglycemia hyperosmolar state, hypertension, COPD, and chronic pancreatitis presented with 10 day history of lower leg jerking/uncontrollable movement that had worsened to point that he was unable to ambulate. He was hospitalized 2 weeks prior to his current admission for shortness of breath secondary to fluid overload from kidney disease and was noted to have some mild involuntary movements of his lower extremities at the time of discharge. Upon this current admission, the patient's Gabapentin, Amlodipine, and Promethazine were held as these each had movement disorders listed as adverse side effects. He also underwent dialysis and received Cogentin but saw no improvement in symptoms. He denied taking any new medications, illicit drug use, trauma, new onset weakness, headache, or changes in vision or hearing. Physical exam revealed normal vital signs and choreiform movements of his bilateral lower extremities. Lower extremities otherwise had 5/5 strength, with toes downgoing bilaterally, and other reflexes untested due to involuntary movement. Exam of his upper extremities was normal. Other than a BUN of 29 mg/dL and creatinine of 5.62 mg/dL, chemistries and iron studies were within normal limits. Urine drug screen was negative. Creatine phosphokinase and erythrocyte sedimentation rate were elevated at 1480 IU/L and 68 mm/h, respectively. Rheumatologic labs (including ds-DNA, Chromatin, Jo-1, Centromere, RNP, Scleroderma, SSA, SSB, and Smith) were negative. A MRI of the brain revealed abnormal T2 signal change in bilateral basal ganglia (image included). Patient was ultimately started on Haldol and showed remarkable improvement in hyperkinetic movements.

DISCUSSION: The presentation of hyperkinetic movements comes with an extensive differential that includes Huntington's disease, Wilson's disease, restless

legs syndrome, Sydenham's chorea, tardive dyskinesia, drug-induced movement disorders, and psychogenic disorders, among others. Many of these causes are able to be rendered improbable based on history, physical exam, laboratory, and imaging studies. We considered many of these in our differential; however it was the history of end-stage renal disease and diabetes mellitus with previous hyperglycemia hyperosmolar states combined with classic MRI findings that directed us towards a diagnosis of diabetic uremic syndrome. Diabetic Uremic Syndrome was first reported by Wang, et al. of Taiwan in 1998. Since then, this syndrome has been characterized as acute hyperkinetic or hypokinetic extrapyramidal disorders associated with uniform neuroimaging findings of bilateral symmetrical basal ganglia changes in diabetic ESRD patients undergoing hemodialysis. The classic image findings in our patient are consistent with reports citing bilateral basal ganglia lesions ranging from focal putaminal and pallidal lesions to widespread involvement of the whole basal ganglia with perifocal edema. Prognosis is not clear but it appears in a number of cases patients had reversal of their acute neurologic impairments with lesions often disappearing during follow-up. The pathogenesis is unknown, with speculation that it may be related to uremic toxins, diabetic microangiopathy, metabolic acidosis, and hypoglycemia. Treatment seems to be primarily symptomatic with dialysis recommended if a toxic or metabolic mechanism is present. In our case, Haldol was relatively successful at suppressing involuntary movement. Most reported cases are from patients of Asian descent; however this case demonstrates that this syndrome is likely independent of genetic influences. It has also been discussed in the literature that this may not be a rare condition but rather underdiagnosed due to relative ambiguity. Better recognition of this syndrome can lead to better physician and patient education.

EVALUATION AND MANAGEMENT OF ACUTE INFERIOR MESENTERIC VEIN THROMBOSIS Sara-Megumi Naylor, UCLA Medical Center, Los Angeles, CA. (*Tracking ID #1926398*)

LEARNING OBJECTIVE 1: Mesenteric venous thrombosis (MVT) is a rare condition that can be due to inherited or acquired thrombophilia, local factors causing vessel wall injury from abdominal infections or surgery, or stasis. Patients can be asymptomatic or present with abdominal pain or signs of portal hypertension depending on the acuity of the thrombosis. With the increasing use of computed tomography (CT), the detection of MVT is increasing. Most sources recommend anticoagulation to prevent bowel infarction and recurrent thrombosis.

CASE: A 59 year-old Caucasian homeless man with history of alcohol abuse and cigarette smoking related COPD presented to the emergency department for progressive abdominal pain over 1 week. The abdominal pain was diffuse but most prominent in the left lower quadrant, severe, crampy and constant with no radiation. He reported associated fevers, chills, nausea, vomiting, and diarrhea. On exam he was well-nourished, in mild distress, afebrile, tachycardic and had mild abdominal tenderness in the left lower quadrant. Admission CT abdomen and pelvis with contrast showed extensive diverticulosis with significant sigmoid diverticulitis and colonic wall thickening with associated thrombus of the inferior mesenteric vein (IMV) extending into the splenic vein. The patient was initially admitted to the General Surgery service, however, with the plan for conservative management, was transferred to General Medicine. He was kept NPO, given IV fluids, and started on IV antibiotics. The patient refused therapeutic anticoagulation with heparin and received enoxaparin SQ while bridged to oral warfarin. We evaluated for a thrombophilic state which was negative except for mildly decreased protein C and antithrombin III activity levels which can be seen in infections. He improved and was discharged on a prolonged course of oral antibiotics and warfarin with the plan for a colonoscopy with eventual elective sigmoidectomy. The patient returned to the hospital 10 days later with recurrent abdominal pain and was found to have a large, multiloculated abscess and now air-filled IMV which was thought to be in direct connection with the diverticular abscess. He underwent surgical drainage of the abscess, sigmoid colectomy, with diverting colostomy. He was eventually discharged from the surgery service without prolonged anticoagulation. He was last seen in clinic 3 months after his surgery and was doing well. There has been no re-imaging of his abdomen.

DISCUSSION: In our patient, the IMV thrombus was likely provoked by his diverticulitis. We also suspect the IMV thrombosis caused relative ischemia and exacerbated the colonic inflammation. The case highlights the complexity of medical and surgical considerations and the importance of co-management of patients with MVT. In the era of widespread availability of CT scans and >90 % accuracy of CT scans to detect MVT, the diagnosis of MVT is no longer a challenge. However, the evaluation for the cause of the MVT and management remain complex. Literature suggests the inclusion of a coagulation profile, thrombophilia work-up, and in a more recent recommendation, a JAK2 sequence variation screen to evaluate acute MVT. Anticoagulation is the mainstay of therapy with supportive care given the most

common cause of death of MVT is sepsis with multiorgan failure. The duration of anticoagulation depends on the cause of the MVT.

EXERCISING HICKAM'S DICTUM: A CASE OF SIMULTANEOUS PARASITIC, FUNGAL, BACTERIAL AND VIRAL INFECTIONS John Romond;

Andrew Hoellein, University of Kentucky, Lexington, KY. (*Tracking ID #1937736*)

LEARNING OBJECTIVE 1: Demonstrate immunosuppression as a setting for multiple simultaneous infections

LEARNING OBJECTIVE 2: Describe the role of steroids in the conversion of Strongyloidiasis to hyperinfection syndrome

CASE: A 76 year-old man from eastern Kentucky presented with abdominal pain and intermittent melena for 1 month. He was recently diagnosed with lupus nephritis and started on mycophenolate and prednisone. On presentation, he was afebrile and in atrial fibrillation with a heart rate in the 120 s, his respiratory rate was elevated to 22 and he was normotensive. He was anemic with a hemoglobin of 7.9 but without leukocytosis. A CXR suggested bilateral lower lung airspace disease and follow up CT showed extensive areas of ground glass opacities. Shortly after admission he had coffee ground emesis and became more dyspneic. Upper and lower endoscopy revealed diffuse mucosal erythema and friability with contact bleeding. Following endoscopy his clinical condition worsened, and he became hypotensive and hypoxic. He was intubated and transferred to the ICU. Blood cultures returned positive for Enterococcus faecalis. Blood CMV DNA PCR was positive at 1100 copies/ml. Serum Cryptococcal antigen was positive with a titer of 1:64 and blood mycological evaluation returned positive for Cryptococcus. Biopsies taken from esophagus, stomach, duodenum and colon showed extensive *Strongyloides stercoralis* infection and bronchoalveolar lavage found both *Strongyloides* and *Cryptococcus* in the lungs. Despite aggressive therapy for each of these infections, our patient died.

DISCUSSION: Although William of Occam in the 14th century stated, "Plurality must not be posited without necessity," the more recent quip of Dr. Hickam, "A patient may have as many diagnoses as he darn well pleases." proved the more applicable in this case. While the multiple diagnoses discovered in this patient were likely secondary to his immunosuppression, the role of steroids specifically in the development of overwhelming *Strongyloidiasis* has been well described. Investigation has shown that steroids diminish circulating eosinophils through decreased proliferation and accelerated apoptosis in addition to directly stimulating the *Strongyloides* to proliferate. Thus, as the worm burden rapidly increases the innate defense of the host is weakened and a massive infection of the gastrointestinal tract, blood stream, and lungs is termed "hyperinfection". There are often secondary infections as bacteria may travel on the parasite or within the gut of the worm. Although wide variation exists in the literature due to small study populations, *Strongyloides* Hyperinfection alone has a mortality rate reported as high as 87 %.

EXTENSIVE AORTIC THROMBUS IN ULCERATIVE COLITIS: COMMON DISEASE WITH UNUSUAL COMPLICATION Sonikpreet Sonikpreet; Alaeddin Maeza; Jasleen Kaur; Sarwan Kumar. Crittenton Hospital/Wayne State University, Rochester, MI. (*Tracking ID #1938323*)

LEARNING OBJECTIVE 1: Thromboembolism is a serious but under-recognized complication of inflammatory bowel disease (IBD). Venous thrombosis is a well recognized but arterial thrombotic complications of IBD is extremely rare and poorly understood.

CASE: We describe a case of extensive arterial thrombus of descending aorta and its branches in association with severe Ulcerative Colitis (UC). A 54 y/o female with the history of chronic intermittent bloody diarrhea, presenting with worsening of symptoms for 3 months. Diagnosed proctitis on outpatient evaluation with no follow up, until the day she presented to the ER with severe bloody diarrhea and abdominal cramps. Associated with fever and weight loss of 30 lbs. Physical examination concluded mild diffuse abdominal tenderness. She was admitted and started on Ciprofloxacin and Flagyl. Stool studies were unremarkable except for positive leukocytes. Colonoscopy was performed suggesting nonspecific colitis with biopsy confirming UC. She was then started on IV steroids and Lialda. However, CT scan including angiography was done in ER, revealing multiple arterial thromboses in the abdominal aorta, distal superior mesenteric artery and the branches of proximal inferior mesenteric artery. Anticoagulation workup was negative. Heparin was started but the patient had massive bleeding episodes, necessitating discontinuation of heparin though APTT was within normal range. Eventually the patient

recovered, following up with repeat CT angiography showing resolution of arterial thrombi.

DISCUSSION: Arterial thrombotic complications are rare in UC and need early recognition and appropriate management to prevent morbidity and mortality. Therapeutic management is difficult because of spontaneous hemorrhage, more clinical trials of therapy required to provide the appropriate options for treatment.

EXTENSIVE ARTERIAL AND VENOUS THROMBI AS A PRESENTATION OF HYPEREOSINOPHILIC SYNDROME WITH A UNIQUE COMPLICATION OF HEMOLYTIC ANEMIA AND POOR RESPONSE TO TREATMENT
Matthew P. Deek; Mansi Shah; Lauren C. Hogshire. Rutgers- Robert Wood Johnson Medical School, New Brunswick, NJ. (Tracking ID #1899545)

LEARNING OBJECTIVE 1: Recognize the various clinical presentations of idiopathic hypereosinophilic syndromes

LEARNING OBJECTIVE 2: Identify unique complications of idiopathic hypereosinophilic syndromes.

CASE: A previously healthy 46 year old man, who recently emigrated from Dominican Republic with a diagnosis of bilateral lower extremity DVT on warfarin therapy, presented with progressively worsening bilateral lower extremity pain, cyanosis of his right foot, and 18 lb unintentional weight loss over 3 weeks. On exam, he was tachycardic with bilateral lower extremity edema, had dusky discoloration of the digits of his hands and feet with weak peripheral pulses. No rash, lymphadenopathy, respiratory wheezes, masses or organomegaly were present. Diagnostic tests revealed severe eosinophilia (WBC 30.4×10³; eosinophils 20.7×10³) and anemia (Hgb 9.6 g/dL). Vascular studies confirmed with CT showed extensive arterial thrombi of the right upper, left upper, and right lower extremity and venous thrombi of the IVC, right peroneal, right posterior tibial, right popliteal, right femoral, right external iliac, left popliteal, left femoral, left external iliac, and hepatic vein. An extensive investigation followed and ruled out infectious etiologies including parasites, HIV, and hepatitis. His hospital course was complicated by the development of hemolytic anemia for which he was treated with IVIG and required transfusions. Subsequent hematological work up including bone marrow biopsy revealed a monoclonal T-cell population, and he was diagnosed with hypereosinophilic syndrome with a clonal T-cell mediated lymphoproliferative disorder (CD3-/CD4-/FIP1L1-PDGFRα-). He was treated with a trial of high dose corticosteroids and adequate control of his eosinophilia was achieved. Due to his widespread arterial and venous thrombi, he was discharged on warfarin. Two weeks later, he returned with a gangrenous right foot and was found to have refractory hypereosinophilia (WBC, 21×10³; eosinophils 5.3×10³) with recurrent thrombosis, which required a transmetatarsal amputation.

DISCUSSION: Idiopathic hypereosinophilic syndrome (HES) is defined as persistent eosinophilia with end organ damage in the absence of a neoplastic process or reactive eosinophilia. Major organ damage can occur due to eosinophil infiltration, which may manifest as fibrosis, thrombosis with or without thromboembolism, cutaneous or mucosal involvement, edema, and neurologic deficits. Amongst idiopathic HES is a lymphocytic variant caused by an aberrant T cell lymphocyte population that overproduces the cytokine interleukin-5. Some patients with the lymphocytic variant HES may eventually develop T-cell lymphoma. This case represents a unique presentation of T-cell mediated HES with a lymphocytic variant for multiple reasons. Principally, the extent of eosinophil-mediated venous and arterial thrombi in this patient is greater than typically found in literature. Many patients with HES show some degree of hypercoagulability, but the precise cause of this is not known. One hypothesis is that the eosinophil-mediated protein release causes endothelial damage and activates the coagulation cascade, which may account for the persistence of thromboses and failure of anticoagulant therapy. Moreover, autoimmune hemolytic anemia is not a well documented clinical phenomena in the literature surrounding HES and the presence of complications such as this may be a marker for disease refractoriness and prognosis, and should be considered when determining treatment options.

EYES: A WINDOW TO THE HEART Radha S. Mehta; Surbhi Rohatgi; Aliya Laeq. Mount Auburn Hospital, Cambridge, MA. (Tracking ID #1931906)

LEARNING OBJECTIVE 1: To know the association of various organ systems involved in a patient presenting with one of the features of a rare syndrome.

LEARNING OBJECTIVE 2: To know the management including close follow up of a patient with a known rare mitochondrial encephalomyopathy.

CASE: 40-y/o gentleman with history of Kearns-Sayre syndrome presented at outside hospital with flu like symptoms where he was noted to have a heart rate in the 40s with complete heart block and was sent to our hospital for further management. He had symptoms of progressive fatigue and worsening shortness of breath waxing and waning over the last several weeks to months. He was a former smoker, used alcohol socially and had no family history of premature atherosclerosis. Physical examination was significant for pulse rate of 35 and eye exam showing ptosis and ophthalmoplegia. Rest of the exam was reassuring. His labs included BNP of 2000, INR of 1.3, WBC 6.8, hemoglobin 13.7, hematocrit 40.2, platelets 130. Sodium 143, potassium 4.3, chloride 106, CO₂ 25, glucose 87, BUN 6, creatinine 0.5, calcium 8.8, magnesium 2.7. Troponins <0.04, 0.11. TSH 1.78. CRP 33.5. albumin 3.2, total protein 5.7, T.bilirubin 1.7, D.bilirubin 0.7, AlkPhos 144, ALT 50, AST 79. HbA1c 6.5. PTH 59.1. Lyme antibody was negative. Echocardiogram showed a decreased EF of 20 %. He had received Isoproterenol at the outside hospital. We observed the patient overnight and he was hemodynamically stable. He got a single ventricular pacemaker with implantation of the ICD lead in case he needs ICD for his cardiomyopathy in the future. He was also started on B-Blocker and Lisinopril for his cardiomyopathy.

DISCUSSION: Kearns-Sayre syndrome (KSS) is a rare syndrome characterized by the triad of progressive external ophthalmoplegia, pigmentary retinopathy and cardiac conduction system disturbances; it is a mitochondrial encephalomyopathy which usually presents before the patient reaches the age of 20. Cardiac involvement has been shown to be the most important prognostic factor for life expectancy, and complete heart block is known to be the major cause of death in patients with KSS. Other cardiac manifestations reported are first or second degree of AV block, QT prolongation, torsades de pointes ventricular tachycardia, and rarely dilated cardiomyopathy. Intracardiac electrophysiological studies showed that the primary abnormalities are in the AV node-His-Purkinje system. In cardiac histopathological studies, fatty infiltration and fibrosis of the bundle branches and of the sinoatrial and atrioventricular nodes have been observed. The European Society of Cardiology guidelines for cardiac pacing, 2007 recommend pacemaker implantation with any degree of fascicular block in patients with neuromuscular diseases with class IIa indication, level of evidence C, or with second- or third-degree AV block with class I indication, level of evidence B.

FACIAL RASH AS A RARE INITIAL PRESENTATION OF PRIMARY CUTANEOUS CRYPTOCOCCOSIS Amornpol Anuwatworn; Pramil Cheriyath. Pinnacle Health System - Harrisburg Hospital, Harrisburg, PA. (Tracking ID #1939763)

LEARNING OBJECTIVE 1: Recognize the clinical features of primary cutaneous Cryptococcosis

LEARNING OBJECTIVE 2: Investigate and manage primary cutaneous Cryptococcosis

CASE: A 26 year-old male with history of HIV and lymphoma presented with a 3 month history of facial rash associated with itching. He had been on antiretroviral medications since the age of 17 but stopped taking medicine 5 years ago. Two weeks prior to the admission, HAART regimen and bactrim were prescribed. He underwent skin biopsy by dermatologist and the histopathology showed cryptococcus. On examination, temperature was 38 centigrade. There were umbilicated erythematous plaques and papules all over his face. There was no rash on all extremities or trunk. Laboratory results revealed white cell of 12 K/uL, hemoglobin of 8.2 G/DL, platelet count of 116 K/uL, CD4 count of 70 and HIV RNA of 9,908 copies/mL. Blood cultures grew Cryptococcus neoformans. Chest x-ray was unremarkable. Amphotericin B was initiated however it was discontinued after he developed acute kidney injury. Intravenous fluconazole was administered. His symptoms improved and he was discharged with a 6 month course of oral fluconazole. He is currently following with his primary physician.

DISCUSSION: Primary cutaneous cryptococcosis (PCC) is an opportunistic infection in immunocompromised patients, and is characterized by cutaneous lesions, positive culture with no evidence of systemic manifestations. Skin lesions usually involve upper or lower extremities. We described a case of facial rash as an extremely rare initial presentation of PCC. PCC is caused by *Cryptococcus neoformans* or *Cryptococcus gattii*. Acneiform, palpules, plaques, tumoral mass, cellulitis, ulcerated and necrotic lesions are varied cutaneous forms. Umbilicated papules may be found in HIV patients as illustrated in this case. The main therapy includes systemic fluconazole or amphotericin. As PCC incidence is rare, the diagnosis may be delayed. PCC should be considered in the differential diagnosis of facial rash in immunocompromised patients. Skin biopsy and culture should be done.

FATAL ACUTE RESPIRATORY DISTRESS SYNDROME CAUSED BY DISSEMINATED NOCARDIOSIS: A CASE REPORT Satoshi Okamori; Nagano Hiroyuki; Yukio Tsugihashi; Hiroyuki Akebo. Tenri Hospital, Nara, Japan. (*Tracking ID #1933943*)

LEARNING OBJECTIVE 1: Recognize that suppression of cell-mediated immunity is a risk factor of Nocardia infection.

LEARNING OBJECTIVE 2: Recognize that disseminated nocardiosis has the potential to cause acute respiratory distress syndrome (ARDS) even under appropriate antibiotic therapy.

CASE: A 66-year-old Japanese woman was admitted to our hospital with wrist pain and fever. Approximately 5 months before admission, she developed hemophagocytic syndrome. She was treated with steroid pulse therapy and oral prednisolone and cyclosporine. One month before admission, she noted pain in her left wrist with progressive swelling. Three days before admission, she developed a fever which peaked at 38 °C. She was then admitted to our hospital. On examination, oxygen saturation was 92 % while breathing ambient air. On auscultation, coarse crackles were heard bilaterally. Subcutaneous nodules were palpable on the left wrist, left thigh and right inframammary region. Computed tomography (CT) revealed multiple nodules not only subcutaneously but also in the bilateral lungs and retroperitoneal space. Surgical biopsy of a subcutaneous nodule revealed an abscess with bloody pus, and bacteriological examination detected Nocardia farcinica. A diagnosis of disseminated nocardiosis was made and treatment with trimethoprim-sulfamethoxazole and imipenem-cilastatin was initiated. Shortly thereafter her respiratory status deteriorated with rigor and shivering. Chest X-ray and CT revealed bilateral consolidations, presenting acute respiratory distress syndrome (ARDS). The patient was intubated and treated with mechanical ventilation. Nocardia farcinica bacteraemia was confirmed by blood culture. The patient responded poorly to antibiotic therapy and died of respiratory failure. Postmortem examination revealed multiple inflammatory regions with necrosis of the lung, kidney and perinephric tissue, confirming the diagnosis of disseminated nocardiosis. Diffuse alveolar damage, which is pathological feature of ARDS, was also observed.

DISCUSSION: Immunocompromise is a well-established risk factor for nocardiosis. Our patient had suppressed cell-mediated immunity due to oral prednisolone and cyclosporine, and was at a high risk of Nocardia infection. We informed the laboratory staff and they immediately conducted not only a standard gram stain but also a modified Kinyoun acid-fast stain, which provided the diagnosis of disseminated Nocardiosis and led to prompt antibiotic therapy. The incidence of nocardiosis has increased substantially in the past two decades, in association with an increase in the population of immunocompromised hosts. Nocardiosis should be considered in the diagnosis of fever and multiple nodules in immunocompromised patients, and this possibility should be communicated to laboratory staff. On admission, CT in our patient showed multiple nodular lesions. Even though antibiotic therapy was initiated, the CT findings changed to bilateral consolidation, with concurrent respiratory failure requiring mechanical ventilation. The patient was clinically diagnosed with ARDS, and post mortem examination of the lung pathologically confirmed diffuse alveolar damage. Nocardiosis can follow a rapidly progressive course in patients with severe immunosuppression. In particular, as Nocardia farcinica has a higher risk of dissemination and mortality and is more resistant to antimicrobial agents, distinguishing it from other Nocardia species is important.

FATAL CEREBRAL AIR EMBOLISM AS A COMPLICATION OF ESOPHAGOGASTRODUODENOSCOPY David E. Kim; Julie Yam; Tejaswini Jognipally; Woo J. Chang; Shilpa Kavuturu. Michigan State University, East Lansing, MI. (*Tracking ID #1939483*)

LEARNING OBJECTIVE 1: Recognize an uncommon but fatal complication of endoscopy

LEARNING OBJECTIVE 2: Manage suspected acute air embolism

CASE: An 88 year old female with a history of Alzheimer's, hypertension, and a duodenal ulcer presented to the ED with 3 day history of generalized weakness, dizziness, and multiple falls. She used NSAIDs regularly for her arthritis. The patient was diagnosed with an upper GI bleed and symptomatic anemia with a hemoglobin of 4.7 g/dL. CT brain was unremarkable. After transfusion and stabilization she underwent an EGD under conscious sedation with propofol. Endoscopic findings included a grade B distal ulcerative esophagitis, an obstructive pyloric stenosis which was balloon dilated to 12 mm, and a 6 cm × 6 cm post bulbar duodenal ulcer with visible vessel and active bleeding with hemostasis achieved with clips and gold probe coagulation. Within minutes following the procedure, patient became hypotensive with blood pressure of 70/30 mmHg and tachycardic with pulse of

120 bpm and then became unresponsive with a GCS of 3. No arrhythmias were noted on telemetry. The patient was intubated for air way protection. Her hypotension shortly resolved after minimal IV fluids. Repeat CT brain showed multiple foci of air in the right frontal, temporal, and occipital regions with significant infarctions of the right cerebellum, left occipital lobe, and left parietal lobe. A transthoracic echocardiogram did not show evidence of an intracardiac shunt, air, wall motion abnormalities, or elevated pulmonary artery pressures. The left ventricular ejection fraction was 65 %. The patient was treated with 100 % oxygen therapy but the prognosis was poor. The patient was declared brain-dead and life support was withdrawn on hospital day 5. Post mortem autopsy did not show signs of a ruptured duodenal ulcer, GI AVM, GI fistulas, barotrauma, intracardiac air or shunt, or evidence of portocaval shunting.

DISCUSSION: Cerebral air embolism due to EGD is a rare but potentially fatal complication. To our knowledge there are only 10 other reported cases. There is increasing evidence that a certain volume and rate of air entry may overwhelm the filtration capacity of the pulmonary capillaries and allow the passage of venous air into the arterial circulation. In our patient we hypothesize that a combination of insufflated air and balloon dilation created an entry point and a large pressure gradient to introduce air into the visible duodenal vessel. This may have caused the transient hypotension via a temporary obstruction of the right ventricular outflow tract that was relieved when the venous air passed into the arterial circulation. The patient's advanced age with dementia and sedation with Propofol were complicating factors for initial diagnosis and likely the clinical outcome. Cerebral air embolism can be indentified through CT scanning if done early. If venous air embolism is suspected, the patient should be placed head-down in a left lateral decubitus position to prevent the air bubble from obstructing the right ventricular outflow tract. Some authors have suggested that aspiration of air from the right ventricle through a central catheter may improve outcomes. The initial treatment is 100 % oxygen and hyperbaric oxygen (within 30 h) therapy to rapidly reduce the volume of air embolus.

FEVER OF UNKNOWN ORIGIN WITH TELANGIECTASIA AND INFLAMMATORY LESION OF ABDOMINAL SKIN AND RESPIRATORY FAILURE Motosuke Tomonaga¹; Motoshi Fujiwara¹; Masaki Tago¹; Yuka Naito¹; Jun Tokutomi¹; Akiko Eiri¹; Hiroki Aihara¹; Tsuneaki Yoshioka¹; Masaki Hyakutake¹; Yuta Sakanishi²; Itaru Kyoraku¹; Takashi Sugioka²; Shu-ichi Yamashita¹. ¹Saga Medical School, Saga, Japan; ²Saga Medical School, Saga, Japan. (*Tracking ID #1902509*)

LEARNING OBJECTIVE 1: Diagnose the cause of fever of unknown origin associated with telangiectasia

CASE: A 75-year-old woman was admitted to our hospital because of redness and swelling of skin of lower abdomen and left thigh, dyspnea and fever. Two months before admission, pain developed in her lower abdomen, which also showed reddening of the skin. She visited another hospital and was diagnosed as cellulitis and was prescribed antibiotic, but her symptoms didn't improve. Skin biopsy was performed, which showed only nonspecific inflammatory findings. In addition, dyspnea and high fever developed, so she was transferred to our university hospital. On examination, the temperature was 36.3 °C, the blood pressure 100/60 mmHg, the pulse 84 beats per minute, the respiratory rate 16 per minute, and the oxygen saturation was less than 90 % while the patient was breathing ambient air. Her skin of lower abdomen and left thigh was red, swollen, feverish and coarse with slight tenderness. The capillaries in the same area showed dilatation. The white blood cells were 3300/μl, and atypical lymphocytes were detected on microscopic image. LDH was 472 IU/l, soluble interlokin 2 receptor 1485 IU/l. The chest X-ray showed pleural effusion in both sides. Paracentesis was performed and pleural effusion was exudative without malignant cell. Her pleural effusion was intractable in spite of the treatments with chest drainage or diuretics. Gradually, the skin inflammation and telangiectasia extended to the upper abdomen, so we performed skin biopsy again showing invasion of large lymphoid cells to vessels that was considered as nonspecific findings. On the 21th hospital day, consciousness disturbance occurred. Laboratory data on the day showed serum sodium 113 mEq/l and blood glucose 45 mg/dl. Since we suspected the presence of adrenal failure, we started intravenous administration of hydrocortisone before the results of endocrinological examinations came back, which showed that she had panhypopituitarism. Since we suspected her illness as intravascular lymphoma (IVL), we performed random skin biopsy, which made the diagnosis of diffuse large B-cell lymphoma (DLBL). At this time, she was in severe respiratory failure. She was intubated and put under ventilator treatment. Since her general condition was too bad to receive chemotherapy, we chose the treatment of best supportive care. She died 2 months after her hospitalization. We performed

postmortem examination. The color of peritoneum was brown, and we suspected the invasion of lymphoma cells. On intracranial survey, there was adhesion of dura mater, and pituitary body was swollen, which suggest the intracranial invasion including pituitary body. Histopathological examination is currently in process, which we are going to show on our presentation.

DISCUSSION: Random biopsy of skin is essential when IVL is suspected, especially when a patient shows telangiectasia and inflammation of skin with diverse symptoms including fever of unknown origin.

FIBRINOLYSIS SECONDARY TO UROKINASE PRODUCTION BY TRANSITIONAL CELL CARCINOMA Jorge Fuentes; Jesse Victor. University of Florida, Gainesville, FL. (*Tracking ID #1939778*)

LEARNING OBJECTIVE 1: Recognize the diagnostic, prognostic and therapeutic implications of urokinase production by transitional cell carcinoma.

LEARNING OBJECTIVE 2: Diagnose secondary fibrinolysis by thromboelastography analysis.

CASE: Seventy-three year old male with history of prostate cancer treated with androgen deprivation therapy, transitional cell bladder cancer with partial resection and deep venous thrombosis on coumadin presented to clinic for three-week duration of painless hematuria. CT of abdomen and pelvis revealed large bladder mass with mild to moderate hydronephrosis in the setting of creatinine of 1.0 and INR of 2.3. Patient was instructed to discontinue coumadin and return to clinic in 5 days for cystoscopy. Patient complied with coumadin discontinuation however returned in 3 weeks. During this visit cystoscopy revealed necrotic posterior bladder mass suspicious for transitional cell carcinoma. Labs revealed acute kidney injury with creatinine of 11.5 and INR of 8.3 despite discontinuation of coumadin. Renal ultrasound confirmed severe bilateral hydronephrosis. Intravenous hydration was initiated along with vitamin K and two units of fresh frozen plasma. Three-way foley was placed for continuous bladder irrigation. Interventional Radiology consulted for placement of bilateral nephrostomy tubes for obstructive nephropathy. Prior to nephrostomy tube placement, patient was afebrile and hemodynamically stable with moderate suprapubic tenderness and bright red blood with visible clots in foley bag. Labs consisted of creatinine of 12, corrected INR of 1.7 and decreased hemoglobin from 8.9 to 6.7 g/dL. Patient transfused two units of packed red blood cells with adequate response. He tolerated nephrostomy tube placement well with no requirement for blood products. Approximately 6 h post procedure, significant hypotension developed with decreased hemoglobin from 8.7 to 4 g/dL, lactic acid of 15 mmol/L, D-dimer 17.79 mg/L, fibrinogen <35 mg/dL, INR 3.7 and protamine 36.1 s. Thromboelastography (TEG) analysis showed evidence of clot lysis with prolonged LY30 of 15 % (0-8 %), coagulation index of 3.1 (-3 to 3) and decreased MA of 40 mm (55-73) suggestive of secondary fibrinolysis. There was no evidence of microangiopathic hemolytic anemia given lack of thrombocytopenia and schistocytes on peripheral smear. Abdominal CT revealed developing retroperitoneal hemorrhage with new hematomas in left proximal thigh. Angiogram revealed no evidence of contrast extravasation in right/left renal and right/left iliac arteries. Patient was transferred to intensive care unit for management of hemorrhagic shock and transfused six units of packed red blood cells, four units of cryoprecipitate, four units of fresh frozen plasma with correction of coagulopathy. Renal function gradually improved over the course of hospitalization. Patient subsequently underwent successful urologic resection of bladder mass.

DISCUSSION: Urokinase is a serine protease produced by urothelium that promotes conversion of plasminogen to plasmin. It is used clinically as a thrombolytic agent in the treatment of massive deep venous thrombosis, pulmonary embolism and myocardial infarction. Effective thrombolysis with urokinase is evidenced by reduced fibrinogen, increased concentration of fibrinogen degradation products, shortened clot lysis time and prolonged PT and PTT. Urokinase plasminogen activator (uPA) has been implicated in tumor invasion and metastases as activated plasmin directly cleaves components of the basement membrane and extracellular matrix; permitting tumor cells to access lymph vessels and vasculature. Patients with transitional cell cancer have increased levels of plasma uPA compared to healthy controls. Moreover, patients with advanced stage transitional cell cancer and high uPA levels have poorer prognosis compared to similar staged tumors with low uPA levels; suggesting that uPA may serve as an independent prognostic marker. Hyperfibrinolysis in this patient was attributed to increased levels of urokinase in the setting transitional cell cancer. Hyperfibrinolysis is diagnosed on TEG analysis by LY30 >7.5 % or EPL >15 %. Coagulation index (CI) is used to distinguish primary and secondary fibrinolysis with values greater than 3.1 suggestive of secondary fibrinolysis. Therefore, LY30 of 15 % and CI of 3.1 in the setting of decreased fibrinogen, increased D-dimer and prolonged PT and

PTT were suggestive of secondary fibrinolysis. Additionally, acute kidney injury from obstructive nephropathy may have exacerbated fibrinolysis by impaired renal clearance of urokinase. Antifibrinolytic drugs such as aminocaproic acid or tranexamic acid are used to treat fibrinolysis; however this was not administered as fibrinolysis resolved with improvement in renal function after nephrostomy tube placement. Further investigation of urokinase utilization by tumor cells is required as urokinase may serve as a marker for tumor recurrence or therapeutic target for prevention of metastasis.

FIRE IN THE BELLY Jessica Pacifico; Sheira Schlair. Montefiore Medical Center, Bronx, NY. (*Tracking ID #1937714*)

LEARNING OBJECTIVE 1: Identify the differential diagnosis for recurrent abdominal pain and fever

LEARNING OBJECTIVE 2: Recognize the clinical manifestations of Familial Mediterranean Fever

CASE: A 37-year-old man presented with severe mid-abdominal pain and fever for 2 days. His temperature at home measured 102° Fahrenheit and he had associated rigors. He reported no nausea, vomiting, diarrhea, constipation, reflux symptoms, weight loss or rash. The abdomen was diffusely tender but not distended with no rebound or guarding; he had no rash and no lymphadenopathy. Liver tests, amylase and lipase were within normal limits and white blood cell count was not elevated. Computed tomography of his abdomen was unremarkable. For the past 3 years, he had similar episodes as often as once per week. At other times, up to 6 months would pass between episodes; they typically lasted 1–3 days with associated fevers ranging from 101 to 105° Fahrenheit. During some of the episodes, he would have thigh myalgias but no frank joint swelling, redness or warmth. Between episodes, the patient was asymptomatic. Prior studies included a colonoscopy, ultrasound of the abdomen and computed tomography of his abdomen that were all normal. The patient was born in Egypt and lived with his wife in New York City; he had smoked cigarettes infrequently in the past but quit many years ago, had minimal alcohol intake and noted no risk factors for human immunodeficiency disorder. The pain and fever resolved with no intervention the next day. Several months later, on a trip to visit his family in Egypt, he was diagnosed with Familial Mediterranean Fever through genetic testing and initiated on colchicine. Since that time, he has had no subsequent episodes of abdominal pain and fever.

DISCUSSION: A typical, basic evaluation of abdominal pain includes history, physical examination, labs including complete blood count, liver tests, amylase and lipase and imaging as needed. While the differential diagnosis for abdominal pain and fever is quite extensive, it narrows with several recurrences and repetitive non-revealing basic work ups. At that point, evaluation for infectious etiologies (e.g. typhoid fever, brucellosis, borreliosis, malaria, tuberculosis, HIV), rheumatologic etiologies (e.g. vasculitis, systemic lupus erythematosus) and malignancy (e.g. lymphoma) should be undertaken. Additionally, the periodic fever syndromes should be considered. Amongst the periodic fever syndromes, abdominal pain is a common feature in Familial Mediterranean Fever (FMF). TNF-receptor 1 associated periodic syndrome, hyperimmunoglobulinemia D syndrome and Muckle-Wells syndrome. FMF is a genetic disease (most commonly autosomal recessive inheritance) that occurs mainly in people of Sephardic Jewish, North African, Arab, Turkish, Italian, Greek and Armenian descent. FMF is characterized by paroxysmal attacks of fever and serosal inflammation including peritonitis, pleuritis and synovitis, typically lasting 1–3 days and then resolving spontaneously. The most common manifestation of the disease is peritonitis presenting as abdominal pain. The presentation of the abdominal pain can range in severity from aching, generalized tenderness to guarding, rebound tenderness and rigidity that can mimic an acute surgical abdomen. Other acute manifestations include, but are not limited to, erysipelas-like dermatologic lesions, pericarditis, orchitis and aspetic meningitis. Laboratory abnormalities include elevations in the serum markers of systemic inflammation including leukocytosis, erythrocyte sedimentation rate and C-reactive protein, amongst others. The major long-term complication is secondary AA amyloidosis. Diagnosis can be made clinically via a detailed criteria set; the most commonly used has 4 major and 4 minor criteria, as well as 10 supportive criteria. FMF can also be diagnosed through genetic testing for mutations in the MEV gene. MEV encodes pyrin, a protein which plays a key role in the innate immune system and the inflammatory response. The exact mechanism triggering attacks is unknown at this point. A few founder mutations account for the majority of cases; it has been suggested that two of the most common mutations, V726A and M694V, originated in common ancestors from the Middle East that lived about 2500 years ago. The typical treatment of FMF is colchicine which both reduces the frequency of attacks and reduces the risk of secondary AA amyloidosis. Since a key feature of FMF is robust health between attacks, clinicians should guard against concluding the workup when a flare resolves. A high clinical suspicion for FMF should

be maintained in a patient with recurrent abdominal pain and fever, especially when the patient belongs to a typical ethnic group. Expedited diagnosis is paramount because the initiation of colchicine therapy markedly reduces the risk of renal failure secondary to AA amyloidosis, which remains the greatest source of mortality.

FROM A SORE THROAT TO A CEREBELLAR ABSCESS AND SEPTIC PULMONARY EMBOLI; AN ATYPICAL PRESENTATION OF A “FORGOTTEN DISEASE” Puneet Gill; Richard M. Butler. Virginia Tech Carilion, Roanoke, VA. (*Tracking ID #1928647*)

LEARNING OBJECTIVE 1: Recognize the potential for diagnostic error in the initial clinical presentation of Lemierre’s syndrome.

LEARNING OBJECTIVE 2: Recognize that Lemierre’s syndrome may present without the classic radiographic finding of thrombus in the internal jugular vein.

CASE: A 21-year-old female with a history of asthma presented to the emergency department for evaluation of left ear pain, sore throat and productive cough for the past 3 days. She was found to be febrile (T 102.7 F) and tachycardic, which resolved after receiving antipyretics. Rapid Strep screen was negative and patient was discharged home with presumed viral pharyngitis. She returned to the emergency department 5 days later with complaints of headache, neck pain and back pain. Family reported symptoms of confusion, drowsiness and slurred speech over the past 2 days. On exam patient was somnolent but arousable, ill appearing with dry mucous membranes and in mild respiratory distress. She had tender left-sided facial and neck swelling without erythema. A complete neurological exam was difficult due to altered level of consciousness, however no obvious focal deficits were noted. She was hypotensive, tachycardic, afebrile and saturating well on room air. Initial labs revealed leukocytosis, profound thrombocytopenia and elevated creatinine. CT head did not show any intracranial abnormality. CT chest showed multiple bilateral cavitary and non-cavitary parenchymal lesions increasing the index of suspicion for Lemierre’s syndrome with septic emboli to the lungs. Subsequent imaging of the neck revealed multiple small retropharyngeal abscesses and thrombophlebitis of left facial vein; the internal jugular veins appeared patent. Blood cultures returned positive for *Fusobacterium necrophorum*. Despite appropriate antibiotic coverage, her respiratory status declined. Repeat imaging of the brain and neck revealed a cerebellar mass and newly developed thrombus of the left internal jugular vein. The left internal jugular vein was ligated to prevent further septic emboli. The patient had a three-week hospital course, complicated by pleural empyema.

DISCUSSION: Lemierre’s syndrome was first coined in 1936, describing a condition that started as tonsillitis and progressed to suppurative thrombophlebitis of the internal jugular vein. It is usually caused by the gram negative anaerobe, *Fusobacterium necrophorum*. Diagnosis is supported by imaging studies showing thrombus in the internal jugular vein. This case of Lemierre’s initially lacked this classic radiographic finding, but instead showed thrombophlebitis of the facial vein. As antibiotics gained popularity, Lemierre’s syndrome became known as “the forgotten disease”. *Fusobacterium necrophorum* is generally sensitive to penicillin and amoxicillin. However, due to increasing concerns regarding overuse of antibiotics, physicians are encouraged to utilize conservative measures with symptomatic treatment for what is likely a viral illness. As antibiotic stewardship has become customary, there appears to be a resurgence of this syndrome in the literature. Unfortunately, the initial clinical presentation of Lemierre’s is vague and resembles viral pharyngitis. A high index of suspicion is needed when making this diagnosis, as it progresses rapidly and is associated with high mortality. It is important to recognize that there may be variations in the typical radiographic findings.

FULL COURT PRES: ALTERED MENTAL STATUS IN THE IMMUNE-COMPROMISED Cady (Blackey) Brown. Tulane University Health Sciences Center, New Orleans, LA. (*Tracking ID #1926243*)

LEARNING OBJECTIVE 1: Review the work-up for altered mental status (AMS) in immune-compromised patients

LEARNING OBJECTIVE 2: Illustrate a less common cause of Posterior Reversal Encephalopathy Syndrome (PRES)

CASE: A 48 year-old woman with a history of diffuse large B-cell lymphoma, status-post allogenic stem cell transplant on cyclosporine, presented complaining of dysuria and fever. She was found to be neutropenic; she was admitted and treated with cefepime. Over the ensuing 24 h, she developed myoclonus and AMS. She was afebrile, mildly tachycardic and normotensive. ——The physical exam revealed a woman with a Glasgow coma score of seven. She did not have abdominal distension or tenderness; her cardiac and lung exams were benign. She had myoclonus, but normal reflexes and intact cranial nerves. Her liver and renal function were normal. The blood cultures from admission showed no growth. Her cerebrospinal fluid studies

(CSF) were normal. An EEG was consistent with encephalopathy. Both a non-contrast head CT and a brain MRI were normal. She remained unarousable over the following week. Bacterial cultures and viral studies of the CSF, including, herpes simplex virus, cytomegalovirus, arboviruses and west nile virus, were all negative. CSF toxoplasma and cryptococcus antigen tests were negative. A repeat MRI was done and showed edema in the bilateral occipital lobes consistent with PRES. Her immunosuppressive medication was changed from cyclosporine to sirolimus. One week later, her mental status began to improve and a repeat MRI showed less edema.

DISCUSSION: As transplant medicine increases in prevalence, more patients are immune-compromised. Thus, it is important to have an approach to AMS in this patient population. The differential diagnosis for AMS in immune-compromised patients is broad, but can be simplified into categories of infection, malignancy, metabolic, vascular and toxin/medication-induced. A thorough infectious workup, including lumbar puncture, blood cultures and serologic studies for possible pathogens must be initiated. Medications should be reviewed for possible culprits. Brain imaging and an EEG should be done to evaluate for structural and/or metabolic abnormalities. Among the less common causes for AMS in the immune-compromised, is PRES. This is a syndrome based on clinical and radiologic findings, with heterogeneous etiologies. Classic clinical manifestations include headache, AMS, visual disturbances and seizures. Symmetric white matter edema in the posterior cerebral hemispheres on MRI is the classic radiologic finding of PRES. Most commonly, uncontrolled hypertension is the underlying cause for PRES. However, immunosuppressive and immunomodulatory medications can also be the cause. Treatment involves removal of offending agent or control of offending cause (hypertension) in addition to supportive care. Recognizing PRES as a possible cause for AMS in the immune-compromised patient is particularly important because most patients recover fully if the underlying cause is reversed.

FULMINANT DISSEMINATED VARICELLA ZOSTER INFECTION IN AN IMMUNOCOMPETENT ADULT Neal Shah; Arthur Jeng. Olive View Medical Center, Sylmar, CA. (*Tracking ID #1938866*)

LEARNING OBJECTIVE 1: Varicella zoster virus (VZV) is a contagious childhood disease that affects both immunosuppressed and immunocompetent adults. While childhood vaccination efforts have significantly decreased those afflicted, a substantial adult population still exists who are at risk. VZV can have severe disease manifestations uncommonly seen in the current era, causing serious morbidity and mortality in the immunosuppressed.

CASE: A 44-year-old woman with no medical history presented to the ER with 3 days of non-radiating epigastric pain, shortness of breath, subjective fevers and rash that started on her trunk and spread to her arms, legs and face. She received a steroid injection 1-day prior at an outside clinic for her abdominal pain with no relief. She denied any travel, drug usage, new exposures, pets or other identifiable risk. She endorsed having “chickenpox” when young. On exam, she was febrile to 39.3 with mild tachycardia. She had bilateral conjunctival suffusion. Oral exam revealed extensive ulceration and stomatitis over her buccal mucosa, palate, and posterior oropharynx. On her skin, there were multiple erythematous maculo-papular lesions, some of which were vesicular and some of which were papular, throughout her face, back, chest, abdomen, legs, and arms including both palms. Abdominal exam revealed epigastric tenderness to palpation. Labs revealed a leukocytosis, hepatitis, and coagulopathy, consistent with disseminated intravascular coagulation (DIC). Serologies and PCR for HIV, syphilis, and typhus were negative. Viral cultures and HSV/VZV PCRs were sent from scrapings of the lesions. CT scan of the chest/abdomen/pelvis revealed extensive, bilateral nodular infiltrates and scattered ground glass opacities, along with fatty infiltration of the liver. She was empirically started on IV acyclovir and doxycycline, for concern of severe VZV or (murine) typhus. On day 2, the rash and oral/gingival lesions worsened. PCR for VZV returned positive, and she was switched to oral valacyclovir; all other antibiotics were stopped. Her VZV IgG was negative and IgM positive. Her coagulopathy and hepatitis gradually improved. On day 4 the skin lesions began crusting over and she was discharged on day 5 with complete resolution on follow-up.

DISCUSSION: This case demonstrates the atypical severity of VZV in an immunocompetent adult. Although VZV is common in adults, it is usually reactivation (ie, shingles). Primary infections (ie, chicken pox) are less commonly seen in adults. Well-known adult complications of VZV include pneumonitis, can be life-threatening. However, conjunctivitis, severe hepatitis, and DIC are rarely seen and illustrate the wide spectrum of presentation. The steroid injection given in the outpatient clinic may have allowed this severe presentation of VZV. This case reminds clinicians of the severity that primary VZV can present with, even in an immunocompetent adult, underscoring the necessity of vaccination efforts.

FULMINANT MYOCARDITIS: THE ROLE OF VENTRICULAR ASSIST DEVICE AS A BRIDGE TO RECOVERY Ambreen Mohamed; Richard Soucier. University of Connecticut Health Center, Farmington, CT. (*Tracking ID #1939220*)

LEARNING OBJECTIVE 1: Recognize the clinical features of fulminant myocarditis

LEARNING OBJECTIVE 2: Discuss the role of mechanical circulatory support in fulminant myocarditis

CASE: This is a 52-year-old Japanese female with no significant past medical history who presents with complaints of fatigue and subjective fevers for 1 week. Patient had her sister recently visit from Japan as well as two daughters who were sick with upper respiratory tract infections. On the day of admission, patient developed chest comfort with increased pallor with weakness which concerned her family and was brought to the emergency room. On arrival, patient was noted to be febrile to 101.3, tachycardic in the 150's and in significant respiratory distress. Physical exam revealed jugular venous distention, bibasilar crackles, and cool extremities. Patient became progressively more lethargic and was placed on BiPAP of which she did not tolerate well and subsequently was intubated. Bedside echocardiogram showed an ejection fraction (EF) of 10 % to 20 %, trace pericardial effusion and a globally dyskinetic heart. With acute coronary syndrome (ACS) high on the differential, patient was started on a heparin drip and immediately taken to the cath lab only to find clean coronaries, normal right and left sided pressures, however a depressed cardiac index of 1.98. She continued to decompensate and was started on milrinone and lasix drips as well as an aortic balloon pump post cardiac cath. Patient was in cardiogenic shock, non-ischemic in origin with the working diagnosis of fulminant myocarditis. She was transferred to an outside hospital where biventricular assist device (BiVAD) was placed so her heart could slowly recover. Patient's course was unfortunately complicated by an ischemic stroke and she soon after was taken off life support and passed.

DISCUSSION: Fulminant myocarditis most often presents with cardiogenic shock. As seen in our patient, despite using maximal medical therapy, additional mechanical ventilatory support may be needed. Ventricular assist devices offer a bridge to transplant or even recovery. Prognosis of acute viral myocarditis depends on several risk factors such as clinical presentation, ejection fraction and lower blood pressure levels on admission. Although fulminant myocarditis has been shown to have a higher in-hospital mortality rate in comparison to those with acute nonfulminant myocarditis, early recognition of risk factors along with aggressive hemodynamic support has been shown to have an excellent long term prognosis.

FUNCTIONAL HYPOPARATHYROIDISM CAUSED BY HYPMAGNESEMIA Haleigh James; Murali Duggirala. Mayo Clinic, Rochester, MN. (*Tracking ID #1936960*)

LEARNING OBJECTIVE 1: Diagnose and manage functional hypoparathyroidism as a result of hyponatremia

LEARNING OBJECTIVE 2: Recognize proton pump inhibitors as a potential cause of hyponatremia

CASE: A 68 year-old woman with CREST syndrome was brought to the emergency department after her husband witnessed her having a convulsive episode. She had no history of seizures. Physical exam revealed a mildly confused woman not oriented to time. She had no tongue lacerations or focal neurologic deficits. Initial ECG showed a prolonged QTc of 519 milliseconds. CT scan of the head was negative for any acute findings. Glucose was normal, but laboratory evaluation revealed several electrolyte abnormalities including a total calcium of 5.7 mg/dL (reference 8.9–10.1 mg/dL), magnesium of <0.5 mg/dL (reference 1.7–2.3 mg/dL), and potassium of 3.1 mmol/L (reference 3.6–5.2 mmol/L). Albumin was 3.5 g/dL (reference 3.5–5 g/dL) and parathyroid hormone (PTH) was 24 pg/mL (reference 15–65 pg/mL). Intravenous calcium gluconate, magnesium sulfate, and potassium chloride were administered prior to admission to the medical ICU. Upon admission, further questioning revealed that the patient had been experiencing episodic nausea and vomiting over the preceding several months and was recently diagnosed with gastroparesis. Past medical history was significant for gastroesophageal reflux disease, for which she was taking esomeprazole twice daily, and hypertension, but she was not taking any diuretics. With supplementation, the patient's serum magnesium rose to 2.3 mg/dL (reference 1.7–2.3 mg/dL) and total calcium rose to 9.4 mg/dL (reference 8.9–10.1 mg/dL) by day 3 of hospitalization. PTH at that time was found to be elevated to 92 pg/mL (reference 15–65 pg/mL). The etiology of her hyponatremia was presumed to be a combination of her poor oral intake with frequent vomiting over the preceding few months, along with proton pump inhibitor use. She had no further seizures and was dismissed home on an oral calcium and magnesium supplementation regimen, as well as a lower dose of esomeprazole. She was instructed to follow up

with her primary care physician for electrolyte monitoring and further investigation hyponatremia persisted.

DISCUSSION: This case illustrates functional hypoparathyroidism due to severe hyponatremia, resulting in marked hypocalcemia and seizure. Low serum magnesium causes hypocalcemia via inhibition of PTH release and bone resistance to PTH. Proton pump inhibitors (PPIs), as in this case, may cause hyponatremia via impaired active magnesium transport across transient receptor potential melastatin-6 and -7 (TRPM6/7) channels on intestinal epithelial cells. The risk is increased with concomitant vomiting, diarrhea, and diuretic use. Recognizing and treating hyponatremia is integral to correcting associated hypocalcemia because calcium supplementation alone does not reverse the functional hypoparathyroidism. When PPIs are the inciting factors of low magnesium, discontinuation of them leads to magnesium recovery.

GASTRIC ULCER PERFORATION: AN UNCOMMON CONSEQUENCE OF VOMITING Neema Heivand; Sarah B. Fleisig; Hanna Freyle. Lenox Hill Hospital, New York, NY. (*Tracking ID #1936233*)

LEARNING OBJECTIVE 1: Clinically diagnose a perforated peptic ulcer

LEARNING OBJECTIVE 2: Recognize the clinical features of a perforated peptic ulcer

CASE: A 60-year-old female with a past medical history of Peptic Ulcer Disease (PUD) presented to the Emergency Department with a 3 day history of vomiting and diarrhea. She complained of 10–15 loose bowel movements per day and non-bloody, non-bilious emesis. Her presentation was prompted by inability to tolerate food or liquids without aggravating her symptoms. The patient did not complain of any abdominal pain or dyspepsia on presentation. She denied recent travel or ill contacts. PUD was diagnosed about 20 years ago and she currently was not on any antisecretory therapy. She did not take any medications and denied the use of non-steroidal anti-inflammatory drugs. The patient complained of worsening nausea, vomiting, and retching that was refractory to antiemetics overnight on hospital day one. On the morning of hospital day two, the patient complained of intense, abrupt-onset epigastric pain radiating to the back with associated right shoulder pain radiating down her right arm. Other than low-grade fever, vital signs were stable and within normal limits. On physical exam, the patient was in acute distress, writhing in pain. Abdominal exam revealed a soft, non-distended abdomen with bowel sounds present. However, the patient complained of intense tenderness to light palpation over the epigastric region and displayed guarding. Electrocardiogram was unremarkable with no change from prior studies and troponins were negative. Blood pressures taken in both arms were within 5 mmHg of each other and within normal limits. Lipase was mildly elevated at 419. Ultimately, a chest x-ray revealed free air below the right hemidiaphragm. An emergent surgical consultation was placed and the patient was sent to the operating room where a perforated gastric ulcer was revealed. Gastric tissue biopsy revealed H. Pylori infection.

DISCUSSION: Perforation is a life-threatening complication of Peptic Ulcer Disease. Although the pathophysiology of PUD is well known, aggravating factors that could result in perforation are not. The increase in intra-abdominal pressure and subsequent stomach contraction during vomiting may be a potential mechanism for perforation of an underlying gastric ulcer. This mechanism may be similar to that found in Boerhaave's syndrome, where increased pressure results in rupture of the esophagus. The patient's right shoulder pain could be explained by the right subphrenic presence of gastric contents. This case highlights the importance of early diagnosis of the acute abdomen and underscores the utility of the history and physical examination. Perforation should be kept on a clinician's list of differential diagnosis in a vomiting patient with history of PUD who complains of severe abdominal pain.

GIANT SPLENIC ARTERY ANEURYSM PRESENTING AS LOWER GI BLEEDING Chandra S. Dasari; Amreshwar Podugu; Steve Sanofsky. Canton Medical Education Foundation, Canton, OH. (*Tracking ID #1926347*)

LEARNING OBJECTIVE 1: We present a case in which a giant SAA, by causing venous obstruction in the intestinal circulation, led to extrahepatic venous hypertension causing GI bleeding, and was successfully treated with endovascular means using coil embolization.

LEARNING OBJECTIVE 2: Splenic artery aneurysms occur in slightly less than 1 % of the population. Rupture of a splenic artery aneurysm (SAA) carries a high mortality. Aneurysms generally are not treated unless they are larger than 2 cm, most treated aneurysms falling within the 2.5 to 3 cm range.

CASE: A 77 year male presented to the ER with a 3 week history of bloody stools and fatigue with a hematocrit of 16.5 which stabilized after receiving 4 units of blood.

Neither upper GI endoscopy nor colonoscopy was able to localize the source of bleeding. A CT Angio of the abdomen demonstrated a heavily calcified $8.0 \times 7.5 \times 7.6$ cm SAA. The patient continued to have ongoing episodes of slow GI bleeding while on the medical service. A bleeding scan was non-diagnostic. An arteriogram performed during an episode of bleeding also failed to locate the bleeding source, but did demonstrate the splenic artery aneurysm along with dilated veins felt to be part of the Superior Mesenteric venous system. Coil embolization of the giant splenic artery aneurysm, with occlusion of both inflow and outflow arteries, was performed in the Interventional OR Suite. The patient did not have any further episodes of GI bleeding and was discharged a few days later. A follow up CT angiogram the next day confirmed successful occlusion of the aneurysm. The patient has had no further bleeding episodes since.

DISCUSSION: SAA's are the third most common abdominal aneurysm, following aortic and iliac aneurysms. They are usually discovered as an associated finding on an abdominal X-ray or CT scan, appearing as a spherical calcified mass in the right upper quadrant along the expected course of the splenic artery. The vast majority of SAA's are asymptomatic. There is some controversy regarding when to prophylactically treat an asymptomatic aneurysm, although such considerations don't occur until the aneurysm is more than 2 cm in diameter. There are a few groups of patients considered at higher risk for rupture, and these include women of childbearing age and those who are to undergo liver transplant. Treatment in these higher risk groups is considered for aneurysms 1.5 cm or greater. Treatment is indicated for symptomatic aneurysms. Aside from rupture of the aneurysm, which presents as abdominal pain and shock, and which carries a high mortality, symptoms can include abdominal pain in an otherwise stable patient, and rarely as GI bleeding due to erosion into surrounding organs such as the stomach, or as in our case, from venous compression causing portal hypertension. The most common etiology of SAA's is atherosclerotic disease. Other etiologies include collagen vascular disease and portal hypertension. Pancreatitis can lead to false aneurysms of the splenic artery due to erosion of a pancreatic pseudocyst into the splenic artery. Although SAA's have been treated with open surgery, the most common present day treatment for nonruptured aneurysms utilizes catheter based methods using either coil or glue embolization. Catheter based treatments have a low complication rate. Although treatment requires occlusion of the splenic artery at the site of the aneurysm, the spleen usually remains viable due to collateral flow from the short gastric arteries. Only on a rare occasion is a splenectomy required due to splenic infarction. There is a syndrome called PES (post embolization syndrome) which presents as fever, abdominal pain, pleural effusion, and rarely, pancreatitis. The syndrome probably involves partial infarction of the spleen and perhaps occasional embolic particles ending up in the pancreas. This syndrome can occur in up to 30 % of patients but is typically self limiting. Giant SAA's causing extrahepatic portal venous obstruction has been reported but is very rare. We believe that the GI bleeding in our patient was due to elevated intestinal venous pressure caused by SMV compression by the 8 cm splenic artery aneurysm. Once the aneurysm was thrombosed as a result of coil embolization, the patient had no more bleeding episodes. He has remained symptom free for the 6 months that we have followed him since his treatment.

GIVE ME DOXYCYCLINE OR GIVE ME DEATH Naomi Karlen; Matthew N. Peters; Jared Roussel. Tulane University Health Sciences Center, New Orleans, LA. (Tracking ID #1926161)

LEARNING OBJECTIVE 1: Recognize that serology for tick-borne illnesses can be negative during the first week and that PCR and close examination of peripheral blood smears should be performed in patients with high suspicion.

LEARNING OBJECTIVE 2: Identify doxycycline as a low cost, well tolerated treatment option to prevent potentially fatal infection with tick-borne illnesses.

CASE: A 62-year-old man presented with 5 days of fever. He described the fevers as intermittent and reported a maximum temperature of 103° F. He had a medical history of ischemic stroke and ongoing well-controlled hypertension. The patient recently completed a 30-day trip from Boston to New Orleans, during which he spent several days walking outside. However, he reported no insect bites. He denied recent sick contacts, cough, myalgia, and previous illicit drug use. On physical examination, all vital signs (including temperature) were within normal limits. Physical examination revealed no abnormalities; no rashes or breaks in the skin were noted. Initial laboratory values including CBC, CMP, PT and INR were within normal limits aside from a white blood cell count of 2.6 K/ μ L with 70 % segmented neutrophils, 10 % bands, and 12 % lymphocytes. Additional laboratory tests including blood/urine cultures, HIV, hepatitis panel, ehrlichia IgM/IgG, histoplasma antigen, HSV PCR, CMV PCR, ANA, and RPR were all negative. Despite the negative diagnostic testing, the patient was started on doxycycline due to a high suspicion for infection. Less than 48 h following admission, the patient

acutely decompensated, went into hypoxic respiratory failure, and was intubated. Further review of the admission peripheral blood smear revealed rare neutrophils with single basophilic intracytoplasmic inclusions highly suggestive of anaplasma morulae without intracytoplasmic monocyte inclusions. Doxycycline was continued. Within 48 h of intubation, the patient was extubated and reported feeling asymptomatic. He left the following day against medical advice. Anaplasma phagocytophilum was confirmed by polymerase chain reaction (PCR) more than a week after initially drawn.

DISCUSSION: Tick-borne diseases are an under-recognized cause of fever of unknown origin and accurate diagnosis requires documentation of a thorough and detailed history. It is critical to recognize that while antibody detection represents the gold standard of diagnosis, false negatives are frequently encountered during the initial (first week) of infection (polyvalent antibody sensitivity 82–100 %). PCR represents an alternative means of confirmatory test (sensitivity 67–90 %). However, the result is not readily available and thus cannot aid in immediate diagnosis. In patients with high-suspicion for tick-borne illness, further evidence for diagnosis can be provided by close re-examination of peripheral blood smears for the presence of morulae (stippled blue intracytoplasmic inclusions in neutrophils, present in 25–75 % reported cases in US, highest sensitivity during first week of infection). In patients highly suspected of carrying a tick-borne infection, doxycycline should be initiated early in the disease course. Doxycycline is not only a cheap and well-tolerated antibiotic, but also treats a variety of other tick-borne illnesses including Rickettsia and Borrelia spp.

GLIOMATOSIS CEREBRI AND THROMBOCYTOPENIA: A PREVIOUSLY UNKNOWN ASSOCIATION Sarah Nickoloff^{1,2}; Appesh Mohandas¹. ¹Medical College of Wisconsin, Milwaukee, WI; ²Zablocki VA Medical Center, Milwaukee, WI. (Tracking ID #1935835)

LEARNING OBJECTIVE 1: Recognize that gliomatosis cerebri may be associated with idiopathic thrombocytopenic purpura that is resistant to therapy with intravenous immune globulin.

LEARNING OBJECTIVE 2: Recognize the implications of gliomatosis cerebri associated thrombocytopenia on choice of therapy.

CASE: A 68 year old male with a past medical history significant for myotonic muscular dystrophy, first degree AV block and subsequent pacemaker implantation, initially presented with dizziness. CT head revealed a large infiltrative mass involving the right temporal and parietal lobes, with extension into the white matter. Neurosurgery was consulted and MRI was requested, but could not be performed due to pacemaker implantation. The patient was medically stable at that time and was discharged home. Approximately 1 month later he was readmitted for altered mental status. Labs on readmission were significant for a platelet count of 4,000/uL. Thrombotic thrombocytopenic purpura and other secondary causes, such as disseminated intravascular coagulation, sepsis, HIV infection and bone marrow disorders, were ruled out. The etiology of his thrombocytopenia was determined to be idiopathic thrombocytopenic purpura (ITP), likely related to his brain tumor. Treatment with intravenous immune globulin (IVIG) was initiated, however it was not as effective as expected. Following IVIG therapy, platelet levels would temporarily recover to greater than 40,000/uL but would then fall to pre-treatment levels within 4 to 5 days. The patient received three IVIG infusions during his hospitalization, without lasting effect. Definitive therapy for this patient was dependent upon better characterization of the intracranial mass. MRI was performed under a specialized protocol for patients with implanted pacemakers, and results were consistent with gliomatosis cerebri. Radiation oncology and hematology oncology services determined that chemo- or radiation therapy would not be of therapeutic or palliative benefit. The patient's mental status continued to decline, and he died on the inpatient hospice unit 18 days after admission.

DISCUSSION: Gliomatosis cerebri is a relatively rare clinical entity that is considered a high-grade glioma, and is associated with a very poor prognosis, typically measured in months. It often involves the majority of one brain hemisphere, but may affect both hemispheres, and diagnosis can be made with MRI. It is known that patients with central nervous system malignancies are at risk for developing bleeding disorders, however this is the first known case of a patient with concurrent ITP and gliomatosis cerebri. There is data to support treatment of gliomatosis cerebri with temozolamide and radiation, however high grade thrombocytopenia may occur in patients who receive temozolamide. Clinicians should be aware that gliomatosis cerebri may present with concurrent thrombocytopenia, which may impact treatment considerations.

GOOGLE IT: HYPERAMMONEMIA + ROUX-EN-Y Rohit Godbole¹; Susan Stein². ¹Olive View - UCLA Medical Center, Sylmar, CA; ²Olive View - UCLA Medical Center, Sylmar, CA. (Tracking ID #1938826)

LEARNING OBJECTIVE 1: Diagnose L-carnitine deficiency in a patient with altered mental status by using the internet

CASE: A 58 year old morbidly obese woman was admitted for nausea, vomiting, abdominal pain, and poor oral intake of food. The patient had a history of Roux-en-Y bypass surgery 10 years prior to admission to treat her obesity (BMI of 83). She had been admitted multiple times in the past year for the same chief complaint with diagnoses of chronic relapsing pancreatitis and gastric dysmotility. BMI at this admission was 50. She complained of generalized weakness but otherwise appeared comfortable. After admission, she was awaiting placement of a jejunostomy tube for nutritional support. On hospital day 30, she suddenly became less responsive and the rapid response team was called. Her O₂ saturation was 80 %, heart rate was 160 beats per minute, and finger stick glucose was 25 mg/dL. Fifty grams of glucose was administered by IV push and the patient became more responsive but did not return to baseline mental status. She aroused to voice but could not follow any commands. Neurological exam was non-focal other than diffuse muscular weakness. The patient was transferred to the ICU, started on empiric antibiotics for sepsis and heparin drip for a possible pulmonary embolus given a prior history of VTE. Basic chemistry, lactate, liver function tests, TSH, venous blood gases, blood and urine cultures were normal. An ammonia level was sent due to persistent altered mental status and was elevated at 119 μmol/L (ref 9–35 μmol/L). Over the next day, the patient remained altered and an encephalopathy due to metabolic derangement was suspected. Multi-vitamin and thiamine infusions were administered. Lactulose was started given the hyperammonemia but led to no discernible clinical improvement. At this point, work-up for altered mental status (AMS) had included ruling out infections, cerebrovascular events, myocardial infarction, endocrine abnormalities, and common metabolic and toxic insults. Once we had exhausted a number of options for diagnosis, we conducted an internet search using Google as our primary search engine. We entered the keywords “hyperammonemia + Roux-en-Y” into Google search, which revealed a case report with striking similarities to ours: a case of hyperammonemic encephalopathy that was caused by L-carnitine deficiency, as well as several reports of refractory hyperammonemia in Roux-en-Y cases resulting in death. As a result of our search, we provided intravenous L-carnitine repletion and our patient’s mental status improved to baseline over the next several days. The total L-carnitine level prior to infusion was 15 μmol/L (ref 25–58 μmol/L) and free L-carnitine level was 6 μmol/L (ref 19–48 μmol/L) while 1 week post-infusion total L-carnitine level was 81 μmol/L and free was 70 μmol/L. The initial ammonia level of 119 μmol/L improved to 66 μmol/L after L-carnitine infusion.

DISCUSSION: After a search for common causes of AMS failed to reveal a specific etiology, we discovered a case report on the internet with similarities that led to the diagnosis. Both the case report patient and our patient had (1) a history of Roux-en-Y gastric bypass several years prior complicated by recurrent pancreatitis, (2) acute onset of altered mental status with diffuse muscular weakness, (3) low carnitine (total and free) level with hyperammonemia, (4) improvement in AMS with L-carnitine intravenous infusion, and (5) improvement in ammonia level with L-carnitine infusion. Primary L-carnitine deficiency is well recognized in pediatric literature however the disorder, primary or secondary, is not commonly described in general internal medicine literature. L-carnitine is involved in the transfer of fatty acids into mitochondria for beta oxidation and deficiency can lead to muscular weakness and encephalopathy as seen in this patient. Our case lends further evidence for secondary L-carnitine deficiency as a cause of hyperammonemic encephalopathy in a patient with prior Roux-en-Y bypass surgery complicated by chronic pancreatitis and poor nutritional status. It is noteworthy that the case report referenced was listed second on the list of search results, making it extraordinarily relevant. A simple Google search likely saved our patient’s life.

GROUP B STREPTOCOCCAL LEAD-ASSOCIATED ENDOCARDITIS IN A POORLY CONTROLLED DIABETIC Ilya Karagodin; Krutika Kuppalli; Marcie Berger. Medical College of Wisconsin, Milwaukee, WI. (*Tracking ID #1934824*)

LEARNING OBJECTIVE 1: To manage and treat the risk factors that predispose patients to Group B Strep endocarditis.

LEARNING OBJECTIVE 2: To recognize the most common complications and sequelae of GBS endocarditis, as well as associated mortality rates.

CASE: Group B Strep (GBS) endocarditis, caused by the bacteria Streptococcus Agalactiae, is a rare infection traditionally thought to be a newborn disease. In recent years, the incidence of GBS endocarditis has been rising, particularly in the elderly and the immunocompromised. Populations at particular risk are patients suffering from diabetes, liver disease, alcoholism, cancer, COPD, urinary tract disease, chronic kidney disease, or HIV infection. The infection typically arises in native valves, and usually causes rapid clinical deterioration and valve destruction. Complications associated with GBS endocarditis include embolic phenomena, cardiac abscesses and fistulas, and heart failure. Mortality due to GBS endocarditis is high, with reported rates of 35–50 %. We report on a case of GBS endocarditis in a 55-year-old African-American male with a history of poorly controlled Type II Diabetes Mellitus, Stage 3 chronic kidney disease,

coronary artery disease, ischemic cardiomyopathy (LVEF = 30–34 %), and NYHA Class II heart failure s/p single-chamber AICD placement for primary prevention 7 months prior to presentation. Ten days prior to presentation, the patient underwent surgical amputation of his right fifth toe due to gangrene and suspected osteomyelitis. The patient was subsequently admitted to the hospital for fever and abdominal pain, and found to have acute appendicitis. He underwent laparoscopic appendectomy, and following surgery, was found to have two positive blood cultures for Group B Strep. The patient was started on IV Ceftriaxone. Transesophageal echocardiogram showed a large, mobile cystic structure (2.4×1.1 cm) in the right ventricle that appeared to be attached to the right ventricular AICD lead. In addition, there was a small echodensity noted on the AICD wire as it crossed the tricuspid annulus, as well as mild tricuspid regurgitation. The differential included vegetation, abscess, or thrombus. At this point, IV Gentamicin was added to the patient’s regimen. CT chest showed three focal areas of consolidation in the upper lobes of the lungs consistent with septic emboli. Electrophysiology was consulted and proceeded to explant the AICD capsule and extract the AICD lead. Both the capsule and distal lead were sent for culture, and came back negative for GBS. The patient was sent home on IV Ceftriaxone (6-week course) and IV Gentamicin (2-week course) in improved and stable condition.

DISCUSSION: Our patient’s co-morbidities, particularly his poorly controlled diabetes (HbA1C = 10.3) and Stage 3 chronic kidney disease, placed him at high risk for GBS bacteremia. We postulate that the source of our patient’s infection was his diabetic foot ulcer, and that following his right toe amputation, the Streptococcus Agalactiae bacteria spread hematogenously, finding a nidus for infection on the right ventricular AICD lead, leading to GBS endocarditis of the tricuspid valve, and ultimately embolizing to the upper lobes of the patient’s lungs. To the best of our knowledge, this is the first reported case of GBS endocarditis in a patient with an AICD device.

HAND SANITIZER: THE NEW VODKA? Livia Hegerova; John Eaton. Mayo Clinic, Rochester, MN. (*Tracking ID #1899672*)

LEARNING OBJECTIVE 1: Use of hand sanitizer as an infection control strategy has become ubiquitous amongst health-care workers and the general public. Unfortunately, a new epidemic has emerged of cheap and easily accessible hand sanitizer ingestion, which contains greater than 60 % ethyl alcohol. This dangerous trend of toxic ingestion has recently been reported amongst teenagers in emergency rooms across the nation. Our institution treated multiple cases of hand sanitizer ingestion that required intensive level care and intubation.

CASE: Police brought a 50 year-old woman with past history significant for heavy alcohol use into emergency department after she was found inebriated lying in feces. Blood ETOH level in admission was 353 mg/dL, lactate 4.5 mmol/L, and she had a metabolic acidosis with anion gap of 15. CT head was performed which was negative for acute process. Upon awakening, she admitted to binging on wine prior to the episode. Her systolic blood pressure was in 90s after fluid resuscitation, thus she was transferred to ICU for concern of possible sepsis. Blood and urine cultures were negative, antibiotics were discontinued, and she was transferred back to the general floor service. A few hours after transfer to the medical floor, she was found to be unresponsive with incontinence of bowel and bladder. Her obtundation required intubation and transfer back to the ICU. CT head #2 again showed no acute process. Her spell was thought to be due to ETOH withdrawal seizure. She had no further episodes, was extubated and transferred out of intensive care. The next day, she was unresponsive and hypotensive once again. For the third time she was transported to the ICU and CT head #3 was negative. Interestingly, blood ETOH level was 369 mg/dL, which was curiously higher than her admission ETOH. It was noted that the bottle of instant hand sanitizer in the patient’s room was opened and empty lying near the bed.

DISCUSSION: Alcohol gel hand sanitizer in 70 % ethyl alcohol by volume and also contains isopropyl alcohol, hydroxyethyl urea, isopropyl myristate, and propylene glycol. Its widespread use has been shown to decrease infection rates in health-care settings. However, dispensers should be such that they do not allow removal and bedside ingestion by patients. Ingestion leads to a metabolic acidosis and lactate elevation consistent with acute ethyl alcohol and isopropyl alcohol ingestion. Physicians and public health officials may also consider warning parents of young people to watch for danger signs of over-the-counter cleanser ingestion.

HAPPENED IN MY SLE-EP—LUPUS MYELITIS Mike Butterfield; Sarah Tribune; Kate Hust. Tulane University Health Sciences Center, New Orleans, LA. (*Tracking ID #1925923*)

LEARNING OBJECTIVE 1: Generate differential diagnosis for symmetric lower extremity weakness.

LEARNING OBJECTIVE 2: Recognize the clinical presentation of transverse myelitis as a classic, though rare, neurologic manifestation of systemic lupus erythematosus.

CASE: A 21-year-old man with a year-long history of rash presented with bilateral leg weakness, first noticed upon waking 3 weeks prior. Its severity was unchanged over time, and the patient was able to ambulate with difficulty. He noted an unintentional 30-lb weight loss over the preceding month. Medical history was otherwise notable for hypertension diagnosed 2 weeks earlier, with initiation of a combination anti-hypertensive medication. On examination, blood pressure was 157/89 mmHg and pulse 103 beats/min. Neurologic examination was significant for proximal leg weakness (3+/5), diffuse hyperreflexia (3+), bilateral upgoing plantar reflexes, and ataxia with heel-toe gait. He had a pink, rectangular patch on his posterior neck, faded patches on his dorsal forearms, and soft, non-tender pretibial nodules. Initial laboratory workup revealed mild pancytopenia and low reticulocyte count. Creatinine was 1.51 mg/dL, and urinalysis revealed hematuria with moderate proteinuria. ESR was 72 mm/h, CRP <0.50 mg/dL, and complement levels were low. T2 MRI of the cervical spine showed hyper-intensities at C1-2 and C5-6 levels. Anti-cardiolipin IgG, ANA and anti-dsDNA were positive, the latter two with high titers.

DISCUSSION: Internists commonly encounter weakness in clinical practice. Having a thorough approach is important to initiate appropriate management. The acute presentation of symmetric lower extremity weakness prompts a broad differential diagnosis, as pathology may be present anywhere from the spinal cord "on down"—the anterior horn, neuromuscular junction, peripheral nerves, or leg musculature. The presence of upper motor neuron signs should greatly assist in focusing the differential on spinal cord disorders. Transverse myelitis (TM), multiple sclerosis (MS), and space-occupying lesions are among the most concerning etiologies. If associated with autonomic symptoms (e.g. bowel or bladder incontinence), such findings should raise concern for cauda equina syndrome. Neuropsychiatric sequelae complicate over 60 % of cases of systemic lupus erythematosus (SLE), and are included among the diagnostic criteria for the disease. Transverse myelitis, an inflammatory disorder of the spinal cord, is a rare but classic manifestation of SLE (1–2 % of cases). Along with more common neurologic complications of lupus such as cerebrovascular disease and seizures, there is a strong association between TM and antiphospholipid antibodies, though their role remains controversial. The typical presentation of TM is an acute onset of motor and sensory deficits below the level of the lesion, sometimes associated with autonomic dysfunction. Though complete lesions occur, partial cord inflammation is more common; motor symptoms may exist in absence of sensory deficits or vice versa. MRI showing high-signal lesions with cord edema, typically on T2 imaging, is diagnostic. Intravenous corticosteroids are given to treat lupus-associated TM acutely, while plasmapheresis may be initiated in refractory cases. Prognosis is variable, with complete recovery occurring in approximately 50 % of patients, partial recovery in 30 %, and no improvement or clinical deterioration in the remaining 20 %.

H B V - A S S O C I A T E D C R Y O G L O B U L I N E M I A W I T H M E M B R A N O P R O L I F E R A T I V E G L O M E R U L O N E P H R I T I S Akane Ryu; Christine Kwan; Yoshinosuke Shimamura; Koichi Hasegawa; Norihito Moniwa; Hideki Takizawa. Teine Keijinkai Hospital, Sapporo, Japan. (Tracking ID #1937444)

LEARNING OBJECTIVE 1: Recognize that hepatitis B virus (HBV), not just hepatitis C virus (HCV), can also cause cryoglobulinemia

LEARNING OBJECTIVE 2: Treat mixed cryoglobulinemia (MC) in a multi-step approach based on its pathology

CASE: A 65-year-old Asian woman presents with proteinuria and elevated creatinine (Cr) on labs. She also has associated rash and edema on her bilateral legs \times 5 years. She has no other symptoms. The patient's past medical history includes latent HBV infection and hypertension for which she takes olmesartan, hydrochlorothiazide, and amlodipine. She does not use tobacco, alcohol, or recreational drugs. Her family history is insignificant. On physical exam, the patient's vital signs include temperature = 37 °C, heart rate = 84, blood pressure = 158/84, respiratory rate = 16, and O₂ saturation = 100 % room air. She appears in no acute distress; alert/oriented \times 3. Jugular venous pressure = 5cmH2O. Bilateral lower extremities have pitting edema up to knees and multiple scattered 1–3 mm dark red, round purpura. The rest of the exam shows no irregularities. Abnormal laboratory results include hemoglobin 8.9 g/dL, albumin 2.9 g/dL, Cr 1.6 mg/dL (baseline 0.85 mg/dL), proteinuria (2.74 g/24 h), and hematuria (>100 red blood cells/high power field). Cryoglobulins and rheumatoid factor are positive with hypocomplementemia (C3 0.45 g/L-normal range 0.8–2.14 g/L and C4 0.06 g/L-normal range 0.13–0.6 g/L). Serum kappa:lambda ratio is 5 (normal range 0.26–1.65). HCV-RNA is negative while HBV surface/core/e- antibody are positive but negative HBV surface/e- antigen and viral load. Renal biopsy shows membranoproliferative glomerulonephritis (MG) with hyaline thrombus in the glomerulocapillary, consistent with cryoglobulinemic glomerulonephritis. Skin biopsy of the purpura reveals leukocytoclastic vasculitis. Bone marrow and inguinal lymph

node biopsies show B-cell lymphocytic infiltration suggestive of lymphoproliferative disease. According to the results, a diagnosis of MC vasculitis with MG due to HBV infection causing B-cell proliferation is made, and treatment is initiated with methylprednisolone and rituximab. Meanwhile, her HBV load turns positive (<2.1 log copies/mL), and entecavir is started. Her purpura, edema, and proteinuria gradually improve (0.64 g/day), but her renal function does not completely return to baseline. HBV load becomes undetectable 5 months later.

DISCUSSION: Cryoglobulinemia is a disease characterized by immunoglobulins that are soluble at 37 °C but precipitate in the cold, even in the microvasculature, and usually associated with inflammatory manifestations in the vessel walls. In type I cryoglobulinemia, a monoclonal immunoglobulin exists while in types II and III, called MC, a polyclonal immunoglobulin G (IgG) and an immunoglobulin M (IgM) with rheumatoid factor activity exist, the latter of which is either monoclonal in type II or polyclonal in type III. MC is often associated with HCV infection but less commonly with HBV. Few cases of cryoglobulinemia with HBV infection have been reported, so conventional treatment of HBV-associated cryoglobulinemia is not yet standardized. In this case, based on the pathology of HBV-associated MC, the patient receives multi-step treatment: antiviral therapy for suppressing HBV activation and stopping B-cell proliferation and steroid for controlling MC nephritis.

H E M A T E M E S I S : M O R E T H A N M E E T S T H E E Y E Robert Mocharl; Natalie Spaccarelli; Michael Janjigian; Douglas Bails. NYU School of Medicine, New York City, NY. (Tracking ID #1938941)

LEARNING OBJECTIVE 1: Recognize deviations from common clinical presentations that may indicate additional or alternate pathology.

LEARNING OBJECTIVE 2: Investigate abnormal diagnostic tests that are not explained by a working diagnosis.

CASE: A 22-year-old woman with no past medical history presented to the emergency department after an episode of hematemesis. One hour after drinking 2 alcoholic beverages, she began to retch and soon vomited non-bloody gastric contents. Minutes later, she vomited frank blood. She denied abdominal discomfort prior to or during the events. She denied using any medications, including non-steroidal anti-inflammatory agents. Her alcohol intake was limited to 1–2 drinks once monthly. She denied a family history of hematologic or gastrointestinal diseases. She reported an identical event 3 months prior that was not preceded by retching. Her initial physical examination was notable for a heart rate of 114 and pallor. The rest of the examination was normal. Laboratory testing revealed a pancytopenia (white blood cells 3,700, hemoglobin 8.6 g/dL, platelets 40,000), decreased total protein of 5.6 g/dL and albumin 3.0 g/dL (otherwise normal liver function tests), elevated INR of 1.49 and aPTT of 41.9 s. Emergent endoscopic evaluation revealed 2 columns of non-bleeding esophageal varices and diffuse petechial hemorrhage throughout the gastric mucosa. Abdominal ultrasound revealed a cirrhotic liver with normal biliary tree and no evidence of portal or splenic venous thrombosis. Additional examination and laboratory testing directed toward causes of cirrhosis revealed brownish rings in the corneal limbus (visible to the naked eye) and a low ceruloplasmin level of 5.9 mg/dL. Ophthalmologic slit-lamp examination confirmed the presence of Kayser-Fleischer rings and sunflower cataracts, establishing the new diagnosis of Wilson's Disease (also known as Hepatolenticular Degeneration). The patient had no further episodes of hematemesis and was referred for copper chelation treatment.

DISCUSSION: Hematemesis is a common presentation encountered by clinicians. As this clinical entity can be the end result of a myriad of underlying pathology, possible diagnoses included in its differential diagnosis are many. In order to aid in a rapid and accurate diagnosis, clinicians are guided by the clinical context in which the event occurred, known medical history, and epidemiological characteristics. For our patient, experience with otherwise young and healthy individuals would usually dictate more benign causes of hematemesis (i.e. Mallory-Weiss tears, Peptic Ulcer Disease, Gastritis, etc.). However, her clinical presentation and history did not conform purely with what would be expected from these benign conditions. Particularly, she did not report repeated instances of dry retching or non-bloody emesis prior to hematemesis as would be expected with Mallory-Weiss tears. Additionally, she provided no symptoms to suggest a subacute or chronic gastrointestinal illness as may be expected with ulcerative disease or gastritis. Her history of a similar event (and with no preceding retching or non-bloody emesis) also was not easily explained if attributing her disease to a benign condition. Due to these clinical inconsistencies, we found it prudent to broaden our differential to include more chronic and serious pathology. With laboratory data showing pancytopenia and impaired synthetic liver function, we further suspected serious underlying pathology. Once it became evident that our patient exhibited cirrhosis at such a young age, we shifted our differential entirely and eventually arrived at the diagnosis of Wilson's Disease. Wilson's Disease, or Hepatolenticular Degeneration, is an exceedingly rare

cause of cirrhosis and hematemesis. It is an autosomal recessive disease estimated to affect 30 per 1,000,000 individuals. It is characterized by impaired copper excretion and resultant deposition throughout the body, with a predilection for hepatic and neurologic structures. Patients generally present from age 20–40 with evidence of hepatic damage or dysfunction. Evidence of neuropsychiatric involvement usually manifests later in the course. Although investigation of hematemesis will rarely result in a new diagnosis of Wilson's Disease, the points illustrated above are applicable to any clinical evaluation. Our patient's history and laboratory data simply could not easily be grouped and explained by diagnoses normally expected among otherwise healthy patients of her age. A critical component of rapid and accurate diagnosis involves pattern recognition, but it is equally important to recognize deviations from these patterns and investigate them thoroughly. HEMOLYTIC ANEMIA IN CHRONIC HEPATITIS C: ROLE OF RIBAVIRIN AND INTERFERON Dipenkumar Modi; Hirva Mamdani; Diane L. Levine. Wayne State University, Detroit, MI. (*Tracking ID #1939118*)

LEARNING OBJECTIVE 1: To recognize ribavirin as one of the causes of anemia in patients receiving therapy for chronic hepatitis C

LEARNING OBJECTIVE 2: To recognize key aspects of managing anemia in patients on treatment for chronic hepatitis C

CASE: A 64 y/o African American woman with past medical history of chronic hepatitis C, and Iatrogenic hypothyroidism secondary to RAI ablation for Graves' disease was admitted for severe anemia with hemoglobin of 4.8. Patient complained of significant fatigue, weakness and light headedness immediately after getting up from bed over couple of months prior to presentation. She was also feeling chest discomfort, worsening exertional dyspnea and palpitations over 3–4 weeks duration. Vitals showed no fever but marked tachycardia and hypotension. On physical examination, patient was profoundly pale. She had known Hepatitis C, Group 1a genotype, G1/S2 liver disease with fibrosis of 72. She had been on week 40 of Hepatitis C therapy with Ribavirin 1200 mg/day and Pegylated INF 180mcg/week with first 12 weeks of Telaprevir therapy. Laboratory findings showed severe anemia (hemoglobin 4.8 g/dl), normal MCV (90.2FL), normochromia (MCH 29.3 pg), leukopenia (WBC 1.7 K/CUMM), and thrombocytopenia (platelets 107 K/CUMM). Hemolytic work up showed elevated LDH (464Units/l) level, severely reduced haptoglobin (<8 mg/dl), but disproportionately low reticulocyte count (1.7 %; 26,900/ CUMM). She had negative coombs' test, normal vitamin B12 and folic acid levels. Iron studies showed elevated Iron (259mcg/dl), ferritin (1750 ng/ml), Iron saturation (87 %) and normal Iron binding capacity (297mcg/dl). Baseline HCV PCR 14,630,419 IU/ml; <43 at 4 weeks, and undetectable at 8, 12, 24 & 36 weeks. Based on above laboratory findings and active Hepatitis C treatment history, diagnosis of anemia secondary to Ribavirin induced hemolysis and Interferon induced bone marrow suppression was made.

DISCUSSION: Hepatitis C virus (HCV) infection is a major cause of chronic liver disease, leading to cirrhosis, end-stage liver disease, and hepatocellular carcinoma. Combination therapy with Ribavirin (RBV) and Interferon (IFN) is associated with higher rates of sustained virological, biochemical, and histological response compared to IFN monotherapy with improved response rates 42 to 46 % for patients with genotype 1 and 76 to 82 % for patients with genotypes 2 and 3. Hemolytic anemia is a major concern of treatment with Ribavirin. Anemia mainly results from increased RBC turnover with relative ATP deficiency and increased susceptibility to oxidative damage. Ribavirin is predominantly accumulated in Erythrocytes where it is principally phosphorylated by adenosine kinase into Ribavirin phosphates (monophosphate, diphosphate, and triphosphate). Ribavirin phosphates are unable to cross erythrocytes membrane. Overall the resultant effect would be an accumulation of Ribavirin and its active metabolites in erythrocytes which eliminate very slowly from Erythrocytes (half-life 40 days). After accumulation of Active triphosphate metabolites in erythrocytes, deficiency of adenosine triphosphate (ATP) in erythrocytes occurs. The low ATP level might indirectly affect the antioxidant defense mechanisms, by decreasing hexokinase-mediated production of glucose 6-phosphate. Genetic variants leading to ITPA deficiency protect against hemolytic anemia in HCV-infected patients receiving RBV. Interferon alfa contributes to hepatitis C treatment-induced anemia by directly inhibiting erythropoiesis by suppressing the proliferation of erythroid progenitor cells. Because bone marrow suppression caused by interferon prevents an adequate reticulocyte response, a compensatory reticulocytosis is often impaired in response to ribavirin induced hemolysis. The standard-of-care management of ribavirin induced anemia has been dose reduction to 600 mg/d when the hemoglobin level decreases to <10 g/dL. However, if the hemoglobin level remains <10 g/dL after RBV dosage reduction, the administration of EPO should be considered as well as reducing the dosage of pegy

interferon to 1.0 mg/kg/week, especially if the reticulocyte counts are low. If RBV is permanently discontinued for management of anemia, then pegy interferon alfa and boceprevir must also be discontinued. Once the hemoglobin level is >10 g/dL, the dosage of RBV should be increased in 200 mg/d steps to a dosage less than the initial dosage of RBV. Once the hemoglobin level is >11 g/dL, the administration of EPO should be discontinued. It is important to recognize ribavirin as one of the causes of anemia in patients receiving therapy for chronic hepatitis C. Absence of brisk reticulocyte response should not preclude the diagnosis of ribavirin induced hemolysis because of co-administration of Interferon-alpha.

HEMOLYTIC ANEMIA IN PREGNANCY Ragavi Elangovan. UCR SOM, Riverside, CA. (*Tracking ID #1939855*)

LEARNING OBJECTIVE 1: Identify high risk complications of paroxysmal nocturnal hemoglobinuria (PNH) and provide appropriate management.

LEARNING OBJECTIVE 2: Recognize clinical situations in which the benefits of eculizumab will outweigh the risks.

CASE: 23 year old female P0G1A0 at 23 weeks gestation presents to ER with headache, right lower extremity weakness and foot drop for 2 days. Platelet count upon presentation was 45. LDH, indirect bilirubin, and reticulocyte count were elevated. Coomb's test was negative, and peripheral smear was also negative for schistocytes. Blood test for ADAMST13 protease activity was drawn upon admission. Presumptive diagnosis of thrombotic thrombocytopenic purpura (TTP) was made and patient was treated with plasmapheresis and steroids for 5 days. LDH declined but platelet count failed to improve. MRI of the brain revealed dural venous sinus thrombosis. Flow cytometry was done which revealed deficiency in CD 55/59 proteins and diagnosis of paroxysmal nocturnal hemoglobinuria (PNH) was made. ADAMST13 test returned as 95 % normal, therefore plasmapheresis and steroid treatment were discontinued. Patient was vaccinated against meningitis, and started on prophylactic penicillin, enoxaparin, and weekly eculizumab after extensive review of the Class C drug with colleagues and discussion with patient. Patient was followed by hematology and obstetrics for the rest of her pregnancy. She delivered a healthy baby at 38 weeks gestation via C-section. Patient will continue eculizumab and enoxaparin indefinitely.

DISCUSSION: PNH is a rare disease affecting 3000–6000 Americans with an incidence of 1.3 per million each year. Median age of onset is in thirties. PNH is a disorder characterized by an abnormality in PIG-A gene which leads to absence of complement regulatory proteins CD 55 and CD 59, with resulting increased sensitivity of red blood cells to hemolytic action of complement. Diagnosis is made with flow cytometry which reveals missing CD 55 and CD 59 proteins. PNH increases morbidity and mortality of the mother and fetus. Several complications may present in PNH including thrombocytopenia, smooth muscle dystonia, renal insufficiency, bone marrow failure, and thrombotic events. Thrombosis is the leading cause of death in PNH patients and this risk is increased in pregnancy. Anticoagulation with low molecular weight heparin (LMWH) is necessary if history of prior episode of thrombosis is present, if recurrent late fetal losses have occurred, or if PNH clone is >50 %. Treatment with eculizumab for patients with PNH has shown to decrease intravascular hemolysis and thrombotic events. Eculizumab is a monoclonal antibody that binds to C5 and inhibits terminal complement activation. It is made of IgG2 and IgG4 heavy chain sequence. Although IgG2 has minimal transmission, IgG does cross the placenta, and therefore eculizumab is a category C drug. There are no published studies on the use of eculizumab during pregnancy, so the decision to treat a pregnant patient with this drug must be made on a case by case basis. Smooth muscle dystonia, resulting from depletion of nitric oxide from the ongoing hemolysis, may prevent the progression of labor, and only 30 % of women deliver vaginally. However, administration of this drug will decrease smooth muscle dystonia, decrease the risks of premature delivery, and increase the likelihood of a vaginal delivery. Use of Eculizumab in the third trimester for patients with increased risk of thrombotic complications may be a good option. Pregnancy is not recommended for women with PNH given the high risk of adverse outcomes. Pregnant women with PNH should be followed closely by a hematologist as well as an obstetrician.

HEMORRHOIDS AS A CAUSE OF SEVERE TRANSFUSION DEPENDENT IRON DEFICIENCY ANEMIA Venu M. Ganipiseti; Pratyusha Bollimunta; Malav P. Parikh; Harsh V. Gupta; Harvey Friedman. Presence Saint Francis Hospital, Evanston, IL. (*Tracking ID #1931908*)

LEARNING OBJECTIVE 1: Recognize that Hemorrhoids are a common source of lower GI bleeding; however, hemorrhoids causing bleeding that leads to severe transfusion dependent iron deficiency anemia is quite rare.

LEARNING OBJECTIVE 2: Recognize that other causes for anemia should be thoroughly evaluated before considering treatment for hemorrhoids.

CASE: A 61-year-old Indian female presented to our hospital with a low hemoglobin of 2.1 g/dl. She had an episode of bright red bleeding per rectum about 15 days prior to presentation. She reported a chronic history of anemia for about 12 years requiring several blood transfusions in the past. She had a history of multiple self-limiting rectal bleeding episodes for which she sought medical attention and underwent multiple endoscopic studies. She had multiple colonoscopies, EGDs, and small bowel studies (including capsule endoscopy, push enteroscopy, and Merkel cell scan), which were all negative except for the presence of hemorrhoids. She was advised to undergo surgery for hemorrhoids, which she refused. She had taken ferrous sulfate tablets for a few years, but she stopped taking them as they made her constipated. Other tests including for celiac disease, gynecological disorders and coagulation tests were negative. She had four caesarian sections in the past that were all uneventful, and she denied any family history of bleeding disorders. Over the last few months, she had experienced severe fatigue, exertional chest pain, shortness of breath, and bilateral leg swelling and heaviness. On labs, she had microcytic anemia with a MCV of 57.9 fL and iron studies suggestive of severe iron deficiency anemia with a ferritin level of 3 ng/ml. Upon admission, she was given five units of PRBC transfusion with which her hemoglobin (Hb) improved to 10.5 g/dl. She again complained of an episode of a small amount of bright red bleeding in her stool, and a colonoscopy was performed. The colonoscopy showed Grade 2 hemorrhoids and was negative otherwise. She underwent a hemorrhoidectomy under anesthesia. She was discharged on ferrous sulfate tablets and was asked to continue taking them for at least 1 to 2 years without any interruption. No further bleeding episodes have been reported. The follow-up of hemoglobin at 1 month showed it has remained stable, and our plan is to follow up on hemoglobin monthly for at least another 5 months.

DISCUSSION: Hemorrhoids are an extremely common source for rectal bleeding. Chronic hemorrhoidal bleeding can lead to iron deficiency anemia; however, massive amounts of bleeding leading to transfusion-dependent, iron deficiency anemia is quite rare. For example, a retrospective analysis done at two medical centers over a period of 15 years showed that the incidence of hemorrhoidal bleeding causing iron deficiency anemia was 0.5 patients per 100,000 population per year, and the mean Hb of the patients who were anemic before treatment in this study was 9.4 (± 0.97 SD). (1) It is imperative to exclude other causes before starting treatment for suspected hemorrhoidal bleeding. Only after thorough exclusion should the treatment of hemorrhoids begin. In our patient, a thorough evaluation over a period of at least 6 years did not show any other cause except for hemorrhoids. In these patients, transfusion independence and stable hemoglobin are expected after treatment. It is also important to follow up hemoglobin closely for a few months after treatment, and any further bleeding and/or drop in hemoglobin should be evaluated again. Reference: 1) Kluiber RM, Wolff BG. Evaluation of anemia caused by hemorrhoidal bleeding. Diseases of colon and rectum. 1994 Oct;37(10):1006-7.

HEPATIC SARCOIDOSIS PRESENTING AS CHYLOPERITONEUM Brett K. Sharpe; Atena Lodhi; Michael Schmalz; Kurt J. Pfeifer; Lawrence Ryan; Tessa Damm. Medical College of Wisconsin, Milwaukee, WI. (Tracking ID #1926911)

LEARNING OBJECTIVE 1: Identify chyloperitoneum as both a presentation and complication of sarcoidosis.

LEARNING OBJECTIVE 2: Describe the diagnosis and management of hepatic sarcoidosis.

CASE: A 38-year-old female of mixed ethnicity with partial empty sella syndrome presented for unintentional weight loss, early satiety, constipation, and abdominal pain. Physical examination was significant only for diffuse abdominal tenderness. Labs were notable for elevated transaminases and alkaline phosphatase. Abdominal ultrasound detected ascites with a partially-occlusive portal venous mass. CT confirmed a soft tissue mass encasing the celiac and mesenteric arteries with extensive retroperitoneal adenopathy. Hepatology and Oncology were consulted for suspected lymphoma, but CT-guided biopsy of a celiac axis lymph node was negative for malignancy. Wedge resection liver biopsy revealed well-formed granulomatous infiltration, multinucleated giant cells, steatosis, and no significant fibrosis. Focal granulomas showed central necrosis without geographic necrosis, caseating necrosis, dysplasia, or malignancy. Stains for acid fast bacilli and fungal organisms were negative, as was workup for common variable immunodeficiency (CVID) and immunoglobulin G4 (IgG4) disease. Serum angiotensin converting enzyme (ACE) levels were normal. One month after initial presentation, the patient returned with profound ascites. Rheumatology was consulted. Paracentesis drained yellow-white opaque fluid with a serum ascites-albumin gradient >1.1 , lymphocyte predominance, and no signs of infection. Visualization of the fluid prompted triglyceride analysis confirming chylous ascites. A presumptive diagnosis of hepatic sarcoidosis was made. No other organ systems were found to be symptomatically or radiographically involved to suggest widespread disease. The patient was started on medium chain

triglycerides, furosemide, spironolactone, and high-dose prednisone. Liver enzymes, including alkaline phosphatase, normalized over 3 months. Despite aggressive treatment and improvement in biomarkers, serial large-volume paracentesis was required for symptom management.

DISCUSSION: To our knowledge, this is the first reported case of chyloperitoneum as a manifestation of previously undiagnosed sarcoidosis. Epidemiologic data suggests that clinically significant gastrointestinal involvement occurs in less than 0.9 % of all sarcoidosis cases, though subclinical hepatic granulomas are common. While chylothorax is a well documented complication of systemic sarcoidosis, there remains a relative paucity of literature describing chyloperitoneum attributable to this disease. Moreover, this has only been reported in chronic, severe disease. Even more infrequent are cases of isolated hepatic and peritoneal sarcoidosis leading to chylous ascites. Identification of noncaseating granulomas on biopsy remains essential to the diagnosis of sarcoidosis. All other etiologies, including infectious (notably mycobacterium), malignancy, drugs, CVID, and IgG4 related disease should be effectively ruled out prior to making the diagnosis of gastrointestinal sarcoidosis. Corticosteroids endure as a mainstay of treatment for symptomatic gastrointestinal sarcoidosis, with Methotrexate being reserved for those intolerant or unresponsive to steroids.

HEPATIC SUBCAPSULAR BILOMA Larry J. McMann¹; Sayf Al-tabaqchal¹; McKenzie Thompson²; Azzat A. Ali^{1,2}. ¹Wayne State University School of Medicine, Rochester, MI; ²American University of the Caribbean School of Medicine, Cupecoy, Saint Martin (French part). (Tracking ID #1936978)

LEARNING OBJECTIVE 1: Recognize and diagnose biloma as a differential diagnosis of abdominal pain after laparoscopic cholecystectomy.

CASE: An 81-year-old male with a history of ischemic cardiomyopathy presented with epigastric pain and was admitted to our Internal Medicine service. He was found to have pancreatitis and had biliary sludge on abdominal ultrasound. He was scheduled for a laparoscopic cholecystectomy soon after resolution of his pancreatitis. The laparoscopic cholecystectomy was uneventful. He returned 7 days post-operatively with worsening right upper quadrant (RUQ) abdominal pain that radiated to his right shoulder. He had no other gastrointestinal or infectious symptoms. His comorbidities included chronic atrial fibrillation and ischemic cardiomyopathy with an implantable cardioverter-defibrillator (ICD). His medications included warfarin. He was afebrile. His physical exam was remarkable for exquisite RUQ tenderness but no guarding or rebound tenderness. Incision site was clean. His labs were notable for a direct bilirubin of 0.9 mg/dL, alkaline phosphatase of 230 u/L, International Normalization Ratio of 1.8 and leukocytosis of 20 thousand/mcL with a left shift. Computed Tomography (CT) of the Abdomen revealed a hepatic subcapsular fluid collection and was subsequently empirically started on ampicillin/sulbactam. Percutaneous drainage of the fluid collection under CT guidance, instantaneously drained 1.7 L with immediate pain relief. Fluid analysis revealed a bilirubin concentration of 20.6 mg/dL confirming the diagnosis of biloma. Fluid cultures had no growth. Attempts at localizing the leak were unsuccessful by endoscopic retrograde cholangiopancreatography (ERCP) and magnetic resonance cholangiopancreatography (MRCP) was contraindicated due to the presence of the ICD. The percutaneous drain output progressively declined over the course of 4 days indicating spontaneous resolution of the leak. A repeat CT scan showed complete resolution of the biloma. He was discharged home and seen in clinic a week later with no recurrence of symptoms.

DISCUSSION: Biloma is an extra biliary collection of bile. The incidence has become uncommon after the widespread acceptance, use as well as continued improvement in surgical technique in laparoscopy. Some studies suggest the incidence to be as low as 0.3 % to 0.6 %. Bile leakage usually originates from the cystic duct stump due to misplacement of the clips or injury of the common bile duct or accessory duct. Early CT or abdominal ultrasound to determine the extent of the bile leak can help. Standard cholangiographic techniques (ERCP & MRCP) usually cannot fill small bile ducts delineating the leak. Bile leakage may resolve by spontaneous sealing after percutaneous drainage. ERCP is therapeutic by allowing bile to run transpapillary rather than to allow extravasation at the site of the leak. Internists are commonly co-managing surgical complications. Biloma should remain on the broad differential diagnosis of abdominal pain after laparoscopic cholecystectomy. Reference #1: Pavlidis T, Atamatidis K, Papazogas B, Galanis I, Koutelidakis I, Papazogas T. Biloma after laparoscopic Cholecystectomy. Annals of Gastroenterology. 2002; 15(2), 178-180. Reference #2: Binmoeller KF, Katon RM, Shneidman R. Endoscopic management of postoperative biliary leaks: review of 77 cases and report of two cases with biloma formation. Am J Gastroenterol. 1991; 86(2):227-231.

HEPATITIS B VIRUS-ASSOCIATED CRYOGLOBULINEMIC NEPHRITIS Yoshinosuke Shimamura; Hideki Takizawa; Norihito Moniwa; Koichi Hasegawa. Teine Keijinkai Medical Center, Sapporo, Japan. (Tracking ID #1935339)

LEARNING OBJECTIVE 1: Highlights the benefit and efficacy of rituximab in association with antiviral therapy in small vessel vasculitis related to hepatitis B virus-associated cryoglobulinemia.

CASE: A 65-year-old Japanese female with histories of hypertension and chronic hepatitis B infection presents with a three-year of relapsing rash, and a three-month of proteinuria was admitted to hospital for further investigation. She has never smoked or used recreational drugs and only occasionally drinks beer. She has no family history of kidney diseases. On physical examination, blood pressure 158/84, pulse 84, and temperature 37.0° celcius. She had bilateral pitting edema of legs, extending up to her thighs. Raised purpuric lesions were noted on bilateral legs. The remainder of the physical examination, including neurologic examination was not significant. On her labs, significant values include blood urea nitrogen 35.8 mg/dL, and creatinine 1.6 mg/dL; decreased serum complement levels; and positive serum cryoglobulin. Urinalysis with microscopy reveals heme >100/high power field and dysmorphic red blood cells and urinary protein 2.7 g/day. A skin biopsy revealed leukocytoclastic vasculitis. Renal biopsy specimen included 28 glomeruli, one of which showed cellular crescents. Along with the findings of glomerular capillary endotheliosis, mild proliferation of mesangial cells and increase of mesangial matrix, diffuse segmental endocapillary hypercellularity with double contour, and intracapillary hyaline-like deposits were observed. Immunofluorescence staining demonstrated deposits of IgM and C3 in the glomerular basement region. Bone marrow biopsy revealed several lymphoplasmacytic aggregates, which were positive for CD20. Given her diagnosis of cryoglobulinemic vasculitis associated with HBV, she is given weekly rituximabx4 with subsequent oral prednisolone ×2 months with clinical improvement.

DISCUSSION: Mixed cryoglobulinemia (MC), type II and type III, refers to the presence of circulating cryoprecipitable immune complexes in the serum and manifests clinically by a classical triad of purpura, weakness, and arthralgias. In addition, it is associated with hepatitis C virus (HCV) infection and less common with hepatitis B virus infection (HBV). In recent study, efficacy of rituximab, a chimeric monoclonal antibody directed against CD20 antigen, is reported to treat patients that were refractory to conventional antiviral therapy in HCV-MC patients. However, both established treatments and efficacy of rituximab treatment for HBV-MC vasculitis are still unknown. We report here a case of HBV-MC vasculitis associated with lymphoproliferative disease, which was refractory to antiviral therapy but in which rituximab led to a decline in proteinuria and normalize renal function. In this case, we made two important clinical observations. First, rituximab significantly improves MC vasculitis and several clinical and immunologic parameters in patients with HBV-MC who had been resistant to standard immunosuppression therapies. Second, serum free light chain ratio would be a useful marker for response to rituximab therapy. To the best of our knowledge, the present case should be the first to demonstrate the usefulness of serum FLC ratio to monitor response to rituximab therapy in MC. Future controlled, randomized studies are needed to define the drug indications and the cost-efficacy profile in the different systemic features of the disease.

HEPATOCELLULAR CARCINOMA PRESENTING AS AN ACUTE INTRA-ABDOMINAL BLEED: A FATAL PRESENTATION Abhishek Matta^{1,3}; Abhilash Akinapelli¹; Pavan Tandra²; Savio Reddymasu³; Liyan Xu⁴; Theresa Townley¹; Jahnavi Koppala¹. ¹Creighton University Medical Center, Omaha, NE; ²University of Nebraska Medical Center, Omaha, NE; ³Creighton University Medical Center, Omaha, NE; ⁴Creighton University Medical Center, OMAHA, NE. (Tracking ID #1939192)

LEARNING OBJECTIVE 1: Intra-abdominal hemorrhage should be suspected early in patients with a history of liver cirrhosis who present with acute abdomen and hemodynamic instability and/or drop in hemoglobin.

LEARNING OBJECTIVE 2: Ultrasound abdomen or Contrast enhanced CT of the abdomen can identify intraabdominal bleed as well as a hepatic mass and such patients may benefit from transcatheter arterial embolisation or an emergency surgical intervention.

CASE: A 64 y/o African-American gentleman presented to the emergency room with acute non-radiating lower chest and epigastric pain for 6 h. He had a history of hypertension, hyperlipidemia, type 2 diabetes mellitus and Hepatitis C with cirrhosis. Blood pressure was 107/57 mmHg, heart rate 62/min, respiratory rate 18/min and temperature was 98.4oF at presentation. Physical examination revealed mild epigastric tenderness. Laboratory data revealed hemoglobin 11.4 g/dL, WBC 7×103/mcL, Platelets 74×103/mcL. Liver function tests were normal. Chest Xray was unremarkable. Three hours into the admission, the patient's abdominal pain suddenly worsened. His systolic blood pressure was 70 mmHg and heart rate was 110/min. Patient was resuscitated with fluids and started on norepinephrine drip. Laboratory data revealed a drop in hemoglobin to 5.6 g/dL. Nasogastric tube revealed no blood. Packed red blood cells transfusion was immediately initiated. He suffered cardiac

arrest and passed away on the way to the operating room despite aggressive resuscitation. Autopsy report revealed bleeding into the peritoneal cavity and a 3.5×3.0×2.5 cm ruptured, poorly circumscribed superficial tumor in the left lobe of the liver. Histopathology confirmed hepatocellular carcinoma (HCC) with well to moderately differentiated cells. The cause of death was determined to be massive hemoperitoneum secondary to ruptured HCC.

DISCUSSION: Hepatocellular Carcinoma (HCC) is the most common primary malignancy of the liver. Liver cancer in men is the fifth most frequently diagnosed cancer worldwide, and is the second leading cause of cancer-related death in the world. The spontaneous rupture of hepatocellular carcinoma occurs in 3–26 % of all HCC cases, is regarded as one of the most life-threatening conditions associated with HCC. The 30-day mortality ranges from 32 to 66.7 %. Various mechanisms have been proposed for spontaneous rupture of HCC including subcapsular localization, portal hypertension and regional increase of venous pressure due to obstruction of the venous outflow by direct tumor invasion, thrombocytopenia, coagulopathy due to altered prothrombin synthesis, trauma and central necrosis due to rapid tumor growth have been implicated in its Pathogenesis. HCC rupture with intra-abdominal bleed presents with acute epigastric or right upper quadrant pain, abdominal distension and signs of hemorrhagic shock. The diagnosis can be challenging in patients who present with rupture as the first manifestation of HCC and some cases may be misdiagnosed as acute appendicitis or perforated peptic ulcer. Laboratory data generally shows an acute drop in hemoglobin. Focussed abdominal sonography for trauma (FAST) can be performed in the emergency room and can aid in the rapid diagnosis of an intraabdominal bleed. CT abdomen can demonstrate the tumor and identify the high density intra-peritoneal free fluid suggestive of bleeding. Multiple options are available including transcatheter arterial embolization (TAE), surgery or a combination of TAE and staged hepatectomy. Surgical management includes hepatic segmentectomy with perihepatic packing, wedge resection with hepatic artery ligation and lobectomy. The consensus is that TAE followed by staged or delayed hepatectomy has the highest survival benefit and should be the procedure of choice. Patients who are poor candidates for surgery or TAE are managed conservatively.

HEPATOCELLULAR CARCINOMA SECONDARY TO METABOLIC SYNDROME: A MORBID ASSOCIATION FOR ALL PRACTITIONERS TO BE CONCERNED ABOUT Dovid Moradi; Faraj Faour; Alfred Burger. Beth Israel Medical Center, New York, NY. (Tracking ID #1932163)

LEARNING OBJECTIVE 1: Review the prevalence of hepatocellular carcinoma in the United States

LEARNING OBJECTIVE 2: Discuss the association of hepatocellular carcinoma and metabolic syndrome and recognize an emerging health risk associated with metabolic syndrome

CASE: An 82 year old Greek born female, who had been out of contact with an MD for 15 years but previously diagnosed with hypertension, hyperlipidemia, and obesity (BMI>30), was admitted after sustaining a slow fall to the ground. Physical exam was significant only for multiple ecchymosis on the right hip and elbows bilaterally. Labs showed a positive urinalysis, a T bili 3.3 mg/dL, alkphos 334 U/L, AST 138 U/L, ALT 102 U/L. A right upper quadrant ultrasound was ordered to evaluate the abnormal liver function tests and revealed multiple masses in the left hepatic lobe. A CT of the abdomen/pelvis confirmed masses extending from left to right hepatic lobes with portal vein occlusion. Testing was negative for hepatitis A, B, and C. INR was 1.1, alpha-Fetoprotein 48800 ng/mL, and CA19-9 77 U/mL. Liver biopsy showed carcinoma with clear cell features, favoring primary hepatocellular carcinoma (HCC) as the diagnosis. The patient was discharged to sub-acute rehab for her physical therapy and followed up as an outpatient with Oncology. It was determined she was not a candidate for chemotherapy due to ongoing poor functional performance; she was then referred to home hospice and passed away 7 weeks after diagnosis. Her initial fall was attributed to a sensitive E. Coli UTI treated with beta-lactam.

DISCUSSION: We present a case of HCC in a patient with non-alcoholic fatty liver disease (NAFLD) and the metabolic syndrome without other traditional high risk factors of HCC. Liver cancer is the fifth most common cancer in the United States and causes the third most cancer related deaths. Recently, Hepatology research has begun focusing on causes of HCC other than viral hepatitis and alcoholic cirrhosis. NAFLD is reported to be associated with up to 27 % of HCC cases in the United States. The prevalence of NAFLD is as high as 30 % in the general population and 90 % of those with morbid obesity (BMI>40). NAFLD is the direct result of chronic liver damage due to metabolic syndrome. According to the CDC, the prevalence of metabolic syndrome was 34 % in the United States from 2003 to 2006, affecting up to 100 million people. Metabolic Syndrome increases the risk of developing NAFLD 4–11

times. NAFLD increases the risk of developing HCC by 2.8 %. As Internal Medicine practitioners who routinely manage the epidemic of obesity and the metabolic syndrome on a daily basis, we must recognize the emerging and relatively newly described risk factor for HCC. Although screening guidelines have not yet been implemented for this population future efforts should be considered in this high risk population.

HEROIN LIES THE PROBLEM Sarah Moore; Catherine Firestein; Kate Hust. Tulane University Health Sciences Center, New Orleans, LA. (*Tracking ID #1924698*)

LEARNING OBJECTIVE 1: Develop a focused differential diagnosis for shortness of breath in patients with recent intranasal heroin use.

LEARNING OBJECTIVE 2: Recognize the clinical presentation of pulmonary edema and understand the treatment of non-cardiogenic pulmonary edema.

CASE: A 49-year-old man with history of asthma presented with acute shortness of breath. He endorsed a daily, non-productive cough with recently increased frequency. The patient had a ten-year history of daily heroin use, and he had snorted a bag of heroin earlier that day. On exam, his temperature was 103° Fahrenheit, heart rate 117 beats per minute, and oxygen saturation 80 % while breathing room air. Pulmonary exam revealed diffuse wheezing with decreased breath sounds in the right lower lobe. Laboratory data was significant for normal brain natriuretic peptide, negative troponin, and white blood cell count of 22,000/ μ L. Chest radiograph and computed tomography showed right-sided alveolar infiltrates. Initial treatment was for community-acquired pneumonia and an asthma exacerbation. Bi-level non-invasive ventilation was started for respiratory support given his low oxygen saturation and pulmonary edema seen on chest imaging. Over the next 2 days, his symptoms improved, he was weaned from respiratory support, and there was complete radiographic resolution of the pulmonary edema.

DISCUSSION: Internists often encounter shortness of breath; when it is accompanied by fever, hypoxia and infiltrate on chest x-ray, infectious etiologies are generally at the top of the differential. In drug users who snort or smoke the substance, it is important to consider a wide differential. Heroin users are susceptible to aspiration pneumonia, acute lung injury, pneumonitis, and non-cardiogenic pulmonary edema. Cocaine users are at risk for pulmonary alveolar infiltrates, pneumothorax, hypersensitivity pneumonitis, bronchiolitis obliterans and diffuse alveolar damage or hemorrhage. Pulmonary edema generally presents with severe dyspnea, frothy sputum production, and hypoxia. Chest x-ray shows alveolar edema, generally with bilateral peri-hilar infiltrates but may be lobar or unilateral. Echocardiogram and pulmonary capillary wedge pressure help differentiate cardiogenic from non-cardiogenic causes. Most patients require only supportive care for resolution of the pulmonary edema, but they may be treated with intravenous diuretics, non-invasive positive pressure ventilation or intubation as needed. Non-invasive positive pressure ventilation can help prevent carbon dioxide retention and assist oxygenation. Nitrate therapy may be considered if there is associated hypertension and inhaled beta agonists if there is concern for bronchospasm. Non-cardiogenic pulmonary edema is frequently seen in fatal heroin overdoses, and maintaining clinical suspicion for heroin lung is important for close patient monitoring. The key to establishing this diagnosis is rapid improvement in symptoms and resolution of infiltrate on chest x-ray, usually within hours to a few days. Further investigation into management of heroin-induced pulmonary edema would help physicians better treat heroin overdose and hopefully prevent future deaths. It is important for internists to consider the pulmonary complications of illicit substances as drug use remains prevalent in the community.

HIDA SCAN AS AN IMPORTANT TOOL FOR DIAGNOSIS OF BILIARY DUCTAL OBSTRUCTION IN THE PRESENCE OF A NORMAL ULTRASOUND Kaiming Wu; Esther Hwang; Anthony A. Donato. Reading Hospital, West Reading, PA. (*Tracking ID #1926870*)

LEARNING OBJECTIVE 1: Describe the utility of various imaging modalities in the early diagnosis of choledocholithiasis

CASE: The patient is a 25 year old woman with no significant past medical history who presented with complaint of several episodes right upper quadrant abdominal pain over the prior 2 days which had resolved at the time of her admission. On exam, her abdomen was soft and non-tender with no fever or jaundice. She had no elevation in white blood cell count but was found to have elevated transaminases with AST 601 mg/dl (normal: 10–38 mg/dl) and ALT 602 mg/dl (normal: 10–40 mg/dl) and elevated total bilirubin of 3.2 mg/dl (normal: 0.4–1.4 mg/dl) with a normal alkaline phosphatase of 107 units. A right upper quadrant ultrasound showed the presence of

gallstones within the gallbladder without evidence of cholecystitis and with a non-distended common bile duct (5 mm). Following admission, a surgical consultant ordered a hepatobiliary iminodiacetic acid (HIDA) scan, which showed non-visualization of both the gallbladder and the common bile duct at 1, 2, and 4 h, indicating an obstruction in the common bile duct. She subsequently underwent an ERCP, which retrieved multiple stone fragments and pus from the common bile duct. On day 3, she underwent a laparoscopic cholecystectomy. She tolerated both procedures well and has been asymptomatic on follow-up after discharge.

DISCUSSION: Acute biliary ductal obstruction is potentially life-threatening when choledocholithiasis results in ascending cholangitis and is thus important for the internist to diagnose accurately. In patients with symptoms and laboratory findings suggestive of biliary ductal obstruction, the initial imaging study of choice is a right upper quadrant ultrasound, which can often be diagnostic. However, the sensitivity of ultrasound for detecting choledocholithiasis in the presence of non-dilated ducts is only 50 %. Many cases of early obstruction may be missed with ultrasound alone, since normal bile duct size may be age dependent, and retained stones are found in 9.6 % of ducts 0–4 mm in width. HIDA scan is most frequently used after an inconclusive right upper quadrant ultrasound for the diagnosis of acute cholecystitis. However, HIDA also presents a more sensitive and specific means of diagnosis of early common bile duct obstruction in the face of clinical and laboratory signs of obstruction but a normal right upper quadrant ultrasound.

HIDDEN IN PLAIN SIGHT Devika Nair; Deepa Bhatnagar. Tulane University Health Sciences Center, New Orleans, LA. (*Tracking ID #1924986*)

LEARNING OBJECTIVE 1: Understand the clinical presentation and management of a rectus sheath hematoma

LEARNING OBJECTIVE 2: Know when to suspect rectus sheath hematomas in a patient with a declining hematocrit

CASE: A 65-year-old woman was discovered to have a hemoglobin drop from 9.1 g/dL to 7.2 g/dL in 24 h while in the intensive care unit. She was being cared for after suffering a myocardial infarction. Her course was complicated by new-onset atrial fibrillation, resulting in a prolonged ICU stay. Her medications included prednisone for Graves-disease related ophthalmopathy, clopidogrel, aspirin, and subcutaneous enoxaparin for deep venous thrombosis prophylaxis. Vital signs were as follows: temperature 98 F, heart rate 90 beats/min, blood pressure 132/90 mmHg, and respirations of 20/min with stable oxygen saturations. Exam revealed a palpable mass in the left lower quadrant that did not cross the midline as well as increased pain when the patient tensed her abdominal muscles. She had no visible areas of ecchymoses on her abdomen. Computed tomography of the abdomen and pelvis without contrast revealed heterogenous material in the patient's pelvis consistent with blood products, as well as an inferior left abdominal rectus sheath hematoma. Using Doppler ultrasonography, it was determined that the source of the bleed was the patient's inferior epigastric vein, which had been lacerated during a subcutaneous injection of enoxaparin. She was given transfusions of blood products, and external compression of the vessel was achieved using a bandage secured over her abdomen. Fortunately, her hemoglobin remained stable for the remainder of her hospital course.

DISCUSSION: Rectus sheath hematomas are an often-misdiagnosed cause of blood loss in the intensive care unit. The hematoma occurs when blood accumulates within the rectus abdominis sheath due to bleeding from lacerated inferior or superior epigastric vessels. Risk factors include subcutaneous injections, age, female sex, critical illness, previous paracentesis, and weakened connective tissue from chronic corticosteroid therapy. A study of 1257 patients admitted to the ICU at the Mayo Clinic in Jacksonville, FL revealed that 1.8 % had a previously misdiagnosed rectus sheath hematoma. Recent case reports suggest that with the increased use of anticoagulant therapy, these hematomas are becoming even more common. Fothergill's sign and Carnett's sign are physical exam findings useful in diagnosing rectus sheath hematomas. Fothergill's sign is positive when the patient has a mass that does not cross the midline and remains palpable when the rectus muscles are tensed. Carnett's sign occurs when a patient's abdominal pain is worsened by contraction of the rectus muscles. Both of these maneuvers help differentiate rectus sheath hematomas from intraabdominal pathologies. Currently, no definitive treatment guidelines exist. Typically, the hematomas are self-limiting, as the bleeding tamponades itself. Strategies consist of using external compression, embolization of the bleeding vessel, or surgical evacuation. Surgery has the potential hazard of worsening the hematoma due to reversing the naturally-occurring intra-abdominal tamponade. Patients should be evaluated on a case-by-case basis, and physicians should take comorbidities into account before proceeding with treatment. This case illustrates the importance of including rectus sheath hematomas on the differential for abdominal pain in critically-ill patients.

HIDING THE CROWN: CROWNED DENS SYNDROME MIMICKING ASEPTIC MENINGITIS IN AN ELDERLY WOMAN Akane Ryu; Christine Kwan. Teine Keijinkai Hospital, Sapporo, Japan. (*Tracking ID #1898238*)

LEARNING OBJECTIVE 1: Recognize that another cause of neck pain, headache, and fever in the elderly can be from crowned dens syndrome (CDS)

LEARNING OBJECTIVE 2: Appreciate the usefulness of a cervical computed tomography (CT) scan in diagnosing CDS

CASE: An 86-year-old Asian woman with a significant past medical history of hypertension and osteoarthritis presented with 1 day's history of acute-onset neck pain associated with headache. She described the posterior neck pain as constant throbbing, rated 10/10, non-radiating, not improved by anything, and worsened by movement. She reported a slightly higher temperature of 37.4 °C, but no other constitutional, neurologic, or rheumatologic symptoms. No sick contacts, visual changes, jaw claudication, or trauma. She did not have any medications, allergies, tobacco, alcohol, or recreational drug use; her family history was insignificant. On physical exam, the patient's vital signs included temperature = 37.4 °C, heart rate = 85 bpm, blood pressure = 150/80, respiratory rate = 16, and O₂ sat = 99 % room air. She appeared in no acute distress and alert/oriented ×3. Head and neck exam was significant for stiff neck, decreased active and passive range of motion (rotation, flexion, and extension), and tenderness to palpation over the cervical vertebrae. Neurological exam showed intact CN II–XII, intact sensation to touch and pain, motor strength 5/5 in all extremities, negative Kernig/Brudzinski signs, and 2+ reflexes. The rest of her exam showed no abnormalities. On labs, the patient's complete blood count and chemistry panel showed no abnormalities except for slightly elevated white blood cell count (WBC=10,770/µL) and elevation of C-reactive protein (CRP) (22 mg/dL). Cerebrospinal fluid (CSF) exam was within normal limits as was the cervical X-ray, head CT scan, and head magnetic resonance imaging. CDS was then suspected, so a cervical plain CT scan was done which revealed curvilinear calcifications of the transverse ligament of the atlas and crown-shaped calcium deposits surrounding the odontoid process. She was thus prescribed a nonsteroidal anti-inflammatory (naproxen 300 mg Qday) with relief of her symptoms within 1 week and normalized CRP.

DISCUSSION: Some typical causes of neck pain with possible fever and headache include meningitis, spondylitis, and polymyalgia rheumatica. While the above patient has acute onset of symptoms like in meningitis, she does not have altered mental status, and her CSF is normal. In addition, her time course is inconsistent with typical spondylitis and polymyalgia rheumatica. Crowned dens syndrome is characterized by acute neck pain in the elderly, especially women, and usually presents with radiodense deposits of hydroxyapatite or calcium pyrophosphate dihydrate in ligaments around the odontoid process, which create the appearance of a crown or halo surrounding the odontoid process on radiographic imaging. Evidence of inflammation, such as high CRP, is typical, as is a history of osteoarthritis. A short course of nonsteroidal anti-inflammatory medication usually completely alleviates symptoms. Given this woman's presentation, therefore, in patients complaining of neck pain, headache, and fever, but with a low likelihood of meningitis or rheumatologic diseases, recognize that CDS can also present with a similar picture, and use a cervical CT scan for diagnosis.

HOLD ON STILL! THINK BEFORE ACTING Jae Yoon Park¹; Louis Letendre².

¹Mayo Clinic, Rochester, MN; ²Mayo Clinic, Rochester, MN. (*Tracking ID #1936865*)

LEARNING OBJECTIVE 1: Recognize the clinical features of adult onset Still's disease

CASE: A 24-year-old woman with no significant medical history presented for evaluation of several weeks history of joint pains involving her wrists, ankles, and knees associated with daily fevers and evanescent rash. The symptoms began after an upper respiratory syndrome associated with sore throat, treated with empiric antibiotics. Initial conservative therapy with non-steroidal anti-inflammatory drugs had no benefit. With continued fevers and joint pain, she was admitted at outside institution and was found to have acute kidney injury, with biopsies suggestive of acute tubular necrosis. She was transferred to our institution for further care. On admission, physical exam demonstrated left axillary lymphadenopathy, an irregular erythematous patch on bilateral forearms, lacy reticular erythematous macules on abdomen, and no hepatosplenomegaly. Initial laboratory tests were remarkable for microcytic anemia, thrombocytopenia, mildly elevated transaminases [alkaline phosphatase 215 U/L (normal 37–98 U/L), aspartate and alanine aminotransferase 371 U/L and 561 U/L respectively (normal 7–45 U/L)], lactate dehydrogenase 1232 U/L (normal 122–222 U/L), C-reactive protein of 34 mg/L (normal <8 mg/dL), fibrinogen of 150 mg/dL (normal 200–430 mg/dL), triglyceride of 314 mg/dL

(normal <150 mg/dL), and hyperferritinemia to 40,000 mcg/L (normal 11–307 mcg/L). Infectious work-up including blood cultures and serologic tests were unremarkable. Autoimmune panel was negative. Given concern for hemophagocytic lymphohistiocytosis, she underwent bone marrow biopsy which demonstrated a hypocellular marrow with histiocytic infiltrates and hemophagocytosis. To further evaluate the left axillary lymphadenopathy, subsequent PET scan demonstrated hypermetabolic left neck and left axillary lymphadenopathy with mild uptake in several other lymph nodes. Subsequent left axillary lymph node biopsy was negative for evidence of lymphoma. As evaluations for infectious, neoplastic, and autoimmune disorders were unremarkable, her constellation of symptoms in setting of laboratory and pathology findings were felt to reflect adult onset Still's disease with a component of macrophage activation syndrome. She was initiated on glucocorticoids with improvements in her symptoms and was eventually started on methotrexate. At 6 month follow-up, her symptoms resolved with normalization of her blood counts, inflammatory markers and ferritin levels.

DISCUSSION: This demonstrates a rare case of adult onset Still's disease. In the setting of non-specific signs and symptoms, the differential must remain broad before reaching a final diagnosis and initiation of treatment. Still's disease is a rare multisystem inflammatory disorder characterized by daily fevers, evanescent rash, and arthritis. Yamaguchi criteria can be used after excluding infectious, neoplastic and autoimmune disorders. The initial treatment of choice in those with moderate or severe disease is glucocorticoids. Thus, in the appropriate clinical context of fevers, rash, and arthritis accompanied by supportive laboratory and clinical findings, Still's disease should be in the differential diagnoses.

HOLES IN THE TRACKS OF MY HEART: NEW ATRIOVENTRICULAR BLOCK AND PERIVALVULAR ABSCESS Merrill H. Stewart. Tulane University School of Medicine, New Orleans, LA. (*Tracking ID #1940172*)

LEARNING OBJECTIVE 1: Know the differential for new atrioventricular heart block

LEARNING OBJECTIVE 2: Understand the significance of a perivalvular aortic abscesses

CASE: A 56 year-old man was post-operative day 2 from a toe amputation secondary to gangrene when he began to develop new bradycardia with a heart rate to 35 beats per minute. He reported no chest pain, no shortness of breath, no pre-syncope, and no new symptoms since his surgery. He initially presented 2 days prior with a fever, diagnosed with gangrene, and treated with intravenous clindamycin for the past 72 h in addition to the toe amputation. On exam he was found to be afebrile with a blood pressure of 101/55 mmHg. His heart rate was 47 beats per minute, irregular, without any murmur or rub. Electrocardiogram initially showed a new second degree (Mobitz I) atrioventricular block, and 1 h later a complete atrioventricular block. Troponin was 3.480 ng/mL, and left heart catheterization showed known prior diffuse disease with one discrete lesion eligible for percutaneous trans-luminal coronary angioplasty in the saphenous venous graft to his right coronary artery. Transesophageal Echocardiography revealed several aortic valve vegetations with an aortic valve abscess and likely perforation into the right atrium. He was treated with continuous antibiotics and his heart block improved to a first-degree atrioventricular block after 5 days. A final determination as to his surgical candidacy was pending at the time of this writing.

DISCUSSION: While almost half of atrioventricular heart block cases are simply age-related fibrosis of the conduction system, there are many other etiologies on the differential that the internal medicine physician must always consider. The second leading cause is ischemic, with 20 % of post-myocardial infarction patients developing a heart block. However any cause of cardiomyopathy or myocardial irritation/infiltration can also lead to a heart block. These include hypertrophic cardiomyopathy, rheumatic fever, lyme disease, sarcoidosis, amyloidosis, lupus, viral myocarditis, and bacterial endocarditis as we see in our patient. The etiology of our patient's new heart block was either from direct abscess infiltration into the conduction system, or embolic vegetation into the coronary vasculature causing an ischemic event. Less common causes include familial heart block, hyperkalemia, thyroid dysfunction, neonatal lupus, hematologic malignancies, dermatomyositis, Paget's disease, and cardiac tumors. Perivalvular abscesses in bacterial endocarditis are relatively common, seen in approximately 30–40 % of cases. They are more often seen with prosthetic valves over native valves, and 20 % present with atrioventricular block versus 2 % in those without an abscess. Development of a new atrioventricular block with known endocarditis is 97 % specific for an abscess, and trans-esophageal

echocardiography detects 80–90 % of all abscesses. Detection of perivascular abscess is important in this population as 70 % end of requiring surgical intervention for persistent infection or heart failure versus 30 % in bacterial endocarditis without an abscess. Earlier detection can lead to sooner stratification and closer monitoring and is important to rule out when making the diagnosis of endocarditis.

HOW DEEP SHOULD YOUR FUNDOSCOPIC EXAM GO? A RARE CASE OF ENDOGENOUS ENDOPHTHALMITIS DUE TO KLEBSIELLA PNEUMONIAE Gargi Bajpayee; Jonathan Martin; Isabel Preeshagul; Jason Filopei; David Chun; Jose A. Cortes. Beth Israel Medical Center of Mount Sinai, New York, NY. (*Tracking ID #1939482*)

LEARNING OBJECTIVE 1: Recognize the difference between exogenous and endogenous endophthalmitis as well as its associated predisposing risk factors.

LEARNING OBJECTIVE 2: Understand that endogenous endophthalmitis is a medical emergency that requires prompt diagnosis and immediate treatment in order to prevent devastating outcomes.

CASE: A 60-year-old Japanese man with DM type II presented to the emergency department for left eye blindness. One day prior, he experienced fevers, chills, and flashes of light in his left eye that rapidly progressed to complete eye blindness. He denied any additional symptoms. On physical exam, his right eye was without deficits, while his left eye had extensive erythema, lacrimation, and zero visual acuity. The remainder of his physical exam was normal. Initial laboratory testing was unremarkable, including normal CBC, BMP, and liver enzymes. Fundoscopic exam exhibited dense vitritis and slit-lamp exam showed extensive inflammation of the anterior chamber and vitreous humor. A CT with IV contrast of the orbit revealed uveoscleral inflammation consistent with left eye endophthalmitis. He was promptly given intravitreous antibiotics and steroids. With no history of ocular trauma or surgery, an endogenous infection was suspected, and a CT abdomen and pelvis revealed a 3.5 cm hepatic abscess. The patient was started on systemic antibiotics with Vancomycin, Cefepime, and Metronidazole to cover the most common intra-abdominal and intra-ocular pathogens. Percutaneous drainage of the abscess was performed and cultures revealed pan-sensitive *K. pneumoniae*. In an attempt to restore visual function, the patient underwent left eye vitrectomy. Vitreous cultures also grew *K. pneumoniae*, confirming the liver abscess as the primary source for the patient's endophthalmitis. Following the surgery, the patient completed a 4 week course of intravenous ceftazidime and oral steroids. After this therapy, the patient regained light perception in his eye.

DISCUSSION: The majority of endophthalmitis cases are acquired infections from exogenous sources secondary to ocular trauma or surgery. Endogenous endophthalmitis, however, is exceedingly rare. We performed a literature search and found a single center retrospective chart review spanning 10 years that identified 28 cases of endogenous endophthalmitis. In the United States, patients with endogenous endophthalmitis usually have primary endocarditis caused by *S. pneumoniae* or *S. aureus*. In contrast, in Asia, 60 % of endogenous cases occur from a liver abscess growing *K. pneumoniae*, predominantly found in patients with DM type II. The standard therapy for endogenous endophthalmitis includes intravitreous and systemic antibiotics as well as vitrectomy. Although the effectiveness of vitrectomy is controversial, this aggressive procedure is utilized in most cases of severe vision loss. Fortunately for our patient, vitrectomy resulted in regaining light perception in the affected eye. Our case highlights the need to suspect and recognize the common causes of endogenous endophthalmitis. The cause of endogenous endophthalmitis is greatly dependent on whom you are treating. Given the large non-continental US population many internists may care for, it is important to understand that a sub-acute liver abscess is a prevalent source in Asian patients with DM type II. This information can help minimize the diagnostic work-up entailed in identifying a source resulting in lower cost and prompt therapy thus preventing the catastrophic sequela of blindness.

HOW MANY LICKS DOES IT TAKE? AN UNUSUAL CASE OF BACTEREMIA Andrew Ip; Abeer Memon; Robin Klein; Neil Winawer. Emory University, Atlanta, GA. (*Tracking ID #1927795*)

LEARNING OBJECTIVE 1: Recognize the presentation of *Pasteurella multocida* infections.

LEARNING OBJECTIVE 2: Appreciate the link between pet contact and *Pasteurella* infections.

CASE: A 53 year old African-American Male presents with bilateral leg pain. The patient reported pain and redness that had started around his knees and spread to his ankles bilaterally. The pain increased to the point where he was unable to ambulate.

Past medical history was notable for stage 4 chronic kidney disease, diastolic heart failure and diabetes mellitus. He was recently admitted 10 days prior for generalized anasarca that resulted in bilateral ulcers of the anterior legs. This improved on discharge with local wound care and diuresis. Review of systems was unremarkable and he denied any recent travel, bug bites, or animal bites. Exam revealed tachycardia but no fever. Lower extremities were edematous with pitting to his thighs. His anterior calves were warm and tender with erythema. There was no evidence of joint swelling. Two healed ulcers were noted on both his legs anteriorly with mild overlying erythema but no discharge. Laboratory work revealed a WBC of 14.4 with 88 % neutrophils. The patient was treated for cellulitis with vancomycin. Blood cultures grew *Pasteurella multocida*. Antibiotic coverage was changed to ceftazidime. On further questioning, our patient stated that despite not suffering any animal bites, he acknowledged that his two dogs did frequently lick his legs prior to the development of his pain. Repeat cultures were negative. The patient's lower extremity pain was slow to resolve but imaging of lower extremities only revealed soft tissue swelling. Patient was discharged after 2 weeks of ceftazidime.

DISCUSSION: *Pasteurella Multocida* is a gram negative coccobacilli commonly found in the oral cavity of healthy cats and dogs. It is best known for its association with cat and dog bites. *Pasteurella* infections most commonly present with skin or soft tissue involvement at the site of contact. Other clinical manifestations include upper respiratory infections, pneumonia, septic arthritis, osteomyelitis, and less commonly bacteremia. Complications due to inadequate treatment include tenosynovitis, osteomyelitis, and septic arthritis. There are multiple reported cases of infections following bites and scratches. Less common are reports of infection from contact through licking. Our patient had bilateral lower extremity cellulitis corresponding to areas where his dogs licked. In addition, the patient was found to be bacteremic with *Pasteurella*, which occurs in about 15 % of infections. Risk factors for this are multiple co-morbidities or underlying immune-compromise. In this case, our patient had both chronic kidney disease and diabetes mellitus. *Pasteurella* infections are very receptive to empiric therapy directed either towards a specific infection or in the setting of an animal bite. Second or third generation cephalosporin is recommended due to resistance of *Pasteurella Multocida* to first generation cephalosporins. Duration of therapy should be individualized, as treatment response may vary. This case highlights the importance of obtaining a complete social history including exposure to pet bites or saliva when presented with a case of cellulitis. Prompt recognition allows a clinician to effectively manage the complications of dog bites, or in our case, a dog lick.

HOW TO PREVENT MYOCARDIAL INFARCTION WITH VITAMIN SUPPLEMENTS Nadia El Hangouche; Samian Sulaiman; Muhammad Akbar. Presence Saint Francis Hospital, Evanston, IL. (*Tracking ID #1932360*)

LEARNING OBJECTIVE 1: Coronary artery disease is affecting young population increasingly. Physician should always keep the possibility of acute coronary syndrome among the differential for young patient presenting with chest pain

LEARNING OBJECTIVE 2: In case of acute coronary syndrome occurring in a young patient, physician should consider screening for uncommon risk factors including vitamin B12 deficiency.

CASE: A 30 y old male presented to the emergency department for chest pain. He had a vague history of vitamin deficiency and active smoking for the past 5 years. Chest pain was described as mild squeezing in the left precordial area that started 4 days ago, it lasts couple of minutes, occurs at rest, sometimes triggered by eating or smoking, and resolves spontaneously after 3 to 5 min. Physical exam at presentation was unremarkable and vitals were stable. On the ECG, there was T waves inversion and ST depression in apico lateral leads, that improved after resolution of the chest pain. Cardiac monitor showed multiple premature ventricular complexes. Troponin was borderline elevated : 0.14 at presentation up to 0.19 at 4 h (threshold of positivity : 0.08 ng/mL). A CT angiogram ruled out aortic dissection, pulmonary embolism or pneumothorax. Urine toxicology was negative. Patient was diagnosed with NSTEMI, received aspirin and was scheduled for a cath the day after. The angiogram revealed subtotal ostial LAD occlusion with a thrombus, possibly due to ulcerated plaque. Patient had a successful thrombectomy that left residual stenosis less than 40 %. Due to proximity of LAD stenosis to left main, patient was treated medically with integrillin, plavix, aspirin and the plan was to obtain stress test in 4 weeks later to evaluate hemodynamic significance of this lesion and if needed consider high risk PCI or single vessel CABG. Patient was pain free. The work up revealed low vitamin B12 88 pg/mL (normal range 211–946 pg/mL), high homocysteine level at 40 Umol/L (3.7–13.9 Umol/L), and positive antiphospholipid antibody. Patient was started on coumadin and vitamin B12 supplements. On day 3 after the PCI, he had a severe typical chest pain. The ECG showed ST elevation with Pardee wave in anterior leads. Patient was taken to the cath lab stat and the angiogram revealed subtotal LAD occlusion that was treated with a Drug eluting stent. The recovery was uneventful.

DISCUSSION: Early onset CAD is increasing in frequency. Classical risk factors (age, sex, tobacco, hyperlipidemia, HTN, Diabetes) are well known, but physician need to keep in mind the possibility of advanced CAD in young population that is related to other less frequent risk factors, as in our patient. Our patient was 30 yo and yet he had a STEMI that is now considered related to his vitamin b12 deficiency and hyperhomocysteinemia. The initial workup was more directed toward PE or aortic dissection due to the low likelihood of CAD in young patients. Later on, when he was diagnosed with ACS, his vitamin deficiency wasn't worked up. It is only after the cath showed thrombosis of the LAD that the connection with hyperhomocysteinemia and the ACS was made. The history of vitamin deficiency was initially "neglected" as his CBC was completely normal, with no neurological signs but retrospectively it appeared very relevant to the motif of presentation. He also had a positive antiphospholipid antibody, but this later is more known to cause venous thrombosis, and the connection with arterial thrombosis is less well established.

HYPERKALEMIA BY A MINOR LEAGUE Soohwan Chun¹; Manuela Calvo^{1,2}.

¹Montefiore medical center, Bronx, NY; ²Albert Einstein College of Medicine, Bronx, NY. (Tracking ID #1940101)

LEARNING OBJECTIVE 1: Recognize propranolol as a potential precipitator of hyperkalemia

LEARNING OBJECTIVE 2: Recognize role for an alternative non-selective beta-blocker, that is less associated with hyperkalemia

CASE: A 70 year-old woman presented with asymptomatic hyperkalemia. Her past medical history was significant for type 2 diabetes and liver cirrhosis, secondary to chronic hepatitis C. She reported taking the same dosage of furosemide and spironolactone for many years. There was no recent change in her diet or in the dosage of insulin. Her vital signs were within normal limits and her physical exam was unremarkable. The serum potassium was 6.4 meq/L and glucose was 360 mg/dL. Creatinine and hemoglobin were both at baseline, and creatine phosphokinase was 50 mcg/L. Venous pH was 7.29 [7.32–7.42]. Electrocardiogram was unremarkable. On further questioning, patient revealed that, several days ago, she started taking a new medication, propranolol, prescribed by her gastroenterologist for portal hypertension. The patient was treated with insulin and kayexalate; propranolol was discontinued. Hyperkalemia was corrected and did not recur.

DISCUSSION: Hyperkalemia is a common and probably one of the most worried electrolyte derangement, encountered by an internist. In most cases, the cause of hyperkalemia is readily identifiable (i.e., use of diuretics, or renal failure). However, in a less clear situation, it is important to approach systematically. One method is to think of causes that would lead to either increase in introduction, or decrease in removal of potassium to and from serum. Potassium is consumed from diet and stored mainly in cells. Two main ways of increasing introduction of potassium to serum are increase in consumption from diet and increase in movement of potassium out of the cells. Lysis of cells, such as in hemolysis or rhabdomyolysis, is one simple mechanism of introducing intracellular potassium to serum. Potassium ion shifts from cells to serum, in exchange for a hydrogen ion. Thus, acidemia is another way of pooling potassium from an intracellular source. Potassium is primarily removed by kidney, more specifically by principal cells in collecting tubules, mediated by renin-angiotensin-andosterone system. Problems with the hormone and the principal cells, or even a simple decrease in glomerular filtration will lead to reduction in removal of potassium. Beta-2-adrenergic receptors are present ubiquitously in many cells and their stimulation leads to uptake of potassium from serum. Thus, beta-2-receptor blockade, such as in use of a non-selective beta blocker, leads to small rise in serum potassium, that is often clinically insignificant. However, in presence of other factors that can contribute to rise in serum potassium, use of non-selective beta blocker can precipitate acute hyperkalemia, that can be potentially life-threatening. Both propranolol and nadolol, the two most commonly used non-selective beta-blockers in portal hypertension, have been associated with hyperkalemia. Use of non-selective beta blocker can precipitate hyperkalemia, especially when renal excretion of potassium is impaired, as in our patient with concurrent use of spironolactone, a potassium-sparing diuretic. A general approach is to remove the precipitating factors; however, in many cases, both the beta-blocker and the diuretic are equally important for treatment. Thus, it is necessary to look for a different non-selective beta-blocker, that is less associated with hyperkalemia. Carvedilol seems to be an example of such medication, because of its additional alpha-1 blockade. Inhibiting alpha-1 receptors not only produces smooth muscle relaxation, but also reduces potassium release from liver. Thus, carvedilol is a potential alternative in patients with hyperkalemia, induced by propranolol or nadolol.

HYPEROSMOLAR ANION GAP METABOLIC ACIDOSIS CAUSED BY MOUTHWASH Debjit Saha¹; Seth Gottlieb². ¹Mount Sinai Medical Center, Miami Beach, FL; ²Mount Sinai Medical Center, Miami Beach, FL. (Tracking ID #1939579)

LEARNING OBJECTIVE 1: Identification of an osmolar gap associated with an anion gap is helpful in recognizing fatal intoxications with ethylene glycol or methanol ingestion. Consideration of other unusual etiologies is a crucial step to recognize and manage this deadly metabolic disorder effectively.

LEARNING OBJECTIVE 2: Due to the high ethanol content (21 %) and easy accessibility, mouthwashes can be abused by chronic alcoholics, especially those from a low socio-economic background. Though there are no specific antidotes available for the phenolic compounds in mouthwash (thymol, eucalyptol, and menthol), detailed clinical history, high index of suspicion and identification of the osmolar gap with an AG acidosis can be helpful in identifying this atypical presentation.

CASE: A 35-year old man with a history of alcohol abuse and pancreatitis presented with hematemesis and confusion. He had been binge drinking for a week and upon exhausting his alcohol stocks, he ingested "Listerine". He complained of several episodes of bilious emesis and hematemesis with right upper quadrant pain and generalized abdominal discomfort. Physical exam was unremarkable except for dry mucous membranes and generalized abdominal tenderness. He had no focal neurological deficits. Initial lab work-up showed leukocytosis (21,000), thrombocytopenia (106,000), hyponatremia (122), hypokalemia (2.2), hypochloremia (56) with increased BUN (106) and creatinine (4.85). Arterial blood gas revealed pH of 7.59 and HCO₃ of 40. Serum alcohol was 49 and urine was negative for toxic-screen and crystals. Lactic acid and beta-hydroxybutyrate were normal. Abdominal US and head CT were normal. He was admitted to the ICU where he received normal saline and pantoprazole infusion. Subsequently, hemodialysis was initiated for severe mixed acid base disorder with acute kidney injury. Serum ethylene glycol and methanol levels were drawn due to the high suspicion of toxicity and empiric Fomepizole was started, but the results came back negative. With supportive treatment and hemodialysis, the electrolyte imbalance corrected and his acidosis resolved.

DISCUSSION: The patient presented with an AG (26). Calculated ΔAG was 14 (26–12=14). The measured HCO₃ (40) was more than the corrected HCO₃ (24–14=10), which suggested a concomitant metabolic alkalosis with an AG acidosis. One usually develops hypochloremic metabolic alkalosis with intractable vomiting, but our patient's disproportionate osmolar gap (30) and high AG could not be explained with his serum alcohol level and negative serum ethylene glycol/methanol screens respectively. The cause of this patient's hyperosmolar AG metabolic acidosis was therefore attributed to the phenolic compounds (thymol, eucalyptol, and menthol) in "Listerine".

HYPERTENSIVE EMERGENCY AS THE INITIAL PRESENTATION OF SYSTEMIC LUPUS ERYTHEMATOSUS Charles J. Lenz; Roger Yu. Mayo Clinic, Rochester, MN. (Tracking ID #1934759)

LEARNING OBJECTIVE 1: Diagnose systemic lupus erythematosus (SLE) in a patient presenting to the emergency department with hypertensive emergency in the absence of other classical symptoms of SLE.

CASE: A 25-year-old woman without significant past medical history presented to the emergency department complaining of a headache and fatigue that had been gradually worsening for a month. Over the 5 days prior to admission, the patient had also developed associated blurry vision and vomiting. The patient denied any other symptoms including rashes, arthralgias, oral ulcers, photosensitivity, or chest pain. She had not noticed any change in her urine. The patient was not on any medications at home. No family history of autoimmune diseases or renal disease. Initial assessment in the emergency department revealed a blood pressure of 226/128. Physical exam was otherwise unremarkable. There was no evidence of any neurologic deficits, rashes, or peripheral edema. The patient's blood pressure was stabilized with hydralazine and nicardipine in the emergency department and she was admitted to the medical intensive care unit for further evaluation. Initial lab work revealed a creatinine of 1.6 mg/dL, hemoglobin of 8.9 g/dL, and an ANA>12.0 (Normal <1.0). Urinalysis revealed 9.9 g of predicted 24 h protein, many dysmorphic RBCs, and fat in casts. Anti-ds-DNA antibodies, anti-RNP, and anti-Sm antibodies were elevated. Complement levels (C3 and C4) were low. The patient's headache, blurry vision, and nausea improved after her blood pressure was controlled. However, the patient began to develop swelling of the lower extremities during the hospitalization. Salt restriction was instituted and the patient was started on Lasix to help with edema. The patient underwent renal biopsy which confirmed the diagnosis of class IV and V lupus nephritis. She was started on treatment with mycophenolate mofetil, prednisone, tacrolimus, and an aggressive anti-hypertensive regimen. The patient was discharged with close outpatient follow-up in stable condition.

DISCUSSION: Systemic lupus erythematosus is a rare disease that can present with many different clinical syndromes. The most commonly reported symptoms at initial presentation include arthritis, malar rash, fever, photosensitivity, serositis, and nephropathy. Hypertensive emergency is an uncommon and rarely reported

presentation for SLE. It is important that clinicians are aware of this possible presentation as hypertensive emergency is a relatively common problem in the emergency room setting, and a broad differential needs to be maintained, especially in the setting of an abnormal urinalysis.

HYPERTENSIVE URGENCY, UNSTABLE ANGINA, AND ACUTE ANGLE CLOSURE GLAUCOMA Michael Dietz^{1,2}; Hani Alkhateb^{1,2}; Erika Osterholzer^{3,2}; Joel Tsevat^{1,2}. ¹University of Cincinnati College of Medicine, Cincinnati, OH; ²VA Medical Center, Cincinnati, OH; ³University of Cincinnati College of Medicine, Cincinnati, OH. (*Tracking ID #1939260*)

LEARNING OBJECTIVE 1: Understand the importance of an in-depth review of systems including specific visual complaints when patients present with hypertensive urgency or emergency.

LEARNING OBJECTIVE 2: Recognize that internal medicine, emergency medicine, and family medicine practitioners are often the first clinicians to come in contact with patients with acute angle closure glaucoma, an ophthalmologic emergency.

CASE: A 67-year-old male with hypertension presented to the emergency room with left-sided, sharp, exertional chest pain radiating to his left scapula for 30 min. The pain had occurred once earlier that morning and intermittently for 2 weeks. His past medical history was notable for smoking and a prior ocular history of refractive error; he stated that his optometrist was monitoring him as a "glaucoma suspect" but the patient was asymptomatic and no treatment was planned. In the emergency room, his BP was 210/80 and his EKG showed ST depression in V4 and V5 and T-wave inversion in aVL and V2. Troponins were negative. He was admitted for acute coronary syndrome and treatment of hypertensive urgency. On the evening of his first hospital day, he noted blurry vision of his left eye without pain, redness, or diplopia. His pupillary exam that evening was reportedly normal with reactive, equal pupils. The following morning, the patient reported having had chest tightness when walking in the hallway and a return of blurry vision in his left eye. On exam, his BP was 183/81. His left eye was red; the pupils were reactive but not equal, with the left greater than the right. A head CT was negative. The patient was transferred to the ICU. Ophthalmology was consulted, and the patient was noted to have a normal right eye, and left eye with a fixed mid-dilated pupil (4 mm), conjunctival injection, a mildly hazy cornea, a very shallow anterior chamber, and an intraocular pressure of 60 mmHg (normal 10–21 mmHg). The patient was immediately treated with acetazolamide 500 mg orally and 3 rounds of timolol/dorzolamide and brimonidine eye drops, followed by indentation gonioscopy and additional parenteral and topical medication. His intraocular pressure returned to normal. The patient's BP improved steadily with resolution of the intraocular pressure. The following morning, he underwent successful laser peripheral iridotomy. Though the patient initially denied eye pain, he later admitted to having eye pain prior to resolution of the elevated intraocular pressure, stating that he was anxious about being admitted and did not think about the pain until it was gone.

DISCUSSION: Visual complaints in the setting of hypertensive urgency should be investigated carefully, as many constitute ophthalmologic or neurologic emergencies, including, for example, retinal artery or vein occlusions, vitreous hemorrhage, acute hypertensive retinopathy, and TIAs or CVAs involving visual centers. Angle closure glaucoma is characterized by symptoms of blurry vision, eye redness, and severe eye pain. Patients frequently will also complain of headache and nausea or vomiting. Upon examination, the eye is red, with a mid-dilated, fixed pupil (approximately 5 mm and non-responsive to light), and the cornea may be hazy. Untreated acute angle closure glaucoma quickly leads to vision loss. Careful examination of the eyes and pupillary light response with a penlight should be performed in all patients, and confirmed if any uncertainties arise. Most antihypertensives are safe to use during an acute glaucoma attack, except for the vasodilator fenoldopam mesylate. This patient presented with hypertensive urgency, unstable angina, and acute angle closure glaucoma. A review of the literature revealed only one case report of acute glaucoma coinciding with hypertensive crisis, but the authors couldn't prove cause and effect (1). While we can't prove cause and effect either in this case, eye pain associated with acute angle closure glaucoma might have precipitated the hypertensive urgency, which in turn might have precipitated demand coronary ischemia and angina. 1. Razeghinejad MR, Hekmat V, Mansouri K. Acute-angle closure glaucoma as the presenting sign of hypertensive crisis. Eye. 2010;24:1629–30.

HYPERTRIGLYCERIDEMIA-INDUCED ACUTE PANCREATITIS TREATED WITH PLASMAPHERESIS Mihaela C. Chelu; Mher Onanyan; Akshay Manohar; Tania Calzada; Daniel Goldsmith; Albert Empedrad. Capital Health Regional Medical Center, Trenton, NJ. (*Tracking ID #1940166*)

LEARNING OBJECTIVE 1: Demonstrate plasmapheresis as a definitive treatment for severe hypertriglyceridemia and pancreatitis.

CASE: The phlebotomist was alarmed when he drew milky white blood from the right antecubital of a 49 year-old African American obese man who presented to the emergency department complaining of severe upper abdominal pain for approximately 10 days. Laboratory findings showed: triglyceride 7313 mg/dL, total cholesterol 1153 mg/dL, lipase 2071 units/L, amylase 271 units/L, glucose 347 mg/dL, white blood cell count 17,200 cells/mm³. Computerized tomography of the abdomen revealed infiltration and haziness around the pancreatic head, body and uncinate process, confirming acute pancreatitis. On day 2, the patient's condition was complicated by development of diabetic ketoacidosis (DKA) for which he was transferred to the Intensive Care Unit. Patient was started on insulin continuous infusion, which was continued for 3 days, then transitioned to subcutaneous insulin for 2 more days. This lowered of his TG level by 32 % to 5019 mg/dL. However, the patient still continued to have abdominal pain. Since he was at high risk of necrotizing pancreatitis, plasmapheresis was initiated on the general medical floor and the TG dropped dramatically by 78 % in a single session. Two additional plasmapheresis sessions were done lowering his TG level below 500 mg/dL. His symptoms resolving, the patient was discharged home on a low-fat diet on day 9, his TG 408 mg/dL and total cholesterol 118 mg/dL. He was prescribed Lantus 25 units subcutaneous daily, gemfibrozil 600 mg per mouth twice daily, and pravastatin 40 mg per mouth daily.

DISCUSSION: While intravenous insulin and gemfibrozil lower triglycerides, plasmapheresis is more effective in lowering levels quickly. Plasmapheresis is indicated in emergency situations when TG level is greater than 1000 mg/dL and should be continued until TG level have been lowered to less than 500 mg/dL. After the acute episode, rigorous pharmacological regimen and lifestyle modification are imperative, as is a discussion regarding screening of family members for lipid disorders.

HYPOLYCEMIC HEMIPARESIS, THE STROKE MASQUERADE Alaa Elkhider; Naveen Nannapaneni; Joel Steinberg. Wayne State University/Detroit Medical Center, Detroit, MI. (*Tracking ID #1923336*)

LEARNING OBJECTIVE 1: Recognize hemiparesis as a potential manifestation of hypoglycemia.

LEARNING OBJECTIVE 2: Distinguish hypoglycemia from an acute cerebrovascular event in a patient presenting with hemiparesis.

CASE: The classic presentation of hypoglycemia involves adrenergic symptoms such as diaphoresis, palpitations and tremors. This however, overlooks the multitude of other signs and symptoms that hypoglycemia produces, which if missed, may lead to morbidity and even mortality. We present a case where just such an atypical symptom, hemiparesis, was initially believed to be the result of a stroke. A 63-year-old female smoker with diabetes and hypertension presented to the hospital with right-sided weakness starting acutely the morning of presentation. She reported having three similar previous episodes over the last month. She affirms compliance with her medications, which include glyburide, metformin, hydrochlorothiazide, triamterene and lisinopril, and describes anorexia with poor oral intake for several weeks. EMS evaluation identified a blood glucose of 42 mg/dL, in the absence of hypotension, which corrected with oral glucose, resulting in immediate resolution of her right hemiparesis. At ER arrival the patient had stable vital signs with an unremarkable physical exam including normal motor strength, sensation, reflexes, cranial nerves, and testing of higher cognitive functions. Laboratory investigations revealed abnormalities of blood glucose of 45 mg/dL, creatinine 5.1 mg/dL, BUN 38 mg/dL, albumin 1.8 g/dL and hemoglobin A1c 4.8 % with a normal lipid profile. The reported hemiparesis triggered the hospital's stroke protocol initiating a neurology consultation in the ER. A non-contrast head CT, brain MRI/MRA, neck MRA and transthoracic echocardiography detected no acute abnormalities. After admission metformin and glyburide were discontinued given the suspicion of medication-induced hypoglycemia causing the recurring episodes of hemiparesis. The renal insufficiency resolved with intravenous fluid hydration. No further episodes of hemiparesis occurred during her hospitalization. Endocrinology consultants recommended against prescribing oral hypoglycemics on discharge given her previous episodes of hypoglycemia and euglycemia during hospitalization while off oral hypoglycemics.

DISCUSSION: Hemiparesis is a known, yet rare, presentation of hypoglycemia that can be mistakenly attributed to other etiologies. Our patient's hypoglycemia was precipitated by impaired sulfonylurea clearance in the setting of acute renal insufficiency from poor oral intake and diuretic use. Prompt evaluation of serum glucose and obtaining diabetic history in patients presenting with focal neurologic deficits allow rapid identification of hypoglycemia as a potential cause. At present the

pathophysiology of hypoglycemia induced focal neurologic deficit includes theories based on cerebral vasospasm, asymmetric cerebral blood flow, and selective neuronal vulnerability. Ultimately, should a patient present with acute hemiparesis in the context of significant risk factors for stroke, as in our patient, it would be presumptuous to simply attribute the deficit to hypoglycemia and disregard a cerebrovascular event. Rather, both hypoglycemia and other etiologies of stroke should be considered as they both carry risk of significant morbidity and mortality.

I'M NOT THE RASH YOU THINK I AM—A VASCULITIS WITH AN UNUSUAL CULPRIT Minal A. Shah; Jeffrey T. Bates. Baylor College Of Medicine, Houston, TX. (*Tracking ID #1939695*)

LEARNING OBJECTIVE 1: Recognize that TNF-alpha inhibitors can paradoxically induce secondary autoimmune disorders such as vasculitis.

LEARNING OBJECTIVE 2: Distinguish vasculitis associated with Crohn's Disease from vasculitis associated with TNF-alpha inhibitors.

CASE: A 52-year-old female with a history of well-controlled Crohn's Disease and delusional parasitosis presented with a bilateral lower extremity rash. Over 5 years the rash would intermittently occur and spontaneously resolve. There were no other symptoms or signs, and she took no new medications. Her only medication was infliximab, which she would intermittently refuse because she thought she had a parasitic infection of the skin. Physical examination revealed multiple confluent erythematous papules, plaques and tender nodules ranging from 2 to 4 cm in diameter, extending bilaterally from her feet to her knees. Laboratory studies, including sedimentation rate, C-reactive protein, complement factors, and multiple autoantibodies were all negative. A punch biopsy showed acute inflammatory changes consistent with vasculitis. A careful review of her previous episodes revealed that her flares coincided with the administration of infliximab. Infliximab therapy was discontinued, and her rash resolved.

DISCUSSION: Inhibitors of tumor necrosis factor alpha (TNF-alpha) have revolutionized the management of inflammatory bowel disease. Despite their role as immunosuppressive agents, TNF-alpha inhibitors have been paradoxically implicated in secondary autoimmune disorders, including cutaneous and systemic vasculitides. The incidence of vasculitis caused by TNF-alpha inhibitors is reported to be 0.2–3.9 % in the literature. In contrast to vasculitis associated with Crohn's disease, vasculitis secondary to TNF-alpha inhibitors typically does not coincide with the worsening gastrointestinal inflammatory symptoms of abdominal pain, bloody stools or diarrhea. Furthermore, the rash is actually worsened by administration of the drug and is improved after cessation of therapy. The timing of the rash in relation to gastrointestinal symptoms, worsening of the rash after the culprit drug is administered, and biopsy findings suggestive of vasculitis are features diagnostic of vasculitis secondary to TNF-alpha inhibitors. Although the most common presentation is cutaneous vasculitis, it is also possible to have systemic involvement. The pathophysiology of systemic vasculitis is not well-known, although a type III hypersensitivity reaction is suspected. Treatment consists of switching to an alternative therapy for the primary autoimmune disorder. Interestingly, the formation of autoantibodies to TNF-alpha inhibitors is more likely to occur when maintenance doses of the medication are missed. Therefore, it is likely that our patients' delusions of parasitosis and avoidance of her scheduled medication played a significant role in the development of her rash. Internal medicine physicians should be familiar with the full spectrum of skin manifestations in a patient with inflammatory bowel disease. When a patient presents with a vasculitic rash in the setting of well-controlled inflammatory bowel disease, vasculitis caused by a TNF-alpha inhibitor should be considered.

IDIOPATHIC PULMONARY FIBROSIS ASSOCIATED WITH ANCA VASCULITIS Heena A. Birbal Jain; Saurabh K. Bansal. University of illinois college of Medicine at Peoria at Saint Francis Medical center, Peoria, IL. (*Tracking ID #1917850*)

LEARNING OBJECTIVE 1: Association of Idiopathic Pulmonary fibrosis with ANCA Vasculitis

CASE: A 73-year-old male of Indian descent presented with one-week history of fatigue, lethargy from outlying hospital. He was diagnosed with IPF 2 years ago. His creatinine on admission was 4.7 from baseline of 1.5. His renal failure was non-oliguric and electrolytes were stable. Urinalysis revealed active urinary sediment with RBC and RBC casts and random urine protein:creatinine ratio of 2.2 g. He was diagnosed with rapidly progressive glomerulonephritis (RPGN). Autoimmune workup including ANA, rheumatoid factor, anti-ro, anti-LA, anti GBM antibodies

were negative except ANCA. C-ANCA resulted positive at 1:5620 and was specifically positive for anti PR-3 antibodies. Review of records from multiple hospitals revealed that he was never checked for ANCA antibodies before. He was diagnosed with ANCA related glomerulonephritis. Patient refused renal biopsy and was started on cyclophosphamide and prednisone. In the next few days he developed productive cough with blood streaks followed by respiratory failure and was placed on mechanical ventilation. Bronchoscopy was performed which showed extensive erythema in the bronchioles and return of RBC rich lavage. Cultures were negative and biopsy from the bronchus was negative for any acute pathology. His hypoxemia worsened and eventually succumbed to acute respiratory failure. Histology of lungs on autopsy showed extensive pulmonary fibrosis. Unfortunately, renal pathology was not done as a part of autopsy.

DISCUSSION: Idiopathic pulmonary fibrosis (IPF) is a rare disease with incidence of 20 in 100,000. IPF is a diagnosis of exclusion. Patients usually present with typical respiratory symptoms of dyspnea and cough, and most are not acutely sick at the time of presentation. Diagnosis is sought after pulmonary function test (PFT) reveal restrictive disease pattern and CT scan shows typical changes (bibasilar opacities with honey combing appearance). Autoimmune diseases such as Wegener's, microscopic polyangiitis, lupus should be ruled out with appropriate labs. IPF is an uncommon disorder and is a diagnosis of exclusion. Based on literature review, most of such clinical presentations are associated with ANCA related disease. Also, in rare case reports it has been described that patients were diagnosed with IPF earlier and had ANCA antibody positive later. We believe that our patient had ANCA related vasculitis. It initially manifested as isolated lung involvement and was mistakenly labeled as IPF. Patient eventually developed a full-blown ANCA related vasculitis, which manifested as RPGN, alveolar hemorrhage and pulmonary capillaritis. The extreme levels of cANCA were indicative of high degree of inflammation. We recommend that all patients diagnosed with IPF should have ANCA antibodies checked at the time of diagnosis. This will help in better identifying patients with ANCA related pulmonary fibrosis, which is potentially treatable unlike the idiopathic form where no definite treatment is available.

IDIOPATHIC PULMONARY HEMOSIDEROSIS: AN ORPHAN DISEASE Navneet Kaur; Pahul Singh. SUNY Upstate Medical University, Syracuse, NY. (*Tracking ID #1938947*)

LEARNING OBJECTIVE 1: Early recognition of diffuse alveolar hemorrhage and its underlying cause to treat it in a prompt and timely manner.

CASE: A 62-year-old male presented to our institution with recurrent episodes of hemoptysis and exertional dyspnea for 1 month duration. He denied any chest pain, fever or hematochezia. Past medical history was significant for diabetes mellitus and 25 -pack -year smoking. Examination revealed normal vital signs and bibasilar crackles on lung exam. Laboratory values revealed hemoglobin of 7.3 g/dL, serum iron was 18 mg/dL, iron saturation was 5 %, MCV was 67.5. Chest radiograph showed bilateral lower lobe infiltrates. CT scan thorax showed multifocal ground glass opacities involving bilateral lower lobes consistent with alveolar airspace disease. 2-D echocardiogram was unremarkable. Bronchoalveolar lavage revealed intra-alveolar hemosiderin laden macrophages with no evidence of capillaritis, vasculitis or granulomas. After excluding all other sources of bleeding through extensive gastrointestinal workup and thorough immunologic profile, video-assisted thoracic lung biopsy was done which confirmed the diagnosis of IPH. Treatment was initiated with high dose of oral prednisone leading to marked improvement in the symptoms and the patient has been doing fine in last 6 months of follow-up.

DISCUSSION: Idiopathic Pulmonary Hemosiderosis (IPH) is a rare condition with unknown etiology with an incidence of 0.24–1.23 cases per million, causing recurrent episodes of diffuse alveolar hemorrhage that might lead to pulmonary fibrosis. IPH is characterized by abnormal accumulation of iron as hemosiderin in alveolar macrophages. Various etiological theories have been proposed of which auto-immune mechanism is most widely accepted theory. Clinical manifestations include hemoptysis, exertional dyspnea, iron deficiency anemia and parenchymal infiltrates on chest radiograph. CT thorax shows diffuse ground glass opacities and parenchymal infiltrates. Diagnosis of IPH is established upon eliminating all other secondary causes of alveolar hemorrhage and confirmation with lung biopsy which is gold standard diagnostic tool and reveals bland alveolar hemorrhage with absence of vasculitis or accumulation of immune complexes within lung parenchyma. Systemic corticosteroids are the cornerstone therapy in IPH. They decrease the episodes of alveolar hemorrhage during acute stage of disease and also control progression towards pulmonary fibrosis. To summarize, our case reiterates the importance of early recognition of diffuse alveolar hemorrhage which is a life threatening condition with prompt diagnosis of underlying syndrome to initiate therapy in a timely fashion.

IDIOPATHIC? SOUNDS LIKE A COP OUT Merrill H. Stewart; Deepa Bhatnagar. Tulane University School of Medicine, New Orleans, LA. (*Tracking ID #1940000*)

LEARNING OBJECTIVE 1: Understand cryptogenic and secondary organizing pneumonia

LEARNING OBJECTIVE 2: Identify the extra-articular manifestations of rheumatoid arthritis

CASE: A 63 year-old man presented with 3 weeks of worsening shortness of breath and generalized weakness. He also reported a dry cough and a history of heart failure. He was noted to be afibrile, tachycardic, with an oxygen saturation of 100 %. He had no lower extremity edema. Proximal muscle groups were weaker than distal muscle groups in all extremities. Brain natriuretic Peptide was 50 pg/mL. Chest radiograph revealed no pulmonary edema and bilateral interstitial changes. Chest computed tomography revealed mediastinal lymph nodes and multi-focal “reverse halo,” or “atoll” signs. Serum rheumatoid factor was 860 IU/mL, cyclic citrullinated peptide antibody >3000/mL, creatinine kinase 853u/L, and aldolase 15u/L.

DISCUSSION: Cryptogenic Organizing Pneumonia (COP), formerly Brochiolitis Obliterans Organizing Pneumonia, can be grouped among the 5 idiopathic interstitial lung diseases. Fibroblasts proliferate in the alveolar ducts, moving from one adjacent alveolus to the next forming airway plugs. This preserves the existing lung architecture without any necrosis, while occurring in isolated focal patches throughout the lungs. When associated with an underlying disease or medicine it is termed a secondary organizing pneumonia, however the characteristics are the same as when it is cryptogenic. Implicated medications or conditions associated with organizing pneumonia include amiodarone, cocaine, connective tissue diseases, infectious pneumonias, diffuse alveolar hemorrhage, aspiration, and hypersensitivity pneumonitides. COP presents in 5th-6th decade of life with several weeks of cough, fever, dyspnea, malaise, and weight loss. The work up usually begins after failed antibiotic treatment for atypical pneumonias, and should include an investigation for any of the above associated conditions. Laboratory analysis should focus on ruling out infectious pneumonias and connective tissues disease. Chest Computed Tomography usually shows peripheral patchy focal air-space consolidation and ground glass opacities. Occasionally computed tomography also shows cavitary, crescentic, or ring shaped opacities. A “reverse halo” or “atoll” sign is an area of ground glass opacity surrounded by a dense crescentic ring, and is highly suggestive of organizing pneumonia. Ultimately tissue is required to make a diagnosis of Organizing Pneumonia, and often an open wedge resection is needed to obtain a sufficient sample. Only after all secondary causes have been ruled out and tissue shows consistent histopathology, can a diagnosis of Cryptogenic Organizing Pneumonia be made. Rheumatoid arthritis typically presents with joint involvement, however in 15–25 % of people it can have extra-articular manifestations, and occasionally these can precede joint involvement by years. They include rheumatoid nodules, interstitial lung disease, vasculitis, felt syndrome, sicca syndrome, amyloidosis, coronary artery disease, pericarditis, and peripheral neuropathy. It can also present with other connective tissue diseases in an Overlap Connective Tissue Syndrome. Our patient presents without any joint involvement, elevated cyclic citrullinated peptide titers, laboratory and clinical findings suggestive of polymyositis, and organizing pneumonia. The most consistent diagnosis would be an overlap connective tissue disease syndrome with secondary organizing pneumonia.

IGA NEPHROPATHY PRESENTING AS A RAPIDLY PROGRESSIVE GLOMERULONEPHRITIS IN AN ELDERLY WOMAN Mark H. Adelman; Eduardo Iturrate. NYU School of Medicine, New York, NY. (*Tracking ID #1931286*)

LEARNING OBJECTIVE 1: Recognize the clinical and pathologic features of IgA nephropathy that portend a poorer prognosis and thus require aggressive management

CASE: An 81-year-old woman presented to an outside provider with 3 months of post-prandial abdominal pain and bloating. Her symptoms were not relieved with a proton-pump inhibitor so she underwent upper endoscopy that was reportedly unremarkable. When seen in an outside hospital emergency department for acute worsening of her abdominal pain now associated with increased abdominal girth, the patient had an abdominal CT. This was notable for large volume ascites. The patient denied fevers, chills, cough, diarrhea, dysuria, hematuria and rash. She reported chronic, bilateral knee pain but no new joint pains. She was admitted to the outside hospital for workup of new onset ascites. After several days the patient signed out against medical advice and presented to our hospital for further management. Past medical history was significant for knee osteoarthritis, herpes zoster and bereavement disorder. Home medications were pantoprazole, diazepam and corticosteroid knee injections. There was no family history of autoimmune, renal or hepatic disease. The patient lives at home with her daughter, is independent in activities of daily living and denied tobacco, alcohol or illicit drug use. On physical exam at our hospital, vital signs were notable for a blood pressure of 172/102. She was in no acute distress. Abdomen was distended, firm and mildly tender to palpation diffusely. Legs were massively edematous. Labs were most notable for creatinine that rose from 1.3 mg/dL to 4.5 mg/dL over 12 days. Spot urine protein/creatinine was 9602 mg/g. Ascitic fluid was negative for SBP and malignant cells. ANA 1:640, ANCA negative. HIV, Hepatitis B/C all negative. Renal biopsy showed: proliferative, necrotizing glomer-

ulonephritis, consistent with IgA nephropathy, severe, acute; tubular atrophy and interstitial fibrosis, mild; interstitial edema and inflammation, moderate. Prior to leaving the outside hospital, the patient had received 2 days of pulse-dose methylprednisolone after her renal biopsy results came back. She received a third dose of methylprednisolone at our hospital and cyclophosphamide on the recommendation of our nephrology consultant. We gave IV loop diuretics for her massive volume overload but the patient required initiation of hemodialysis via a tunneled catheter. Further doses of cyclophosphamide were held due to development of anemia and thrombocytopenia, as well as infectious complications including gram-negative sepsis. A long, tapering course of prednisone was continued. The patient has not required hemodialysis for approximately 3 months.

DISCUSSION: IgA nephropathy is believed to be the most common cause of primary glomerulonephritis worldwide. It occurs most commonly in the second and third decades of life and among males more often than females. The typical presentation is painless, macroscopic hematuria (40–50 % of patients), frequently temporally associated with an upper respiratory tract infection. Thirty to forty percent of patients present with microscopic hematuria with or without proteinuria. Much less commonly (<10 %), patients present with nephrotic syndrome or acute kidney injury associated with a rapidly progressive glomerulonephritis. Essential to the diagnosis of this condition is renal biopsy and the identification of glomerular IgA deposits on immunofluorescence microscopy. Several clinical features have been associated with a poor prognosis in studies of IgA nephropathy patients. These include sustained hypertension, persistent proteinuria >1 g/day, impaired renal function at time of diagnosis, and nephrotic syndrome. The Oxford classification is a histologic scoring system, validated in diverse cohorts, that incorporates findings on renal biopsy that are also associated with adverse outcomes independent of clinical features. The cornerstone of management in nearly all patients with IgA nephropathy is treatment of hypertension and/or proteinuria by ACE inhibition or angiotensin receptor blockade. Corticosteroids demonstrated some efficacy for preservation of renal function and improvement in proteinuria among patients with more significant proteinuria and normal baseline renal function in a randomized controlled trial. Immunosuppression with corticosteroids and cyclophosphamide is often used to manage rapidly progressive glomerulonephritis with cellular crescents seen on renal biopsy, based on observational data, but randomized controlled trial data is lacking. Our patient presented with a number of poor prognostic factors, mostly significantly the rapid progression of her condition, massive proteinuria and crescents on renal biopsy. Consequently, we aggressively managed the patient with steroids and a cytotoxic agent given the acuity and fulminant nature of her presentation.

IMMUNODEFICIENCY DIAGNOSED IN ADULTHOOD Jenny Koo¹; Laura Y. Sue¹; Pearl Yu². ¹UC San Diego School of Medicine, San Diego, CA; ²UC San Diego Medical Center, La Jolla, CA. (*Tracking ID #1924024*)

LEARNING OBJECTIVE 1: Recognize the clinical manifestations of IgA deficiency and its associated co-morbidities

LEARNING OBJECTIVE 2: Review the preventive and therapeutic options available for individuals with IgA deficiency

CASE: A 58 year old woman with allergic rhinitis, new onset asthma, gastroesophageal reflux disease, and history of Non-Hodgkins lymphoma [NHL] presented repeatedly in clinic for respiratory infections. Her symptoms included persistent sinus congestion, post nasal drip, productive cough, and wheezing. Fluticasone/salmeterol, montelukast, prednisone, nasal saline irrigation, and an as needed albuterol were prescribed to address the various refractory symptoms. Multiple courses of amoxicillin-clavulanate were ineffective. The patient did not have sensitivity to aspirin or a history of nasal polyps. She did not have a history of food allergies or autoimmune disease. She believed that her recurrent infections started after treatment for NHL 10 years prior. There was no tenderness to palpation over the frontal and temporal sinuses and the lungs were clear to auscultation bilaterally. Chest x-ray was negative and CT scan of the sinuses revealed bilateral inflammatory sinus disease in the maxillary, sphenoid, and ethmoid sinuses. Endoscopic sinus surgery improved sinus symptoms but the patient continued to have frequent respiratory infections. A subsequent serum immunoglobulin panel revealed severely low to absent levels of IgA (<5 mg/dL), with normal levels of IgG and IgM. The patient was therefore diagnosed with IgA deficiency. Testing for serum anti-transglutaminase antibodies, given the association between IgA deficiency and autoimmune processes, was negative. The patient was advised to discuss the new diagnosis, immunology testing of family members, prevention, and treatment options with an allergy/immunology specialist.

DISCUSSION: IgA deficiency is an isolated decrease in IgA with normal levels of IgG and IgM. It is the most common immunologic deficiency and is largely asymptomatic. When symptomatic, individuals have recurrent sinusitis and other

respiratory tract infections, especially those due to encapsulated bacteria. GI infections are also common, including increased susceptibility to Giardia lamblia infection. The differential diagnosis includes emerging common variable immunodeficiency (or other immunodeficiencies) and drug-induced, mostly reversible IgA deficiency. Individuals with IgA deficiency are more likely to have food allergies, allergic rhinitis, and allergic asthma. Twenty percent will have concomitant autoimmune disease, such as rheumatoid arthritis, systemic lupus erythematosus, celiac disease, or inflammatory bowel disease. There is also the potential to develop anti-IgA antibodies and individuals with IgA deficiency may have anaphylactic reactions to blood transfusions. Patients should be vaccinated against Streptococcus pneumoniae and may consider testing for anti-IgA antibodies in case of possible future blood transfusions. Treatment is directed at any concomitant respiratory disorders (such as asthma) and infections as they arise. Prophylactic antibiotics and/or IVIG therapy can be considered.

IMMUNOSUPPRESSION: OPENING A CAN OF WORMS FOR HYPERINFECTION SYNDROME? Marc Cohen; Deborah Hemel. Montefiore Medical Center, Bronx, NY. (Tracking ID #1939077)

LEARNING OBJECTIVE 1: Recognize the signs and symptoms of strongyloides infection.

LEARNING OBJECTIVE 2: Recognize risk factors for Hyperinfection syndrome. **CASE:** A 58 year old female presented with a 2 year history of vomiting after nearly every meal. She also reported epigastric pain associated with vomiting and intermittent watery diarrhea for several years. The patient had undergone previous endoscopy showing gastric reflux disease and a hiatal hernia, but her symptoms did not improve with proton pump inhibitor therapy or lifestyle modifications. Relevant past medical history included longstanding rheumatoid arthritis treated with prednisone, hydroxychloroquine and methotrexate. Her social history was significant for intermittent trips to the Dominican Republic, from which she had emigrated many years prior. Admission labs were notable for white blood count of 12.4 k/uL with slight eosinophilia of 0.6 k/uL (normal range 0.0 to 0.3 k/uL), sodium 128 mEq/L, potassium 3.3 mEq/L, albumin 1.7 g/dL, and INR 1.5. On exam, she was a lethargic, ill-appearing female with vague abdominal tenderness, diffuse anasarca, and confluent bruising along the extremities. During the first week of her hospitalization her frequent vomiting persisted despite an aggressive anti-emetic regimen, her functional status continued to decline, and her albumin dropped to 1.2 g/dL. On hospital day 8 stool studies returned positive for strongyloides stercoralis, therefore she was started on Ivermectin. Her serum subsequently returned positive for strongyloides IgG. Her endoscopic biopsies revealed severe inflammation and strongyloides within the mucosal crypts of the stomach and duodenum, as well as marked villous flattening of the duodenum. The patient improved significantly on Ivermectin. She was discharged home on hospital day 16. She was seen in clinic 2 weeks after discharge at which time she reported resolution of her symptoms.

DISCUSSION: Strongyloides is a nematode that enters the body cutaneously, most classically when bare feet contact soil contaminated with infected human feces. The parasite lives primarily in tropical climates but is also found in parts of Appalachia. Many people with strongyloides are asymptomatic; those who develop symptoms generally have vague, transient pulmonary complaints or vague, chronic gastrointestinal complaints. Gastrointestinal symptoms include poor oral intake, epigastric pain, nausea, vomiting and diarrhea. As the nematodes proliferate in the gastrointestinal tract they can cause destruction of the villous architecture, thereby leading to malabsorption. The combination of anorexia, chronic vomiting and malabsorption can lead to life-threatening malnutrition, as was the case in our patient. A patient with a high burden of disease who is immunosuppressed is at risk of developing the dreaded Hyperinfection syndrome, which occurs when strongyloides travels beyond the gastrointestinal tract via the blood stream. Immunosuppressed patients are at elevated risk of this complication, although how elevated remains unclear. Once disseminated, strongyloides can affect many different organs, thereby leading to variable types of organ dysfunction. Additionally, once strongyloides interrupts the integrity of the bowel mucosa, patients become predisposed to sepsis due to enteric gram negative bacteria. If left untreated, the syndrome is fatal in up to 90 % of patients. Detection of strongyloides infection can be difficult given that stool samples have less than 50 % sensitivity. Serum ELISA testing appears to be much more effective, with reported sensitivities of greater than 80 %. However ELISA testing is costly and may not be widely available. Endoscopic biopsy is also a diagnostic option but should be undertaken only if the patient warrants an endoscopy as part of a gastrointestinal work up. Mild eosinophilia can be one clue to the diagnosis, however it is neither sensitive nor specific for strongyloides. Patients with chronic gastrointestinal complaints who have traveled to endemic regions should be tested for strongyloides as part of a parasitic work up. Physicians who care for patients who have spent extensive time in endemic areas should consider screening for strongyloides prior to starting such patients on steroids or other immunosuppressive

agents given the high fatality rate associated with Hyperinfection syndrome and the ease of treatment with Ivermectin.

INCESSANT PERICARDITIS IN A 31-YEAR OLD MALE FOLLOWING BIOPROSTHETIC AORTIC VALVE REPLACEMENT Theresa L. King; Jeffrey Beasley. University of Kansas, Kansas City, KS. (Tracking ID #1941415)

LEARNING OBJECTIVE 1: Recognize and treat incessant pericarditis, including early involvement by rheumatology for steroid-sparing treatment options.

CASE: A 31-year-old male with a benign medical history presented to an academic medical center with complaint of acute onset of extreme dyspnea with minimal exertion. An ECHO revealed moderate to severe aortic regurgitation and the presence of a bicuspid valve, which was previously unknown. He underwent aortic valve replacement (AVR) with a bovine tissue valve. His hospital course was uncomplicated. At 3 week follow-up, he was found to have a trivial pericardial effusion on ECHO, and was started on ibuprofen. Two weeks later he was admitted due to severe pleuritic, substernal and positional chest pain. He was found to have a moderate pericardial effusion on ECHO and CRP was elevated. A diagnosis of pericarditis/post-cardiac injury syndrome was made. He was started on indomethacin but relief was inadequate so steroids were started. He was discharged on indomethacin and a solumedrol dose pack. Ten days later the steroid taper was complete. Chest pain had resolved but he complained of mild dyspnea with exertion. Colchicine was added. Nine days later he developed severe pleuritic chest pain and was started on prednisone 60 mg qday which was tapered by 10 mg qday each week. Within days following completion of steroids, symptoms of pericarditis returned. During the year following surgery he underwent 4 slow steroid tapers with flares occurring within a month of cessation of steroids. Approximately 1 year following AVR he was again hospitalized with a severe flare. Steroids were initiated and rheumatology was consulted for consideration of starting a steroid-sparing agent. At follow-up with rheumatology, which was 14 months post AVR, azathioprine was started and the slow steroid taper was continued. Approximately 6 months after initiation of azathioprine, the patient was off steroids and continued to be symptom-free. Approximately 1 year after starting azathioprine, a slow taper was begun that was completed 1 year later. He remains symptom free.

DISCUSSION: The development of pericarditis following cardiac surgery is not an uncommon occurrence, with most cases involving men aged 20 to 50. Recurrent pericarditis refers to a syndrome in which acute pericarditis recurs after the agent inciting the original acute attack has disappeared or has ceased to be active. It involves considerable morbidity and can result in cardiac tamponade and constrictive pericarditis. Incessant pericarditis, as opposed to recurrent pericarditis, refers to cases with persistent symptom return within 6 weeks of previous resolution. Incessant pericarditis is extremely uncommon and very few case reports are available to guide treatment. Prolonged steroid use is associated with serious side effects, including an increased risk of infection, osteoporosis, psychosis, insomnia and glaucoma and should not be used long term. Additionally, steroids are a known risk factor for recurrence if used during the index case. Steroid-sparing immune suppressants should be considered, but carry an increased risk of infection, lymphoma and bone marrow suppression. The purpose of reporting this case is to increase awareness of this uncommon condition and to share management decisions and regimens, as no well-prescribed standard treatment exists for incessant pericarditis. Early involvement by rheumatology is encouraged for consideration of steroid-sparing agents.

INCIDENTAL HYPOXEMIA Saroja Bangaru; Arash Harzand. Emory University, Atlanta, GA. (Tracking ID #1938711)

LEARNING OBJECTIVE 1: Recognize the subclinical presentation of hepatopulmonary syndrome

LEARNING OBJECTIVE 2: Anticipate and diagnose hepatopulmonary syndrome early and efficiently

CASE: A 60 year-old homeless man with cirrhosis 2/2 HCV presented to the ED with complaints of lower back pain. On triage, he was found to be hypoxic to low 80's on room air. Further questioning revealed 4-month history of fatigue and occasional shortness of breath with exertion. He was otherwise asymptomatic with a normal CXR, so he was admitted for management. His cardiopulmonary exam was benign, and he had no stigmata of chronic liver disease. CMP revealed mild transaminitis but was otherwise normal. ABG revealed wide A-a gradient hypoxia that corrected with supplemental O₂ to 96 %. Right to left intra-cardiac shunt was initially suspected as there was no evidence of diffusion impairment with normal lung parenchyma and desaturation on ambulating, and CT PE was negative. Surface echo with bubble study revealed late bubbles in the left atrium and left ventricle,

suggesting a pulmonary AVM versus a PFO with intermittent shunt. It was decided that TEE should be performed to visualize atrial septum. A TEE with bubble study confirmed a small PFO without any significant right-to-left shunt or Eisenmenger's physiology to explain his hypoxia. Pulmonar was consulted who agreed that the patient may indeed have pulmonary micro-AVMs that cannot be visualized with CT as they are capillary sized. The only therapeutic option was home supplemental O₂ as the patient would likely not qualify for liver transplant due to untreated HCV. He was arranged with home O₂ and discharged to a nursing facility as he was homeless. He was arranged with follow up at GI clinic for any additional recommendations given new diagnosis of hepatopulmonary syndrome and for consideration, if possible, of liver transplantation in the future.

DISCUSSION: Hepatopulmonary syndrome is characterized by arterial hypoxemia induced by pulmonary vascular dilation in the setting of liver disease. Estimates of its incidence are as high as 47 %, but it is frequently asymptomatic and under-recognized, making it a diagnostic challenge. This case increases awareness of HPS in hopes that it will be more readily recognized in cases of liver disease of varying severity. It demonstrates the need to anticipate a diagnosis of HPS because it is often subclinical and because it is associated with a worse prognosis. In reflecting on this case, the necessity of an extensive inpatient pulmonary work-up and trans-esophageal echocardiogram was debated. Integrating a patient's clinical history with his presentation is necessary in order to make a diagnosis efficiently, without conducting an extensive and invasive work-up when it may not be necessary.

INDUSTRIAL LAUNDRY FACILITIES: NOT AS "CLEAN" AS WE EXPECT

Sean Townsend; Stephen Harder. University of Texas Southwestern Medical Center at Dallas, Dallas, TX. (*Tracking ID #1939547*)

LEARNING OBJECTIVE 1: Recognize the importance of occupational history in timely diagnosis and treatment of Legionnaires' disease.

LEARNING OBJECTIVE 2: Appreciate the appropriate clinical indications for the *Legionella* urine antigen test.

CASE: A 44 year old African-American woman presented with 5 days of high fever, nausea and vomiting, diarrhea, and headache as well as 2 days of worsening productive cough and shortness of breath. She had no medical history prior to this illness. She denied any recent travel or sick contacts at home or work. She was an intermittent smoker, but denied alcohol use. She reported a long time occupation working in an industrial laundry facility handling freshly laundered items. On physical exam, the patient had a temperature of 102.9 F, blood pressure of 141/84, heart rate of 126, and respiratory rate of 28, with an oxygen saturation of 87 %. She was able to talk in full sentences despite breathing quickly. There were bibasilar rales, worse on the left, however no tactile fremitus or dullness to percussion. Laboratory studies revealed a white blood cell count of $12.6 \times 10^3/\mu\text{L}$ with neutrophil predominance, alanine aminotransferase of 53 U/L, aspartate aminotransferase of 79 U/L, and an alkaline phosphatase of 159 U/L. Chest radiograph showed bilateral parenchymal consolidations. She was admitted with a preliminary diagnosis of community acquired pneumonia and sepsis, and treated with vancomycin, piperacillin/tazobactam, and azithromycin. Given the patient's known environmental exposure a *Legionella* urine antigen test was obtained which resulted positive, and she was changed to moxifloxacin monotherapy. A *Legionella* specific sputum culture grew *Legionella pneumophila*. Her clinical course then improved over 1 week with resolution of symptoms.

DISCUSSION: This case highlights an industrial laundry facility as an interesting source for exposure to Legionnaires' disease. The *Legionella* urine antigen test has a sensitivity of 70–80 %, a specificity of >99 %, and remains positive for days to weeks after initial infection. Current IDSA/ATS guidelines recommend obtaining a *Legionella* urine antigen test in the evaluation of community acquired pneumonia in patients with recent travel, alcohol abuse, pleural effusion, failure of outpatient treatment, ICU admission, and nonresponding pneumonia, defined as clinical deterioration despite appropriate broad spectrum antibiotics. Patients should be carefully selected so as to reduce the number of false positive tests. This case is an example of a patient who did not meet accepted criteria, but in whom early recognition of pertinent occupational history leading to utilization of the *Legionella* urine antigen test by the general internist was essential in the timely diagnosis and treatment of Legionnaires' disease. Strong clinical suspicion for Legionnaires' disease based on occupational history should be considered as an addition to guidelines for the use of the *Legionella* urine antigen test.

INFECTIOUS GRANULOMATOUS DERMATITIS: A RARE PRESENTATION OF MYCOBACTERIUM TUBERCULOSIS

Mary Ramirez; Jack Waller; Roger D. Smalligan. Texas Tech University Health Sciences Center, Amarillo, TX. (*Tracking ID #1934995*)

LEARNING OBJECTIVE 1: Recognize the clinical features of cutaneous tuberculosis

LEARNING OBJECTIVE 2: Recognize that cutaneous tuberculosis can persist for years and leave varioliform scars if not treated appropriately

CASE: A previously healthy 31-year-old Burmese male with no past medical history presented with lymphadenopathy, sore throat, nausea, abdominal pain, vomiting, and shortness of breath. A rapid strep test was positive and the patient was prescribed Amoxicillin. Seven days later he felt better but had a new swollen cervical lymph node and his axillary node was sore and swollen. Labs showed anemia and hypoproteinemia. A PPD was read as 50 mm. CT of the chest showed adenopathy of the left axilla, right hilum, and mediastinum. A sputum AFB culture was sent and he was started on directly observed therapy with daily isoniazid, rifampin, pyrazinamide, ethambutol, and vitamin B6. His culture later came back positive for *Mycobacterium TB*. Three weeks after starting treatment the patient presented with pruritic, vesiculopapular, crusted, and hyperpigmented skin lesions on the chest and extremities. The lesions were initially thought to be molluscum contagiosum but when they became more hemorrhagic 1 week later dermatology was consulted and a biopsy was performed to rule out tuberculosis miliaris disseminata and perforating folliculitis. Pathology showed vacuolar alteration along with lichenoid features with no evidence of molluscum and granulomatous dermatitis consistent with an infectious process.

DISCUSSION: Cutaneous lesions are a rare manifestation of *Mycobacterium tuberculosis* (MTB), occurring in only 1 to 2 % of infected patients. MTB is a slow growing acid-fast bacillus which is the predominant cause of cutaneous TB. Cutaneous TB has re-emerged in parts of the world where the incidence of HIV infection and multi-drug resistant TB is high. In the majority of cases, cutaneous TB is a manifestation of systemic involvement and can present in a variety of ways including as inflammatory papules, verrucous plaques, suppurative nodules, warty tumors, scarring reactions, or chronic ulcers among others. The different manifestations may vary due to the quantity of organisms in the lesions and predisposing factors of the host such as the patient's age, immune competence status and previous TB sensitization. Four common forms of cutaneous TB include lupus vulgaris, tuberculosis verrucosa cutis, scrofuloderma, and papulonecrotic tuberculids. Papulonecrotic tuberculids consist of multiple symmetric papules, 1 to 5 mm in diameter with an umbilicated, necrotic center that commonly appear on the trunk and are often seen in adults with active tuberculosis disease elsewhere. This is precisely what was seen in our patient. Tissue biopsy often reveals a palisading granuloma and follicular necrosis. As with our patient, bacilli are usually absent in papulonecrotic tuberculoid lesions, and the PPD test is often strongly positive. Fever and constitutional symptoms often precede the appearance of skin lesions, and associated lymphadenitis is common. Although these lesions may spontaneously resolve over the course of several weeks, they often recur and if left untreated may persist for years, leaving varioliform scars. This case reminds internists of the cutaneous manifestations of TB that can appear even after treatment for TB has been started. It is important to initiate proper, directly observed therapy that encompasses an effective, standard anti-tuberculous regimen based on culture results to insure an adequate response to treatment and ultimately a cure for the patient.

INFECTIVE ENDOCARDITIS: AN UNUSUAL CULPRIT

Nathaniel Ernstoff; Misako Nagasaki; Jonathan Katz; Charles M. Geller. Beth Israel Medical Center, New York, NY. (*Tracking ID #1939094*)

LEARNING OBJECTIVE 1: Recognizing *Citrobacter koseri* as a possible pathogen for endocarditis

LEARNING OBJECTIVE 2: Suspecting septic emboli in patients with visual disturbances

CASE: A 62 year old Haitian woman with past medical history significant for hypertension and end stage renal disease on hemodialysis presented with sudden onset of blurry vision in the right eye. Physical exam was significant only for decreased visual acuity and 3/6 diastolic murmur best heard at the apex. Initial labs were significant only for elevated BUN and creatinine. Initial workup for a transient ischemic attack was started and CT of the head did not show any acute changes. The loss of visual acuity did not resolve and given additional concern for multiple sclerosis, MRI brain was ordered. MRI showed multiple infarcts throughout the brain with the largest being in the left occipital lobe secondary to suspected embolic etiology. This lesion's location was consistent with the patient's symptoms though the rest of her neurologic exam was benign and no other embolic stigmata were observed. Transthoracic echocardiogram showed a thickened mitral leaflet with an opening size of 1.8 cm. Follow up with transesophageal echocardiogram showed a 1-cm mobile vegetation on the mitral valve. Blood cultures at this time returned positive for *Citrobacter koseri* in 2 sets of anaerobic and aerobic bottles and treatment was started

with ceferime. The patient's vision started to improve and the patient underwent emergent mitral valve replacement. Surgical findings included abnormal mitral valve with small friable vegetations on the posterior leaflet, a posterior annular abscess with frank pus and significant pericarditis throughout the pericardial sac.

DISCUSSION: Citrobacter koseri is an exceedingly rare cause of endocarditis. To our knowledge only 5 other cases have been reported. These 5 cases include a hemodialysis patient, two intravenous drug users, one pacemaker patient and a young immunocompetent adult. None of these cases reported additional findings of cardiac abscess and pericarditis. One separate case implicated Citrobacter koseri and Proteus mirabilis in a polymicrobial suppurative pericarditis leading to tamponade. Citrobacter is a gram negative bacillus and facultative anaerobe part of the Enterobacteriaceae family which is distinguished from other members of the Enterobacteriaceae family for its ability to use citrate as a carbon source. Generally, Citrobacter koseri is known for causing infection in two distinct groups of patients. In neonates Citrobacter koseri can cause sepsis and meningitis leading to CNS abscesses and often death. These cases are sporadic and no clear infection source has been identified, though the natural habit of this bacteria is in water, food, soil, sewage and human excrement. The second group includes immunocompromised, elderly, and dehabilitated patients. Our patient does not fit either of these categories suggesting a third category exists that has not yet been defined. Further reports may help develop a clear source for this infection and elucidate this third group.

INFLUENZA A INFECTION IN A PATIENT WITH CONGESTIVE HEART FAILURE, A DYSPNEIC COMBINATION Komal D'Souza; Robin Klein. Emory University School of Medicine, Atlanta, GA. (*Tracking ID #1938669*)

LEARNING OBJECTIVE 1: Identify common clinical manifestations of congestive heart failure and influenza infection.

LEARNING OBJECTIVE 2: Highlight the link between CHF decompensation and influenza infection.

CASE: A 58 year old male was admitted to an urban hospital with respiratory complaints in the month of December. He reported progressive dyspnea on exertion for the past month and a productive cough for 4 days prior to admission. He also noted orthopnea and pleuritic chest pain associated with coughing. He denied myalgias. His past medical history was significant for congestive heart failure (CHF) with a reduced left ventricular ejection fraction of 10–15 %. He reported compliance with an ace-inhibitor and beta-blocker, but did report limited understanding of dietary sodium and fluid restrictions. He also reported his grand-son who had visited with him recently was also ill with respiratory symptoms. On exam, the patient was afebrile, mildly tachypneic and hypoxic, requiring supplemental oxygen to maintain adequate peripheral oxygen saturations. He had crackles in his posterior lung fields and elevated jugular venous distention with a positive hepato-jugular reflex. His labs were significant for renal insufficiency and an elevated brain-natriuretic peptide. His chest x-ray showed cardiomegaly and a pulmonary edema pattern. The patient was treated for acutely decompensated congestive heart failure and the etiology of his decompensation was initially attributed to dietary non-compliance. The patient's work of breathing was marginally improved with initial diuresis. On hospital day two, he became febrile with continued shortness of breath and cough. A respiratory virus panel nasal swab was collected and he was empirically started on an anti-influenza agent. His symptoms gradually improved and on the day of discharge, his respiratory virus panel resulted positive for the influenza A virus.

DISCUSSION: Acute decompensation of congestive heart failure (CHF) is one of the most common reasons for hospital admission in the United States. Most of the acute decompensations of this chronic disease can be attributed to progression of the underlying cardiomyopathy, dietary non-compliance, or inadequate medication regimens. Infections can also precipitate decompensation due to the pro-inflammatory response associated with infection. Influenza infection is also common, particularly in the winter months. Common manifestations include fevers, fatigue, myalgia, shortness of breath and cough. Patients with CHF are considered a high-risk group for severe influenza infections. Also, patients with CHF may be at a higher risk of hospitalization during the influenza season than during non-influenza seasons. Although patients with CHF who have been vaccinated against influenza may have a lower risk of hospitalization, these patients also may have difficulty mounting an immune response to newer antigens included in the annual influenza vaccine. Our patient presented with acute decompensated congestive heart failure triggered by influenza A infection. This case highlights the link between two common but potentially serious conditions: CHF decompensation and influenza. It is important to recognize the association between these conditions and to maintain a broad differential in considering the etiology of acute worsening of common chronic conditions. Furthermore, it is important to consider infectious etiologies for CHF

decompensation so these infections can be managed appropriately to prevent further cardio-pulmonary distress.

INITIAL PRESENTATION OF MULTIPLE MYELOMA AS INTRAPARENCHYMAL BRAIN MASS Ishan Malhotra; Abhinav Chandra; Yiwu Huang. Maimonides Medical Center, Brooklyn, NY. (*Tracking ID #1935319*)

LEARNING OBJECTIVE 1: A rare case of Intracranial periventricular Plasmacytoma who presented with headaches indicating the importance of Plasmacytomas in the differential diagnosis of intracranial/intraparenchymal tumors like meningioma .

LEARNING OBJECTIVE 2: It is critical to follow up patients frequently with a complete systematic work up to identify the transformation of Solitary Plasmacytoma into Multiple Myeloma.

CASE: 38 year old African female presented with complaints of severe headache which had started couple of weeks prior to presentation and was progressively becoming worse. Patient underwent a CT scan of the head which revealed a $3.2 \times 3.3 \times 3.7$ cm lobulated hyperdense periventricular mass in the left temporoparietal area. MRI of the brain revealed a $3.1 \times 2.6 \times 3.6$ cm lobulated mass in left lateral ventricle trigone. Patient underwent left craniotomy for tumor resection and the resected tumor was high grade malignant neoplasm with plasmablastic features and immunohistochemical stains revealed that the tumor cells were positive for CD138, CD30, MUM-1, Bcl-2, vimentin and lambda light chains and were negative for kappa light chains, CD3, CD20, PAX-5, CD79a, GFAP, cytokeratin, AE1/AE3, synaptophysin, chromogranin, EMA, S-100, Melan-A, CD45, CD56 and EBV (EBER-ISH). Ki-67 was about 80 %. Serum protein electrophoresis (SPEP) was sent that showed an M-spike of 3.3 g/dl that was IgG lambda. A bone marrow biopsy showed 100 % infiltration with plasma cells. Patient underwent a CT chest/abdomen/pelvis and a PET/CT scan which revealed multiple scattered subcutaneous masses throughout the body and an asymptomatic mass near spinal cord at C1. Patient was treated with VTD-PACE regimen (bortezomib, thalidomide, decadron, cisplatin, liposomal doxorubicin, cyclophosphamide, and etoposide) with excellent response to the treatment. She was referred for autologous stem cell transplant.

DISCUSSION: Malignancies of plasma cells comprise 1 % of malignant neoplasms which includes multiple myeloma, solitary plasmacytomas (including solitary bone plasmacytoma and extramedullary plasmacytomas) and immunoglobulin deposition syndromes. Cases with initial presentation of intracranial plasmacytomas are extremely rare. Central nervous system (CNS) involvement of multiple myeloma itself is not a common entity with the largest single center report of patients reported by Fassas et al. who published data of 18 cases over a course of 10 years. This is an extremely rare site for origination of brain tumors with differential diagnosis of brain tumors at this site being choroid plexus papilloma, ependymoma, subependymoma, subependymal giant cell astrocytoma, neurocytoma, meningioma, lymphoma and cerebral metastasis. Patients with CNS myeloma have poor prognosis with median survival being around 4–5 months. Our patient had excellent response with two cycles of VTD-PACE regimen with negative M-spike, normalization of IgG and decrease in size of subcutaneous nodules and C1 spinal lesion. She has survived for 5 months without autologous transplant and is currently on weekly cyclophosphamide, bortezomib and decadron.

INTERNAL CAROTID ARTERY DISSECTION - A CLASSIC PRESENTATION Opeyemi Fadahunsi; Joelle Lauchner; Ana Abaroa-Salvatierra; Anthony Donato. Reading Health System, Reading, PA. (*Tracking ID #1931485*)

LEARNING OBJECTIVE 1: Recognize carotid artery dissection in patients presenting with a triad of unilateral headache or facial pain, neck pain and partial Horner syndrome.

CASE: We present an 18-year old female on oral contraceptive pills (OCPs) with a 2 month history of right-sided neck and periorbital pain. One week prior to admission she noticed new miosis and ptosis with no other neurological complaints and presented for evaluation. She specifically denied any trauma, rigorous activity, or personal or family history of connective tissue disease. Physical examination revealed unilateral ptosis and miosis, with no other abnormalities noted on examination. CT angiography of the neck demonstrated a 5 mm dissection of the right internal carotid artery. MRI of the brain was unremarkable. Echocardiography did not demonstrate any aortic root dilatation. This patient was admitted and placed on heparin with a warfarin bridge. She was discharged with instructions to complete 6 months of Coumadin therapy and to discontinue OCP use. At the 6 month evaluation, she continued to demonstrate findings of minimal right-sided ptosis and miosis with no other neurological

findings. Repeat CT angiography of the neck and head revealed minimal residual irregularity of the distal cervical right internal carotid artery without significant stenosis. Coumadin was stopped and the patient was switched to Aspirin at this visit. A follow up appointment was scheduled in 1 year.

DISCUSSION: Although head, neck and facial pain are common complaints in the ambulatory setting, when presented with accompanying complaints of miosis and ptosis (partial Horner's), one should have a high suspicion for carotid artery dissection. Early diagnosis may allow for consideration of anticoagulation or antiplatelet therapy with hopes of preventing a stroke event. Our case did not have any disabling deficit at the 6 month evaluation. This is consistent with findings in literature that showed excellent recovery in 70 to 85 % of cases of extracranial dissection.

INTESTINAL ASCARIASIS IN THE MODERN ERA Paras Karmacharya¹; Madan R. Aryal¹; Pragya Shrestha²; Supriya Shrestha Tamrakar³; Ranjan Pathak¹; Raju Khanal¹; Satyajeet Roy⁴. ¹Reading Health System, West Reading, PA; ²Nanjing Medical University, Nanjing, China; ³Guangxi Medical University, Guangxi, China; ⁴Cooper University, Camden, NJ. (*Tracking ID #1935103*)

LEARNING OBJECTIVE 1: Diagnose intestinal ascariasis which can present with non-specific symptoms and signs. Diagnosis requires high index of suspicion and can be usually made through a combination of blood counts showing marked leucocytosis with eosinophilia, stool studies and radiographic imaging.

LEARNING OBJECTIVE 2: Treat intestinal ascariasis with antihelminthic therapy which is usually effective except in few complicated cases where surgical interventions might be needed.

CASE: A 40-year-old woman presented with altered bowel movements, 10 lb weight loss and abdominal discomfort for 1 month. On examination, the patient was afebrile and had mild tenderness in the epigastric region. Prior to this, she had been on a week-long trip to Mexico. Patient's complete metabolic profile, complete blood count, serum amylase and lipase, urine analysis and culture, and stool studies for white blood cells, ova, parasite, and culture were all either in the reference range or negative. An ultrasonography of the abdomen was normal. A computerized axial tomography (CT) scan of the abdomen with oral and intravenous radiocontrast material showed multiple tubular filling defects about 15 cm in length predominantly located in the jejunal lumen (Figure 1, 2 and 3), highly suggestive of intestinal parasites. She was treated with a one dose of oral albendazole 400 mg. After 1 week, her symptoms improved and she reported passage of 15–20 cm long cream colored cylindrical worms in her stool.

DISCUSSION: Most patients with intestinal ascariasis are asymptomatic, hence it can be undetected for years until they develop some symptoms (1,2). Diagnosis is usually made through a combination of blood counts showing marked leucocytosis with eosinophilia, stool studies and radiographic imaging. Complications can range from nutritional deficiency to obstruction of the bowel lumen, the bile or pancreatic duct, perforation, volvulus, intussusception, appendicitis, cholecystitis, biliary colic, cholangitis, hepatic abscess and pancreatitis depending on the site and severity of infestation (1,3). Antihelminthic therapy is usually sufficient except in few cases where surgical interventions might be needed (4). References: 1. Kanneganti K, Makker JS, Remy P. INTRACTABLE NAUSEA AND VOMITING IMPROVED THROUGH TARGETED SELECTION OF ANTIEMETIC MEDICATIONS Rachel Hayver; Keith M. Swetz. Mayo Clinic, Rochester, MN. (*Tracking ID #1938060*)

LEARNING OBJECTIVE 1: List common pathways leading to nausea/vomiting.

LEARNING OBJECTIVE 2: Describe the various pathways associated with nausea/vomiting and appropriate pharmacologic targeting of receptors.

CASE: We present a case of nausea and vomiting (N&V) severe enough to require nutritional support, and discuss how appropriate evaluation and pharmacotherapy can lead to optimal outcome. An 84-year-old woman was transferred to our institution after a 21-day history of Intractable N&V associated with vertigo and inability to maintain hydration. Head MRI revealed a left cerebellar stroke. Ondansetron and

prochlorperazine were given with no relief and haloperidol provided only modest improvement. The patient was initiated on parenteral nutrition due to lack of progress, and transfer to our institution was requested. Review of symptoms revealed that N&V dramatically worsened with head movement, suggesting a vestibular mechanism. Additionally, the symptoms started abruptly at the time of stroke diagnosis, suggesting a central source. Recommendations were made for anticholinergics (diphenhydramine) targeting the vestibular pathway, and dexamethasone targeting centrally. Haloperidol was continued in order to cover the dopaminergic receptors in the vomiting center. With these changes, the patient's symptoms and quality of life improved significantly, allowing her to resume oral nutrition.

DISCUSSION: Nausea and vomiting is a common symptom that significantly affects quality of life, but all N&V is not the same. Patients with Intractable N&V require a detailed history and physical exam to investigate potential etiologies. Many pharmacologies exist for control of N&V, and some are often used routinely as part of hospital order sets. Medications prescribed for N&V without individual patient evaluation may result in lack of efficacy and results in resource overutilization (e.g. delayed hospital discharge, nutritional support). We promote a structured approach to N&V based on individual patient history and physical, and note that in cases of Intractable N&V, a careful review of etiologies and coverage of multiple neurotransmitters may be necessary to provide adequate symptom palliation.

IS CARDIAC CATHETERIZATION THE DEFINITIVE TREATMENT OF CARDIO EMBOLIC MYOCARDIAL INFARCTION FROM INFECTIVE ENDOCARDITIS? Leena Rahmat¹; Vijay Gadiraju¹; Shanmugam Uthamalingam²; Mathias Stoenescu². ¹Baystate Medical Center, Springfield, MA; ²Baystate Medical Center, Springfield, MA. (*Tracking ID #1922897*)

LEARNING OBJECTIVE 1: Myocardial infarction (MI) as a result of coronary artery septic embolization is a rare complication of infective endocarditis (IE), associated with a high mortality

LEARNING OBJECTIVE 2: Optimal therapeutic strategies remain controversial due to the risks from coronary intervention.

CASE: A 40-year-old male with a history of intravenous drug abuse (IVDA) presented with a three-day history of fever. His past medical history was significant for bacteremia, IE secondary IVDA requiring mechanical aortic valve replacement, hepatitis C, hypertension and hemorrhagic stroke. Physical examination was significant for a temperature of 102.2, sinus tachycardia, a systolic murmur and a normal neurological exam. He had a leukocytosis of 25000, and an echocardiogram revealed a 1.12 cm vegetation on the ventricular surface of the aortic valve. He was diagnosed with IE and was started on IV antibiotics. Blood cultures grew candida albicans and an antifungal was initiated. Cardiac surgeons deemed him a poor surgical candidate given his ongoing IVDA. During the hospitalization, he suffered an acute MI with ST-segment elevations in the infero-lateral leads on EKG and positive cardiac biomarkers (Troponin T 0.15, CK 688, and CK-MB 50.3). After weighing the risks and benefits, he underwent cardiac catheterization which demonstrated 100 % stenosis of the mid left anterior descending artery (LAD), consistent with embolic occlusion of the culprit vessel. The aspirated debris grew candida albicans. After the catheterization he suffered an embolic stroke with a frontal infarct resulting in expressive aphasia, comprehensive deficits, and behavioral issues. He improved during the hospital course and was discharged to rehabilitation.

DISCUSSION: IE is associated with a high in-patient mortality rate, ranging from 16 to 25 % and a high incidence of embolic events ranging from 13 to 49 %. Although septic embolization is a well delineated complication of bacterial IE, cardio embolic MI as a result of septic embolization from cardiac valve vegetation is rare, with an estimated incidence of 0.3–1 %. As rare as coronary artery emboli are, cardiac valves are the most common sources. Coronary angiography may establish the diagnosis of septic emboli in coronary arteries. There is a risk of dislodging a piece of vegetation into the systemic circulation if there is contact between the angiography catheter and the valve surface vegetation, which happened in our patient, resulting in a stroke. Fortunately our patient suffered a minor stroke and eventually improved but one would be at high risk of developing a major stroke and brain abscess from the dislodgement of the infected vegetation. The indication for percutaneous intervention mainly depends on the size of the infarct and degree of complications due to the MI. Surgical embolectomy using direct coronary incision has been described in literature as an alternative therapeutic option in unstable patients too. Cardioembolic MI is an uncommon and lethal complication of IE, associated with a high mortality. Its early recognition is vital in order to optimize management. The decision on coronary intervention should be made on a case by case basis considering the benefits vs. possible life-threatening complications.

IS THAT EFFUSION REALLY PARAPNEUMONIC? THE CHALLENGE OF AVOIDING CHEST TUBES IN HEPATIC HYDROTHORAX AND SPONTANEOUS BACTERIAL EMPYEMA Hirotaka Kato; Dovid Moradi; Cameron S. Page. Beth Israel Medical Center, New York, NY. (*Tracking ID #1935428*)

LEARNING OBJECTIVE 1: Comprehend presentation, diagnosis and management of hepatic hydrothorax and spontaneous bacterial empyema.

LEARNING OBJECTIVE 2: Learn that chest tube is contraindicated for hepatic hydrothorax/SBEM and its complications and also understand the need for a low threshold of suspicion for hepatic hydrothorax in any cirrhotic patients with pleural effusion.

CASE: A 34 year-old male with hepatitis C and alcoholic liver cirrhosis presented with 1 day history of nausea, bilious vomiting and intermittent epigastric pain. The patient had elevated WBC but no fevers, SpO₂ was 92 % on ambient air, and abdomen was tender to palpation in the right upper quadrant. Intra-abdominal processes were suspected, but abdominal ultrasound, HIDA scan, and paracentesis were all negative. Chest X ray revealed right pleural effusion and chest CT showed RLL infiltrate, so ceftriaxone and metronidazole were started for pneumonia with parapneumonic effusion. Thoracentesis showed an exudative fluid. Blood cultures detected Streptococcus pneumoniae but pleural fluid culture was negative. In the 48 h after thoracentesis, he developed aggressive re-accumulation of right pleural effusion and a chest tube was placed. Over the next 2 days nearly 4 L of pleural fluid was drained from the chest tube, and repeat samples showed a transudative fluid, consistent with hepatic hydrothorax. Chest tube was clamped to prevent further nutritional and albumin loss, and aggressive diuretic treatment was begun. His hospital course was complicated by worsening cirrhosis and variceal bleeding, which required blood transfusions and 3 days in the MICU. On hospital day 16 the patient accidentally pulled out his chest tube and a fistula formed between the pleural space and the chest wall. Due to active alcohol use, the patient was not a candidate for liver transplantation, and he was discharged to hospice for comfort care on day 22.

DISCUSSION: Hepatic hydrothorax and spontaneous bacterial empyema (SBEM) are rare complications of cirrhosis. They have been known to occur even in the absence of ascites. SBEM occurs in 15 % of hepatic hydrothorax patients. The diagnostic criteria include culture-positive or culture-negative pleural fluid, with PMN count greater than 500, or flank pus. At the time of chest tube placement this patient did not meet criteria for SBEM. Due to his poor prognosis and refusing tap, antibiotics were started before thoracentesis, however, which may have complicated the diagnosis. The presence of *S. pneumoniae* bacteremia in the setting of pleural effusion is supportive of the diagnosis of hepatic hydrothorax with SBEM. Chest tube placement is contraindicated in SBEM and hepatic hydrothorax. In this case, the clinical course included worsening cirrhosis and variceal bleeding, both of which are known complications of chest tube placement in hepatic hydrothorax. Chest tube placement might have accelerated the patient's clinical course. Physicians should use caution when considering chest tubes in patients with cirrhosis. Even when imaging studies and pleural fluid suggest primary lung pathology, if the patient exhibits signs and symptoms of an intra-abdominal process then chest tube should be deferred until hepatic hydrothorax can be definitively ruled out.

ISOLATED VISCERAL KAPOSI'S SARCOMA Kristin Bateman; Philip J. Putnam. Tulane University Health Sciences Center, New Orleans, LA. (*Tracking ID #1926112*)

LEARNING OBJECTIVE 1: Recognize the incidence and presentation of visceral Kaposi's sarcoma

LEARNING OBJECTIVE 2: Discuss the treatment course for visceral Kaposi's sarcoma

CASE: A 26 year-old man presented with three-day progression of dyspnea on exertion. He experienced associated symptoms of odynophagia and dysphagia with an associated thirty-pound weight loss over 1 month. He has a history of untreated HIV diagnosed 5 years ago. He is not taking any medications. His exam revealed a pulse of 139 and fever of 101°, pale conjunctivae, cervical lymphadenopathy, white plaques in his oropharynx, and anal warts, with no gross blood on rectal exam nor skin lesions. A complete blood count revealed pancytopenia, and CD4 count of 3. Work-up of his microcytic anemia was consistent with iron deficiency and chronic inflammation. He was transfused two units of packed red blood cells. In the setting of oral thrush, iron deficiency anemia, and odynophagia with weight loss, the patient underwent esophagogastroduodenoscopy, which revealed esophageal candidiasis with esophagitis, and Kaposi's Sarcoma of the stomach.

DISCUSSION: Kaposi's Sarcoma (KS) is the most common cancer in HIV-infected individuals. Ninety percent of KS presents with cutaneous lesions, and about one-third of these individuals develop gastrointestinal metastases. KS also may

metastasize to lymph nodes, lung, and liver. Overall, this angioproliferative disorder is an AIDS-defining illness, the spectrum of disease ranges from indolent skin manifestations to fulminant and extensive visceral involvement. Symptoms of gastrointestinal involvement are non-specific, and include chronic blood loss anemia, vomiting, diarrhea, and intestinal obstruction. Patients may also have asymptomatic visceral KS. The identification of visceral KS, particularly gastrointestinal, requires endoscopic biopsy. Endoscopic findings vary from patches to vascular submucosal nodules to bulky masses with ulcerations. Biopsy of patches in early disease tends to have low diagnostic yield, however, a negative biopsy result should not exclude KS. There is up to a 35 % false negative rate in gastrointestinal lesions, due to the variability of gross appearance of the lesions. Typically, disease limited to skin findings is treated with local therapy or electrochemotherapy. If there is visceral involvement, treatment includes antiretroviral therapy and systemic chemotherapy, the first-line treatment being liposomal anthracyclines. As visceral involvement portends a worse prognosis, early identification is crucial to start appropriate therapy. Patients with identified cutaneous lesions should be evaluated for visceral involvement as well. Overall, gastrointestinal KS is a difficult disease to identify, particularly when there are no associated cutaneous manifestations. The only independent risk factors identified in gastrointestinal KS are men-who-have-sex-with-men and CD4 cell count less than 100. With these risk factors and non-specific symptoms described earlier, primary care physicians should have a low threshold to refer for endoscopy to diagnose and treat this AIDS-associated malignancy.

IT IS MORE THAN A VOODOO. THE LIMBIC HEART Ahmed Abuzaid¹; Hitham Al-Alshry¹; Hamza Tantoush¹; Allen Ameri¹; Gale M. Etherton^{2,3}.

¹Creighton university, omaha, NE; ²UNMC, omaha, NE; ³VA Medical Center, omaha, NE. (*Tracking ID #1934912*)

LEARNING OBJECTIVE 1: The nervous system's capacity to injure the heart has been described in a number of clinical reports. Excessive stimulation of the cortical limbic system is associated with hyperactivity of the catecholamine circuits. Cardiac involvement can be seen with excessive stimulation of the limbic system.

LEARNING OBJECTIVE 2: Hyperactivity of the catecholamine circuits can be precipitated by substance abuse, such as cannabis. Neurogenic cardiomyopathy is an uncommon presentation of cannabis can lead to misdiagnosis.

CASE: Our patient was a 60-year-old male with no significant past medical history. He was brought to the ED after persistent retrograde memory loss of 4 days duration. He denied any other complaints. He had a remote tobacco history, did not consume alcohol heavily but consumed cannabis 5 days prior to admission. He had no known drug allergy, no recent prescription drug intake and no significant family history. On examination, he was afebrile, blood pressure was 132/84 mmHg, and heart rate was 86/min. Physical examination was unremarkable except for impaired 3 min recall test. The results of routine biochemical tests were satisfactory. Serial cardiac biomarkers were mildly elevated. Urine screen was positive for cannabis only. An EKG showed NSR with deep T-wave inversions in anterior leads. TTE revealed severe anterior wall hypokinesia with estimated ejection fraction 30–35 %. A non-contrast head CT scan was unremarkable. Head MRI revealed patchy contrast enhancement in the left limbic region without mass effect or evidence of acute infarct, suggestive of limbic encephalitis. An electroencephalogram showed no evidence of seizure activity. Left heart catheterization showed non obstructive coronary disease and apical ballooning. Further evaluation of limbic encephalitis including viral serology and CSF analysis (chemistry, cell count, viral PCR panel, microbial cultures and cytology) were all unremarkable. A malignancy work up including whole body CT scan, paraneoplastic antibodies and a vasculitis panel were all negative. A diagnosis of neurogenic stunned myocardium as a manifestation of cannabis induced limbic encephalitis was established. Mini-Mental Status examination towards the end of the hospitalization was 26/30 with deficits in recalls and date abilities (unchanged since admission). Follow up showed significant resolution of his EKG, echocardiography and memory deficit with complete cannabis abstinence.

DISCUSSION: After excluding viral and autoimmune disorders, many patients with limbic encephalitis have CSF, EEG or MRI abnormalities, and rarely, myocardial compromise. Our patient's cardiac abnormalities included EKG changes, mild elevation of cardiac biomarkers and transient LV dysfunction. Over activity of the sympathetic limb is the common phenomenon that associates the major cardiac pathologies seen in neurological insults. It is thus conceivable that overstimulation of catecholamine circuits in the limbic system due to cannabis ingestion could manifest as neurogenic heart disease. Providers should be aware of an uncommon presentation of cannabis ingestion.

IT'S NOT YET TIME TO HANG UP YOUR HAT Marie Caldwell; Jonathan Kirsch. UNC Hospitals, Chapel Hill, NC. (*Tracking ID #1895542*)

LEARNING OBJECTIVE 1: Diagnose a long term complication of liver transplantation.

LEARNING OBJECTIVE 2: Recognize the anatomic complications of hepatic artery thrombosis.

CASE: A seventy year-old woman presented with 8 weeks of progressive abdominal pain. She underwent a liver transplant 12 years ago and had a previously uncomplicated course. Her abdomen was tender to palpation in the right upper and right lower quadrants without rebound or guarding. She had no scleral icterus or asterixis. Her transaminases (AST and ALT) were both over 2000 U/L, bilirubin was 1.4 mg/dL, INR was 1.2, and white blood cell count was $17 \times 10^3/\mu\text{L}$. Liver ultrasound revealed a hepatic abscess in the right lobe with poor visualization of the right hepatic artery. She was started on intravenous antibiotics and a percutaneous drain was placed into the abscess. Blood and abscess cultures grew Enterococcus faecalis. After abscess drainage a liver ultrasound was repeated and showed no hepatic arterial flow. A hepatic arteriogram confirmed a 100 % occlusion of the common hepatic artery, consistent with complete hepatic artery thrombosis (HAT). She was not a candidate for retransplantation due to her age and comorbidities. Despite the complete hepatic artery occlusion the patient's transaminases and bilirubin trended down to normal. She continued to improve clinically and was discharged home with a drain in place and on antibiotics.

DISCUSSION: As more liver transplants are performed each year and transplanted livers are lasting longer, more hospitalists will be taking care of these patients. Short term complications include graft rejection and infections. Long term complications are not as well characterized in this patient population. HAT occurs in 1–10 % of liver transplant recipients, mostly in the first 30 days, and has a mortality of 73 %. Late HAT has a milder clinical course, likely due to the development of collateral circulation. Clinical presentation includes fever, elevated transaminases, and a biliary leak or hepatic abscess. Our patient had developed collaterals and improved after drainage of the abscess. HAT is diagnosed with Doppler ultrasound and can be confirmed with hepatic angiogram or MRI. Broad spectrum antibiotics are recommended as bacteremia is a common complication. Treatment includes drainage of abscess or fluid collection and broad spectrum antibiotics. Re-transplantation should be considered if the operative risk is acceptable. This case illustrates the unique and complex circulation of the liver, which is important to understand in patients with long lasting liver transplants. The portal vein supplies two thirds of the blood flow to the liver; the hepatic artery supplies the latter one third and supplies all of the blood to the biliary tract. HAT therefore tends to cause ischemia and rupture of the biliary tract. However, the liver parenchyma may be spared due to the unique circulation in the liver. Venous and arterial circulation mix within the hepatic sinusoids and the hepatocytes receive sufficient oxygen even without a functioning hepatic artery.

IT'S NOT ALL IN HER HEAD Neetha Reddy; Manuela Calvo. Montefiore Medical Center, Bronx, NY. (*Tracking ID #1939333*)

LEARNING OBJECTIVE 1: Recognize appropriate approach to hypereosinophilia

LEARNING OBJECTIVE 2: Recognize presentation, management and prognosis of hypereosinophilic syndrome

CASE: A 34 year-old woman presented with a 4 year history of intermittent severe abdominal pain associated with nausea and non-bloody diarrhea. She had no past medical history and took no medications. She had been hospitalized several times for abdominal pain in the past. No organic etiology had been found and psychiatric etiology had been considered. On exam abdomen was mildly tender to palpation in the lower quadrants. Initial eosinophil count was 2700 cells/mcl and peaked at 9500 cells/mcl. Infectious, atopic, and autoimmune workup was unrevealing. CT abdomen revealed diffuse thickening of the esophagus and portions of the small and large bowel. EGD and subsequent biopsy revealed marked eosinophils in the duodenal lamina propria. Bone marrow biopsy revealed marked eosinophilia as well. Bone marrow cytogenetics were normal. Echocardiogram and CT thorax were unremarkable. The patient was started on systemic steroids. Eosinophil count dropped to 0.1 cells/mcl and her symptoms improved.

DISCUSSION: Eosinophilia is defined as >500 eosinophils/mcl of blood. Causes of eosinophilia include medications, infection, atopy and malignancy. Parasites that can cause eosinophilia are strongyloides, toxocara, trichanella, schistosoma, hookworm, filariae, and entamoeba. In patients with pulmonary symptoms, allergic bronchopulmonary aspergillosis should be considered in those that have a history of asthma and coccidioidomycosis should be considered in those that have been in endemic areas. Rarely rheumatologic conditions and immunoglobulin deficiencies

can lead to eosinophilia. Benign and malignant hematologic disorders (leukemia, lymphoma, mastocytosis, hypereosinophilic syndromes) can cause eosinophilia as well. These conditions can be evaluated for though thorough history, laboratory testing, and in the case of hematologic disorder, bone marrow biopsy. Hypereosinophilic syndrome is defined as >1500 eosinophils per microliter of blood with no other apparent etiology of eosinophilia (asthma, parasites etc.) accompanied by eosinophil mediated multiple end organ dysfunction. Hypereosinophilic syndrome can be further sub-classified into primary hypereosinophilic syndrome and overlap hypereosinophilic syndrome. In primary hypereosinophilic syndrome eosinophilic expansion is due to underlying hematologic malignancy. In overlap hypereosinophilic syndrome there is no underlying malignancy and only single organ involvement. Presentation of hypereosinophilic syndrome varies greatly depending on which organ systems are involved. 14% of patients with hypereosinophilic syndrome present with gastrointestinal symptoms such as abdominal pain, gastritis, enteritis, or colitis. Workup of suspected hypereosinophilic syndrome includes, first and foremost, ruling out other possible causes of hypereosinophilia followed by bone marrow biopsy to assess for underlying malignancy. Patients should also have through laboratory and imaging workup to assess for end organ involvement. Once the diagnosis of hypereosinophilic syndrome is made patients are treated with prednisone (and imatinib in the case of primary hypereosinophilia). Prognosis is dependent upon degree of end organ damage, presence or lack of underlying malignancy, and degree of response to systemic steroids.

IT'S NOT ALWAYS A RELAPSE: SPORADIC CREUTZFELDT-JAKOB DISEASE IN A PATIENT WITH RELAPSING-REMITTING MULTIPLE SCLEROSIS Julius Cesar G. Laban; Rex Wilford. Summa Health System, Akron, OH. (*Tracking ID #1912662*)

LEARNING OBJECTIVE 1: Recognize the clinical features of sporadic Creutzfeldt-Jakob disease in a patient with relapsing-remitting multiple sclerosis

CASE: A 47-year-old African-American female with 7-year history of relapsing-remitting multiple sclerosis (MS) was admitted for a 2-month history of rapidly worsening mental status, generalized weakness, gait abnormality, speech difficulty, and hallucinations. The patient denied any recent travel or family history of early-onset dementia. She was diagnosed with subacute MS relapse by her local neurologist 1 month prior to admission. Extensive neurologic, autoimmune, infectious, and metabolic work-up was done. Blood tests were unremarkable. Initial magnetic resonance imaging (MRI) of the brain showed moderate typical MS-appearing demyelination. The electroencephalogram exhibited diffuse slowing without periodic complexes. Cerebrospinal fluid (CSF) analysis revealed a mildly elevated protein (50 mg/dL), normal glucose without leukocytosis, and presence of oligoclonal bands. The CSF 14-3-3 protein test came back positive suggesting the diagnosis of sporadic Creutzfeldt-Jakob disease (CJD). This was further confirmed with repeat MRI of the brain (done 17 days after the previous one) that showed abnormal hyperintensities with diffusion restriction in bilateral caudate nuclei and putamen. The patient was discharged to a skilled nursing facility with progressive neurologic decline (exhibited myoclonus and akinetic mutism), and subsequently died 28 days after her initial presentation.

DISCUSSION: MS and CJD share a number of clinical, pathologic, and immunologic features that may be explained by the proposed “molecular mimicry” and autoimmunity that may exist between the two disease processes. These similarities may pose a diagnostic challenge to the clinician. Hence, it is not always a relapse, sporadic CJD should be considered in the differential diagnosis of a patient with established MS presenting with rapidly progressive dementia. To our knowledge, this is the first report of CJD in a patient with established MS in the United States.

K2, SPICE THE GUT DON'T LIKE: CANNABINOID HYPEREMESIS SYNDROME DUE TO THE SYNTHETIC CANNABINOID K2 Anene Ukaigwe; Paras Karmacharya; Anthony Donato. The Reading Health System, West Reading, PA. (*Tracking ID #1939115*)

LEARNING OBJECTIVE 1: Diagnose Cannabinoid Hyperemesis Syndrome (CHS)

LEARNING OBJECTIVE 2: Recognize that Conventional Urine Drug Screen (UDS) is negative in cannabicyclohexanol (K2) users.

CASE: 38-year-old man with no significant past medical history presented with 1-week history of episodes of nausea and vomiting of clear fluids, associated with ill-defined epigastric pain. He has had previous episodes in the past 3 months. He reports that only hot showers relieve symptoms. Review of symptoms was not contributory.

He admitted using cannabis for over 10 years, changing to K2 spice in the past year. On examination, vital signs were within normal limits. His abdomen was soft and non-tender. Bowel sounds were reduced. The remaining physical examination was unrevealing. He interrupted evaluation and care several times to take hot showers. Laboratory test showed sodium -123 mEq/L, BUN -160 mg/dl, Creatinine -4.78 mg/dl. Liver function test, amylase and lipase were normal. Abdominal x-rays did not reveal any bowel obstruction. Esophagogastroduodenoscopy was unremarkable. UDS was negative. Renal ultrasound and urinalysis was normal. Fractional excretion of sodium (FeNa) was 40 %. Given chronic cannabis use, cyclic vomiting, abdominal pain without other cause found on evaluation, CHS was diagnosed, complicated by pre-renal acute renal failure (ARF). He was treated with intravenous fluids and ondansetron. ARF resolved within 72 h. He was counseled on the need to quit all cannabinoids to prevent further episodes. He remained normal and abstinent at 2-month follow up.

DISCUSSION: Allen et al. recently described CHS in 2004. CHS is characterized by cyclical nausea and vomiting, abdominal pain and an unusual compulsion to take hot showers in the presence of chronic use of natural and now synthetic cannabinoid substances. Although antiemetic properties of cannabinoids drive the "medical marijuana" campaign, it is important to note that it may have paradoxical effects as in CHS. Due to relative novelty of CHS, it is often unrecognized by clinicians leading to huge health care costs in evaluating these patients with cyclical symptoms. It has been reported that it may take up to 9 years to arrive at a diagnosis. This delay may lead to patient and physician dissatisfaction. The treatment consists of supportive care. Intravenous fluids may be needed, as the vomiting may be severe enough to cause renal failure as in our patient. The only definitive treatment is complete cessation of the culprit cannabinoid, as evidenced by the fact that the symptoms resolve as drug levels wane. Cannabinocyclohexanol, is a synthetic cannabinoid, popularly known as K2 spice. It is increasingly used as a marijuana alternative among teenagers and young adult as it is readily available as herbal incense. Unlike marijuana, Cannabinoids are negative on UDS with K2 use, making it even more attractive to these patients. K2 is detected, only with gas chromatography mass spectrometry, which is not widely available. It is imperative for clinicians to recognize CHS, even with negative UDS, to provide cost effective care, help patients break the cycle of cannabinoid and CHS.

KNOWN ENEMY TO THE KIDNEY...ALSO A HEPATIC FOE George Shelton^{1,2}; Nivedita Lakhra³; Pradeep Yarra³; LeChauncy D. Woodard^{1,4}. ¹Michael E. DeBakey VA Medical Center, Houston, TX; ²Baylor College of Medicine, Houston, TX; ³Wake Forest Medical Center, Winston Salem, NC; ⁴Baylor College of Medicine, Houston, TX. (*Tracking ID #1928538*)

LEARNING OBJECTIVE 1: Recognize Ciprofloxacin as a Cause of Drug-Induced Liver Injury (DILI)

LEARNING OBJECTIVE 2: Differentiate DILI from Drug Rash with Eosinophilia and Systemic Symptoms (DRESS)

CASE: A 41 year-old African American male with past medical history significant for dilated cardiomyopathy (EF 30–35 %), diabetes, hypertension, hyperlipidemia, gout, obesity, and recent admission for acute renal failure and urinary tract infection presented to the emergency department 3 days after hospital discharge. He complained of pruritus, rash, nausea, and diarrhea. He was found to have acute renal failure and hepatic dysfunction. Labs at presentation included potassium 6.3, Cr 3.72, BUN 75, total bilirubin 2.9, Alkaline Phosphatase (AP) 351, AST 832, and ALT 959. Medications included spironolactone, allopurinol (last dose 4 weeks ago), lisinopril, ciprofloxacin, furosemide, and metolazone. On admission, urinalysis showed epithelial casts and proteinuria (Protein/Creatinine ratio of 0.46). FENa was consistent with pre-renal azotemia. Abdominal ultrasound revealed hepatosplenomegaly. Non-contrast CT revealed hepatic steatosis. The patient's liver function tests peaked on hospital day 3 (Bilirubin 3.6, AP 493, AST 1059, ALT 1231). His INR was 2.04. Gastroenterology was consulted. Triglycerides, ceruloplasmin, and iron saturation were normal. Screening for viral (EBV, CMV, HIV, Hepatitis A- C) and autoimmune (anti-Smooth Muscle Ab and ANA) etiologies was negative. The patient was diagnosed with ciprofloxacin-induced- liver injury (CILI). Given his deteriorating hepatic failure, he was treated with N-Acetylcysteine and steroids with rapid improvement in hepatic (AP 97, AST 298, ALT 341, and INR 1.2) and renal (Cr 1.5) function at discharge.

DISCUSSION: CILI is a rare complication of a common medication. The mechanism of liver injury is thought to be a hypersensitivity response to fluoroquinolones. It occurs most commonly in adults over 30 years old, presenting with symptoms of liver injury within 1–10 days after drug exposure. Common symptoms include nausea, abdominal pain, jaundice, pruritus, fever, rash, and eosinophilia. In patients with immunologic symptoms such as fever, rash or

eosinophilia, steroids may be effective. In patients with CILI, the R-ratio (percent increase in ALT above upper limit of normal (ULN)/percent increase in alkaline phosphatase above the ULN) is used to predict the pattern of liver injury. R-ratios of >5 suggest hepatocellular injury (5.83 for this patient), R-ratios <2 suggest cholestatic injury, and R-ratios of 2–5 suggest a mixed hepatocellular/cholestatic liver injury pattern. Fever is more common with cholestatic injury whereas rash is found in hepatocellular or cholestatic liver injury patterns. Mixed liver injury pattern confers the best prognosis and is not associated with rash. In one study, CILI carried a 15 % mortality rate—consistent with the 10 to 80 % mortality rate for DILI with acute liver failure. DRESS also primarily occurs in adults. It usually presents 2–6 weeks after exposure to agents such as anticonvulsants, allopurinol, sulfonamides, dapsone, minocycline, or vancomycin. Symptoms include fever, malaise, lymphadenopathy, and rash. Other signs and symptoms are related to liver (hepatomegaly and jaundice), renal (acute interstitial nephritis, proteinuria, and eosinophiluria), or pulmonary (cough, tachypnea, hypoxemia, pneumonitis, etc.) involvement. DRESS has an approximate 5 % mortality rate. This patient had features of DRESS and CILI. His hepatic and renal dysfunction could have represented DRESS with rash, AIN, and liver involvement vs. CILI with rash and renal hypersensitivity nephritis. The time course of his symptoms was consistent with both DRESS and CILI as he was exposed to allopurinol (DRESS) 4 weeks prior to presentation and exposed to ciprofloxacin (CILI) 4 days prior to presentation. However, this patient did not meet diagnostic criteria for DRESS. The European Registry of Severe Cutaneous Adverse Reactions (RegiSCAR) DRESS and Japanese consensus DIHS (Drug-induced hypersensitivity syndrome) diagnostic criteria both include a drug-related rash, fever, adenopathy, organ involvement, and hematologic abnormalities. This patient had a suspected drug-related rash and organ involvement; however, he had no adenopathy, fever, eosinophilia, or other hematologic abnormalities. Thus, he met 2 of the 3 required RegiSCAR criteria and only 2 of the required 5 Japanese Consensus DIHS Criteria. Given that he did not meet diagnostic criteria for DRESS and had an otherwise negative evaluation, his presentation was most consistent with CILI. He was treated with steroids given the presence of a rash indicating likely hypersensitivity. He was also given N-acetyl cysteine as this has been shown to improve transplant-free survival in some cases of DILI-related acute liver failure. His rapid response to these therapies further supported the diagnosis of hypersensitivity-mediated CILI.

LADY WINDERMERE'S RASH Paavani Komanduri. University of Pittsburgh Medical Center, Pittsburgh, PA. (*Tracking ID #1939180*)

LEARNING OBJECTIVE 1: Describe the role of *Mycobacterium Avium* Intracellulare complex in creating cavitary lung lesion

LEARNING OBJECTIVE 2: Discuss the treatment of pulmonary MAI disease

CASE: Mrs. Z is a 53 year old with a history of anorexia nervosa and anemia who presented to her primary care doctor with a new onset of rash. The rash started 4 days prior to the visit as macular non-blanching lesions in her inner thighs that progressed to cover both lower extremities. Over the next 2 days they evolved and became purpuric lesions. She noted that for the last 1 month she had a non-productive cough and night sweats without fevers, dyspnea or orthopnea. She also noted mild arthralgia of her knees over the same span of time. Physical exam demonstrated a thin female in no distress. Her BMI was 14.9 and other vitals were within normal limits. Her cardiac, lung and abdominal exams were unremarkable. Her lower extremities were covered in a numerous 0.5 cm macules with interspersed palpable purpura. Her initial labs were remarkable for normal basic metabolic panel and ESR of 88 with hsCRP of 4.155. Chest X-ray showed an alveolar left lung infiltrate with a thin-walled right upper lobe cavitary lesion which was confirmed on chest CT. CT also showed bronchiectasis and small scattered nodules. She underwent induced sputum which eventually grew *Mycobacterium Avium* Intracellulare. Biopsy of her skin rash was consistent with a leukocytoclastic vasculitis due to the MAI. Further testing for a vasculitic cause of her purpura including ANA, ANCA, C3, C4, hepatitis B and C were all negative. Patient was started on azithromycin, ethambutol and rifampin which resulted in improved in her cough and resolution of her rash. However, after 6 months of therapy, she continued to have positive sputum cultures and moxifloxacin was added. Two months later, her disease worsened radiographically and she was started on inhaled amikacin which resulted in negative sputum culture.

DISCUSSION: *Mycobacterium Avium* Intracellulare is a ubiquitous bacteria composed of two species of bacteria. In the United States, pulmonary MAC can occur in up to 5.6 per 100,000, with 60 % of cases in females. It is traditionally found in AIDS and lymphoma patients with CD4 counts less than 50. MAC in non-immunosuppressed hosts is generally due to pre-existing pulmonary disease. Elderly thin women and anorexic women without predisposing pulmonary disease are thought to develop MAC due to deficient interferon-gamma pathways. Pulmonary

disease in this population is historically referred to as Lady Windermere Syndrome. Patients most frequently present with chronic productive cough, but may not be diagnosed for months or years due to the relatively mild symptoms. Fever and hemoptysis are more common in patients that have culture positive sputum. Unlike patients with pulmonary tuberculosis, patients with pulmonary MAC are not infectious and close contacts and healthcare workers are not at risk of contracting the disease even if sputum cultures are positive. The mainstay of treatment is a triple drug regimen comprised of a macrolide, a rifamycin such as rifampin and ethambutol. In patients who fail this therapy, quinolones may be added, followed by either streptomycin or amikacin. Treatment typically lasts for 12 months. Unfortunately, patients with low BMI frequently cannot tolerate these regimens due to significant GI distress (nausea, diarrhea). Treatment is considered successful if radiographic regression and negative sputum cultures are achieved. Patients who fail chemotherapy and have sufficient lung reserve can undergo surgical resection. Successful treatment ranges from 20 to 90 % depending on the study. Pulmonary MAC is usually an indolent process with 50 % of non-immunosuppressed patients alive after 5 years. Poor prognosis is associated with fibrocavitory pulmonary disease, BMI less than 18.5 kg/m², and anemia. Patients with these factors have high MAI related mortality and all-cause mortality.

LANGERHANS CELL HISTIOCYTOSIS OF LUNG AND BONE Dipenkumar Modi; Hirva Mamdani; Diane L. Levine. Wayne State University, Detroit, MI. (*Tracking ID #1936454*)

LEARNING OBJECTIVE 1: To recognize Langerhans cell Histiocytosis as a rare cause of reticulonodular/cystic lung disease.

LEARNING OBJECTIVE 2: To recognize the wide spectrum of presentation of Langerhans cell Histiocytosis and various diagnostic modalities.

CASE: A 27 y/o African American woman with extensive smoking history was admitted for progressively worsening right sided pleuritic chest pain and dry cough over 2 weeks duration. She had decreased exercise capacity gradually worsening over past few months and on presentation, she was also remarkably dyspneic at rest. Review of systems was positive for fever, night sweats and 14 lb unintentional weight loss over 3 months. Chest x-ray on admission showed inferior scalloping at the posterior aspect of several ribs. CT thorax showed numerous cysts of different sizes and morphology within the upper and mid lung field and a 1.6 cm soft tissue mass within the right sixth rib. Pulmonary Function test showed moderate restrictive lung disease, with reduced total lung capacity, residual volume and DLCO. Thoracoscopic right lung wedge resection was performed which showed Multiple lymphohistiocytic infiltrates, consistent with Langerhans cell histiocytosis (LCH). Pleural biopsy showed fibroadipose tissue with focal chronic inflammation. Diagnosis of pulmonary LCH was made by immunohistochemistry studies which showed histiocytes positive for CD1a and S-100. They were negative for CD68 and AE1/AE3. Since patient was an active smoker, chemotherapy was not started and she was counseled about smoking cessation.

DISCUSSION: Langerhans cell histiocytosis (LCH) is a very rare clonal proliferative disorder characterized by uncontrolled proliferation of Langerhans cells (LC). LC represents the main antigen capturing, processing and presenting dendritic cells in the epithelial surfaces including skin, oral mucosa, and bronchial epithelium. The estimated incidence rate in adults is 1–2 adult cases per million populations with peak age at presentation being 30 years, whereas in pediatric populations, incidence rate is about 5 cases per million and usually affects children younger than 10 years. Various risk factors have been described in literature i.e. cigarette smoking, recurrent BRAF V600E mutation etc. Increased number of dendritic cells by altering normal physiologic turnover as well as non-clonal proliferation of Langerhans cells in cigarette smoking patients has been implicated as possible mechanisms for the development of pulmonary LCH. Resistance to apoptosis has also been proposed by up-regulating expression of anti-apoptotic proteins i.e. Bcl-2 or Bcl-xL by mature LCs. LCH has wide spectrum of presentation. General symptoms are fever, night sweats, loss of appetite, weight loss and asthenia. Pulmonary LCH presents with nonspecific symptoms i.e. nonproductive cough, chest pain and exertional dyspnea. Some patients also present with spontaneous pneumothorax or pulmonary hypertension. Eighty percent of LCH patients have bone involvement with main complaints being bone pain. It can present with various endocrine abnormalities among which Diabetes Insipidus is the most common manifestation, seen in up to 30–40 % of patients. Anterior Pituitary is involved in up to 20 %. In pulmonary LCH, bilateral symmetric reticulonodular infiltration is the most common finding on chest radiograph. Cystic changes may also be apparent within the infiltrates which typically has bilateral distribution with frequent sparing of costophrenic angles. The characteristic HRCT findings are nodules with/without cavitations, and different types of cysts (thin and thick walled) involving mainly upper and lower lung lobes

with both peripheral and central lung field distribution. Obstructive, restrictive or mixed pattern are observed on pulmonary function tests. The reduced DLCO is the most commonly noticed abnormality in 70–90 % of patients. Histologically, LCH cells are characterized by their prominent cleaved nucleus with pale cytoplasm, and characteristically reactive for CD1a, langerin (CD207), S-100 protein, and CD11. The cells are also positive for vimentin, CD68, and HLA-DR. Smoking cessation is of utmost importance in patients with pulmonary LCH. Serial pulmonary function tests every 3 months in first year of diagnosis are performed to assess for progressive disease. Corticosteroid therapy should be initiated in patients with persistent pulmonary or constitutional symptoms, or evidence of progressive disease on serial PFTs. 2-CDA (cladribine), cyclophosphamide, and methotrexate may be considered in progressive pulmonary LCH despite steroid therapy.

LARGE PERICARDIAL EFFUSION ASSOCIATED WITH SEVERE PULMONARY HYPERTENSION Ravi Thimmisetty; Manogna Nookathota; Janardhana Gorthi; Ariel Modrykamien. Creighton University Medical Center, Omaha, NE. (*Tracking ID #1926447*)

LEARNING OBJECTIVE 1: Recognize the challenges in treating patients with large pericardial associated with severe pulmonary hypertension.

LEARNING OBJECTIVE 2: Stabilizes RV function in this group of patients Assess when NOT to drain

CASE: 60 year old female presented with worsening exertional dyspnea for 2–3 days. Past medical history includes: Group I Pulmonary Hypertension (PAH), Diabetes, Hypertension and Gastric antral ectasia. Vital signs were: temperature-97.4 F, B.P-130/80, heart rate-104, O₂ sats 94 % on 2 l. Physical exam revealed jugular venous distension, tachycardia, distant heart sounds and bilateral pedal edema. Rest of the exam was unremarkable. Laboratory data was within normal limits. EKG showed sinus tachycardia with low voltage QRS complexes. Echocardiogram revealed a large pericardial effusion, right ventricular systolic pressure of 74 mmHg (35 mm from a prior study 6 months ago), left ventricular ejection fraction 60–65 %, moderately dilated right ventricle with reduced systolic function, flattened interventricular septum consistent with RV pressure overload, diastolic left atrial compression, severely enlarged right atrium and no evidence of tamponade. She was diagnosed with worsening pulmonary hypertension associated with a large pericardial effusion. In view of high mortality in this setting, pericardiocentesis was not performed as the patient was hemodynamically stable. She was started on IV prostacyclins with significant improvement in symptoms and hemodynamic profile. Echocardiogram prior to discharge showed improved RV function compared to admission.

DISCUSSION: Right ventricular failure is the most common cause of death in patients with pulmonary hypertension, and RV function is the major determinant of morbidity and mortality in this patient population. Even though, pericardial effusion is an independent predictor of mortality in patients with pulmonary arterial hypertension, physiologically and hypothetically it stabilizes RV function. Pulmonary hypertension complicated by pericardial effusion carries a poor prognosis, and little data exists to support management options in this clinical scenario. Perhaps, the removal of large amounts of pericardial fluid from an over-distended right heart results in loss of RV muscle tone with interventricular septal bowing and decreased left heart filling pressures, causing death. Chronic pericardial effusions associated with severe PAH are best managed medically. If attempted, Pericardiocentesis should be done very slowly with a drain in-situ. Our patient was very symptomatic and there was no tamponade physiology described on the echocardiogram. However, the absence of tamponade physiology with severe PAH is misleading due to the lack of collapse of RA and/or RV secondary to elevated right sided filling pressures. IV Prostacyclin use can improve the clinical profile in patients with RV dysfunction in this situation. With early prostacyclin use, our patient improved both clinically and hemodynamically.

LARYNGEAL AMYLOIDOSIS Jenny Koo; Laura Y. Sue; Pearl Yu. UC San Diego, San Diego, CA. (*Tracking ID #1922246*)

LEARNING OBJECTIVE 1: Recognize the clinical manifestations of isolated amyloidosis versus systemic amyloidosis and how to diagnose amyloidosis with histopathology.

LEARNING OBJECTIVE 2: Understand what organs can be affected in systemic amyloidosis and determine what work-up is required.

CASE: A 37 year-old female former singer presents with chronic, progressive hoarseness for 5 years. She had marked worsening of vocal quality over the prior 3 months with associated loss of vocal range, strain, and vocal fatigue. She denies

reflux symptoms, dysphagia, or odynophagia and has no other systemic complaints. Flexible laryngoscopy revealed a stiffened right vocal with a yellow-orange lesion. A small lesion was also noted on the left anterior false vocal fold. Microdirect laryngoscopy was performed and biopsies were taken of the left false vocal fold lesion and the right true vocal fold lesion. Frozen sections revealed no evidence of neoplasm or malignancy. Biopsy specimens were positive with apple green birefringence on Congo Red stain, consistent with amyloidosis. Mass spectrometry revealed AL kappa type amyloid deposition. Additional work up was performed to rule out systemic amyloidosis. Her complete blood count, electrolyte panel, liver panel, thyroid panel, and urinalysis were normal. An electrocardiogram (EKG) revealed normal sinus rhythm and an echocardiogram was performed which showed no cardiac involvement. Patient had a normal 24-hour urine collection which suggested no renal involvement. Serum protein electrophoresis (SPEP) and urine protein electrophoresis (UPEP) were negative for multiple myeloma.

DISCUSSION: Amyloidosis is a process of extracellular deposition of fibrils formed by low molecular weight subunits. There is higher prevalence in males between the ages of 40 and 60. AL (fragments of immunoglobulin light chain) is the more common subtype in developed countries, while AA (fragments of acute phase reactants) is more common in developing countries. Amyloid deposition can occur in any organ, more commonly in the kidneys, heart, liver, spleen, and gastrointestinal tract. Localized forms of amyloidosis are less common, and typically affect abdominal organs and structures of the head and neck. Amyloidosis represents only 1 % of benign laryngeal masses, and is most commonly supraglottic. Diagnosis is made with Congo Red staining which reveals "apple green" birefringence. Treatment is excision by laryngeal microsurgery with the goal of maintaining the structural integrity of the true vocal folds if possible. Although it is rare for laryngeal amyloidosis to be associated with systemic amyloidosis, a number of reports have revealed laryngeal amyloidosis in the setting of multiple myeloma or extramedullary plasmacytoma. Patients with underlying malignancy as the source of amyloidosis are likely to have systemic involvement, and thus require additional evaluation including a complete blood cell count, liver function test, urine tests, EKG, echocardiogram, and SPEP/UPEP. This case represents a rare form of isolated amyloidosis in a patient that does not fit the demographics most commonly associated with this disease. A thorough evaluation was warranted in this patient to rule out any systemic disease given the profound morbidity of systemic disease.

LATE DIAGNOSIS OF CYSTIC FIBROSIS: A MISSED OPPORTUNITY

Broiana S. Siegel; Peter Rattner; Patricia Walker. Beth Israel Medicine Center, Mount Sinai Health System, New York, NY. (*Tracking ID #1938620*)

LEARNING OBJECTIVE 1: Recognize the atypical presentations of cystic fibrosis
LEARNING OBJECTIVE 2: Diagnose non-classic cystic fibrosis in adults.

CASE: A 30-year-old man presented for further evaluation of chronic cough, worsening over the past 3 years. His cough was productive with thick yellow sputum, upwards of a cup per day. Pertinent history included chronic pancreatitis due to pancreatic duct strictures diagnosed at age 16. Patient had multiple pancreatic ductal dilatations and stent placements, eventually undergoing pancreaticojejunostomy Roux-en-Y procedure at age 26. Abdominal CT imaging at the time incidentally noted right lower lobe bronchiectasis. Patient started to develop a productive cough in the following year and was treated for multiple recurrent pneumonias with oral antibiotics. He was a current smoker with a 16-pack-year history, no drug or alcohol use, no pets and no recent travel. Physical exam was notable for crackles in the right lower lobe with digital clubbing bilaterally. Bronchoscopy revealed normal bronchial anatomy without endobronchial obstruction, and cultures grew only normal flora. The sweat chloride test was borderline at 47 mEq/L. Pulmonary function testing showed a mild combined obstructive and restrictive defect. Genetic testing revealed two mutations of the CFTR gene: D1152H/G542X.

DISCUSSION: Cystic fibrosis (CF) is the most common genetic disease affecting Caucasians. In adults, CF is diagnosed by evidence of disease in one or more organ systems with laboratory evidence of dysfunction in the cystic fibrosis transmembrane conductance regulator (CFTR) protein, or the identification of 2 disease causing mutations by DNA analysis. Our patient was found to have the D1152H mutation, which has significant variability in phenotype ranging from normal to CF. It is usually characterized by mild late onset pulmonary disease, pancreatic sufficiency and congenital bilateral absence of the vas deferens. Variability in sweat chloride levels is also common. Recognizing non-classic CF can be a significant challenge due to the wide phenotypic variance seen in these cases. In up to 10 % of cases of suspected CF, patients have been found to have mild disease or dysfunction of a single organ system along with borderline or negative sweat chloride tests. The problem is further compounded when rare or unidentified CFTR mutations are present and not routinely screened on commercial panels. There has been a rise in diagnosis of CF in adults.

However, these diagnoses are frequently overlooked or delayed when physicians are unfamiliar with the expanded spectrum of CF manifestations. It is important for internists to recognize these atypical phenotypes. There is now a wide range in treatments available that can help improve quality of life, delay disease progression, reduce overall morbidity, and increase life expectancy. Patients like ours, with mutations associated with residual CFTR function, continue to represent the population of adult patients who present with atypical CF.

LATENT TUBERCULOSIS INFECTION CAUSING ERYTHEMA NODOSUM

Sridhya Bhadriraju^{1,2}; Jeffrey T. Bates^{2,1}. ¹Baylor College of Medicine, Houston, TX; ²Michael E. DeBakey VA Medical Center, Houston, TX. (*Tracking ID #1939724*)

LEARNING OBJECTIVE 1: Recognize erythema nodosum as a manifestation of latent tuberculosis

LEARNING OBJECTIVE 2: Understand the diagnosis and treatment of tuberculosis-associated erythema nodosum

CASE: An 18-year-old Mexican female presented with a recurrent painful rash. Two years prior to presentation, the rash initially appeared as painful, raised, dark red and purple "bruises" over her shins, thighs and abdomen; it was associated with weight loss, low-grade fevers, malaise, anemia and alopecia. At that time, a clinical diagnosis of panniculitis with erythema nodosum (EN) was made, and she received intravenous corticosteroids with subsequent improvement. During the following year, she had recurrent episodes requiring repeated courses of oral prednisone for relief. Laboratory studies revealed elevated ESR and CRP, negative ANA, and a positive tuberculin PPD with induration to 9 mm; however, she never received treatment for latent mycobacterial infection at that time. At the current presentation, she complained of only the rash and denied any symptoms or signs of pulmonary tuberculosis. Physical examination revealed multiple 3 cm, painful, erythematous subcutaneous nodules on her bilateral upper thighs. Although a repeat PPD was negative, a QuantiFERON Gold test was positive. A punch biopsy of the lesion showed septal panniculitis with minimal lobular involvement. She was diagnosed with EN, and was treated with isoniazid (INH) for latent TB. She was later switched to INH, rifampin, pyrazinamide and ethambutol (four-drug RIPE therapy) after developing recurrent EN while on INH monotherapy. She clinically improved on this regimen and has had no further recurrence of EN.

DISCUSSION: Erythema nodosum is a delayed hypersensitivity reaction to antigens occurring secondary to streptococcal infection, autoimmune disease or fungal infections. A complete blood count, chest X-ray, anti-streptolysin O (ASO) titers, and TB skin testing are recommended to elucidate etiology. A biopsy is required only in atypical cases, and a deep excisional biopsy is preferred. It typically shows panniculitis with septal inflammation in the subcutaneous fat tissue, usually without associated vasculitis. A study from Turkey demonstrated that primary TB was the most common cause of EN, and most patients with primary TB presented with EN. Although men with EN were more likely to have active TB compared to women, women had an increased risk of developing EN from TB. Corticosteroids are discouraged for the treatment of TB-associated EN; a four-drug TB regimen is recommended for treatment. Latent TB-associated EN is rare, and the initial diagnosis can be challenging as repeated courses of steroids may result in a falsely negative PPD. Polymerase chain reaction (PCR) detection of TB in the tissue has high sensitivity and specificity, and should be considered in these cases.

LEFT ATRIAL MYXOMA: A 'ZEBRA' IN THE DIFFERENTIAL FOR ALTERED MENTAL STATUS & SEIZURE

Prasanna Durairaj; Auras R. Atreya; Issra Jamal; Thomas Higgins. Baystate Medical Center/Tufts University School of Medicine, Springfield, MA. (*Tracking ID #1940170*)

LEARNING OBJECTIVE 1: Recognize that neurological manifestations can be the first presentation of atrial myxomas.

LEARNING OBJECTIVE 2: Identify high risk features of embolization on echocardiography.

CASE: A 41-year-old female with a past medical history of chronic migraines and recently diagnosed primary hyperparathyroidism presented to the emergency room with altered mental status associated with a fall and seizure-like activity. As per her family, she had been doing well earlier that day without any headaches, neck pain, fevers, nausea or vomiting. Soon after arrival in the ED, she was intubated for airway protection. It was noted that her pupils were unresponsive and dilated so she underwent an emergent CT scan of the head which did not reveal any bleed. She was admitted to the ICU where cerebrospinal fluid was obtained to evaluate for HSV meningo-encephalitis and empirical IV acyclovir and fosphenytoin load were

administered. Further review of history revealed that she had 2 other episodes of syncope in the past few months that had been attributed to dehydration and orthostasis in the setting of a viral illness. The next day, brain MRI was obtained due to lack of neurological recovery and showed multiple acute to subacute infarcts involving the supratentorial and infratentorial brain parenchyma bilaterally, consistent with an embolic process. Physical examination did not reveal any cardiac murmurs. MRA/MRV obtained at the same time did not show venous thrombosis or arterial aneurysm/Dissection. A transthoracic echocardiogram (TTE) showed an atrial mass concerning for myxoma. Subsequently, a trans-esophageal echocardiogram (TEE) confirmed a large left atrial myxoma attached to the inter-atrial septum, with multiple highly mobile villous processes. She was scheduled for emergent cardiac surgery, which revealed the mass to be gelatinous and fibrous, requiring suction for complete removal. Histological examination confirmed myxomatous tissue. The patient, however, continued to have neurological deterioration, with increased ICP, midline shift on repeat head CT scan and no improvement despite a decompressive hemicraniectomy. Eventually, her family withdrew care to respect her advance directives.

DISCUSSION: Myxomas are generally thought to originate from multipotential mesenchymal cells of the endocardium and are the most common primary cardiac tumors. There is a female predominance in the presentation of myxomas and only a minority of cases is familial (Carney Syndrome). In 90 % of patients with left atrial myxoma, symptoms are either related to mitral valve obstruction, systemic embolization or constitutional symptoms. Neurological manifestations, particularly cerebral infarction, can be the presenting symptoms in nearly a third of the patients with left atrial myxomas while right atrial myxomas frequently cause heart failure and pulmonary embolization. A high degree of suspicion is needed to consider a diagnosis of myxoma. Many cases are detected incidentally during TTE for evaluation of other cardio-embolic etiologies such as thrombus. TEE has been proven to be superior to TTE in the diagnosis and characterization of myxomas. It is the mobility, not the size, of the myxoma which appears to be related to embolic potential. In our patient, the myxoma appeared to be large, villous, frond-like and friable, leading to devastating neurological complications which ultimately led to her death. Prompt cardiac resection of the tumor is associated with good outcomes since the mortality rate of 10–15 % in these patients is related to sudden death in the setting of coronary or cerebral infarction as well as complete obstruction of blood flow at mitral or tricuspid valves. In conclusion, this case highlights that the differential diagnosis needs to be expanded to include rare diagnoses or “zebras” on occasion, especially in young patients with severe atypical presentations.

LEFT ATRIAL SEPTAL POUCH THROMBUS: A COMMON PATHOLOGY IN AN UNCOMMON LOCATION Sourabh Aggarwal; Vishal Gupta. Western Michigan University School of Medicine, Kalamazoo, MI. (*Tracking ID #1940266*)

LEARNING OBJECTIVE 1: To understand emerging pathology of left atrial septal thrombus

CASE: Left atrial septal pouch (LASP) is a recently described anatomical entity that is formed by the caudal fusion of the area of overlap between septum primum and the septum secundum. The potential for thrombus formation inside this pouch remains debatable. We present an extremely rarely reported case of LASP thrombus. Seventy-five year old male, with a known history of coronary artery disease status post stent in right coronary artery and left circumflex artery, presented to us with complains of new onset chest pain which was non-exertional, non-radiating and not relieved by rest. On physical examination, he was tachycardic (110 beats/min) with irregularly irregular rate. No murmurs were heard. Rest of physical examination was unremarkable. 12-lead EKG showed irregular rhythm with no signs of ischemia, confirming the diagnosis of new-onset atrial fibrillation. Initial lab evaluation including troponin were unremarkable. His rate was controlled with Cardizem which alleviated his chest pain. He was taken into echocardiography lab for transesophageal echocardiography (TEE) and potential cardioversion. TEE was significant for moderately dilated left atrium and normal left ventricular systolic function. A thrombus was noted in the left atrium originating from septal pouch. No thrombus was noted in left atrial appendage and contrast study did not show any evidence of inter-atrial shunt. He was diagnosed with LASP thrombus and started on anticoagulation therapy.

DISCUSSION: Left atrial septal pouch thrombus is an extremely rarely described entity. LASP is a newly understood anatomical entity (described as recent as 2010) with prevalence significantly higher than patent foramen ovale (39 % vs 24 %). It is thought to represent an incomplete closure of the foramen ovale resulting in formation of a kangaroo pouch like blind recess with opening in left atrium. Due to its anatomical features, it serves as a potential site of stasis and thrombus formation. In nonvalvular atrial fibrillation, left atrial thrombi almost exclusively tend to arise in the left atrial appendage due to decreased velocity (<20–30 cm/s). In our case, due to

partly preserved contractile function of the left atrial appendage, no thrombus occurred there. Very few case reports have demonstrated LASP as a site of origin of thrombus formation. The 2-D TEE is an established modality for the evaluation of intracardiac mass/thrombus. Further prospective studies are required to determine the impact of LASP as a potential cause of cardiac embolism and its optimum management. The present case report indicates that more attention is needed to diagnose this structure when TEE is performed in susceptible patients.

LEGIONELLA PNEUMONIA IN A PATIENT WITH ADVANCED LUNG CANCER Valida Bajrovic; Christopher Sankey. Yale School of Medicine, New Haven, CT. (*Tracking ID #1924440*)

LEARNING OBJECTIVE 1: Recognize Legionella as an important etiologic factor in community acquired pneumonia, especially in the immunocompromised host.

LEARNING OBJECTIVE 2: Review epidemiological characteristics, diagnostic testing, and treatment options in Legionella pneumonia.

CASE: A 54 year-old Caucasian woman with stage IV non-small cell lung cancer (NSCLC), currently on erlotinib and dexamethasone, presented with a 2 day history of progressive dyspnea. Her family noted a dry cough and mild confusion 2 days prior to admission. She denied fevers, chills, sick contacts, hemoptysis or other associated symptoms. On admission the patient was tachycardic, hypoxemic (O₂ saturation 85 % on room air, 93 % on 6 l of oxygen) and tachypneic. Her physical examination was remarkable for dyspnea at rest making it difficult for her to speak in full sentences. Rhonchorous breath sounds were appreciated bilaterally with bronchophony over the left lower lung field. Laboratory testing revealed hyponatremia (sodium of 129 mmol/L), leukopenia, thrombocytopenia, and an elevated lactic acid. A spiral CT of the chest demonstrated a new dense consolidation involving the left lower lobe and patchy ground glass opacities throughout both lung fields. The patient was admitted for close monitoring of her respiratory status and placed on broad spectrum antibiotics. Her legionella urine antigen returned positive, and moxifloxacin was added to her regimen. The patient's respiratory status continued to worsen, requiring intubation and transfer to the medical intensive care unit. Given her immunocompromised state and continued hypoxemia, azithromycin was added to moxifloxacin to treat severe legionellosis. Her clinical status continued to decline over the next 48 h, and she passed away after being transitioned to comfort measures.

DISCUSSION: Legionella was first identified in 1976 during an outbreak at an American Legion Convention in Philadelphia. It has since been implicated in two clinical syndromes: pneumonia (both hospital and community-acquired) as well as Pontiac fever, a self-limited acute febrile illness. *L. pneumophila* is the most common species; it is a water-borne pathogen, and man-made reservoirs such as water distribution systems amplify the growth of the organism. The most common risk factors for Legionella pneumonia are cigarette smoking and chronic lung disease. Glucocorticoid administration and other forms of immunosuppression are also independent risk factors, as was the case in our patient. The diagnosis of Legionnaires' disease can be made by both a urinary antigen test and Legionella culture of a respiratory specimen. The urinary antigen test is specific for only *L. pneumophila* serogroup 1; the majority of Legionnaires' disease cases from the community are caused by this species and serogroup. The sensitivity is significantly higher in patients with severe compared with mild pneumonia (86 versus 38 %), while specificity is 97 to 100 %. Azithromycin or respiratory quinolones are effective for Legionella infection. In severely ill patients or those with extrapulmonary legionellosis, institution of prompt treatment is paramount and a combination antibiotic therapy of a quinolone plus azithromycin should be considered. Our case demonstrates the importance of recognizing the clinical presentation of legionella pneumonia in the immunocompromised host, as it carries a high mortality and requires timely administration of appropriate antibiotic therapy.

LEMIERRE'S SYNDROME CAUSED BY CLOSTRIDIUM CLOSTRIDIFORME Igor Tkachyk; El-waleed Ali; Sonia Borrà; Harish Patel. Kingsbrook Jewish Medical Center, Brooklyn, NY. (*Tracking ID #1897113*)

LEARNING OBJECTIVE 1: to present a case of Lemierre's syndrome caused by *Clostridium Clostridiforme*

CASE: A 24 year old female with known sickle cell trait developed sore throat and low grade fever and was treated with azithromycin by her physician. Five days later her condition worsened and she was admitted with fever, malaise, dyspnea and vomiting. Temperature 38.8 °C (102 °F), blood pressure 124/72 mmHg, pulse 124/min, respirations 24/min. Her tonsils were red and swollen with mild exudate, neck was supple. Chest examination revealed decreased air entry and bilateral basilar crepitations. Abdomen was with mild diffuse tenderness, active bowel sounds. Laboratory results revealed: hemoglobin 12.4 g/dL, white

cell count 23000/ μ L, platelets 50000/ μ L, blood urea nitrogen 26 mg/dL, creatinine 1.67 mg/dL. Chest X ray showed consolidation at both lung bases. Computed tomography confirmed extensive bilateral infiltrates and loculated pleural effusions, as well as a thrombus in the internal jugular vein. Blood cultures grew Gram negative anaerobic rods after 1 day, later identified as *Clostridium Clostridiforme* sensitive to cefotaxime, clindamycin and metronidazole. She tested negative for Hepatitis B and C as well as HIV. The patient became hypotensive, was hydrated with intravenous fluids, placed on mechanical ventilation and treated with antibiotics and vasopressors. Initially azithromycin, meropenem and vancomycin were given and later switched to metronidazole and piperacillin and tazobactam. Her condition improved and she was extubated and later underwent video assisted thoracotomy for treatment of the empyema. The patient recovered fully.

DISCUSSION: Lemierre's syndrome is a serious infection usually caused by *Fusobacterium necrophorum*, but other microorganisms have been implicated: *Klebsiella pneumoniae*, *Streptococcus intermedius*, *Staphylococcus aureus*, *Arcanobacterium haemolyticum*. This is the first report of Lemierre's syndrome associated with *Clostridium Clostridiforme*, which is one of the predominant anaerobes in the intestinal tract and infrequently cause infections such as intraabdominal abscesses and occasionally have been described as causative agent of deep neck infections. The three clinically important species: *Clostridium botteae*, *Clostridium Clostridiforme* and *Clostridium haltewyi* are morphologically and microscopically indistinguishable from each other are involved in human infections, including bacteremia.

LEUKEMIA OR SARCOMA? ITS A DIAGNOSTIC DILEMMA!! Arushi Khurana; N. Gurukripa Kowlgi. University of Connecticut, Farmington, CT. (Tracking ID #1925979)

LEARNING OBJECTIVE 1: To recognize various and unusual presentation of Acute Myeloid Leukemia and Myeloid Sarcoma

CASE: A 20 year old female with no previous history initially presented with symptoms of generalized weakness, fatigue, progressive dyspnea on exertion and was found to have profound anemia with hemoglobin level of 6 g/dl. After extensive workup for common causes like nutrient deficiencies, blood loss, infections, drugs, connective tissue or autoimmune disorders and bone marrow suppression her labs were suggestive of hemolysis. She was diagnosed with warm type autoimmune hemolytic anemia and given treatment with pulse dose steroids which remarkably improved her condition. She subsequently had 2 more similar admissions with relapsing hemolytic anemia on tapering steroids and hence was given IvIG and rituximab therapy with significant response. She developed sudden hypoxic respiratory failure requiring ventilatory support from unknown cause and eventually died of severe DIC within 1–2 days. Her unusual presentation and sudden death was finally revealed on autopsy which showed disseminated myeloid sarcoma with acute myelomonocytic features involving heart, lungs, liver, spleen, pancreas, adrenal glands and almost every major organ without any bone marrow involvement.

DISCUSSION: Myeloid sarcoma (MS) is a rare condition which consists of immature myeloid cells and occurs at an extramedullary site, most commonly bone, skin, or lymph node, although any part of the body may be affected. MS mostly consists of myeloblasts, with or without features of promyelocytic or neutrophilic maturation, which can totally or partially distort the tissue architecture. Most of the cases are found to have either myelomonocytic or monoblastic features. It may develop de novo or concurrently with acute myeloid leukemia (AML) or as first manifestation, precede it by months or years, or equally represent the initial manifestation of relapse in a previously treated AML in remission. Rarely has it been seen to be disseminated, present as autoimmune hemolytic anemia or manifest as DIC. AML in itself is a commonly seen neoplasm but presentations like these always prove to be diagnostic dilemma. Myeloid sarcoma represents a poor prognostic feature in patients with AML regardless of its spatial occurrence. It is highly unusual for myeloid sarcoma to be diffuse and present with DIC without evidence of AML in blood or bone marrow. We believe this presentation for myeloid sarcoma is first of its kind and cases like this require early multi-specialty consultations for appropriate work up.

LIFE THREATENING HYPOXIA DURING ELECTRICAL CARDIOVERSION Zakaria Almuwaqqat. saint francis hospital, Evanston, IL. (Tracking ID #1923592)

LEARNING OBJECTIVE 1: Reporting a potentially life threatening complication of trans-esophageal echocardiography and local anesthesia.

LEARNING OBJECTIVE 2: Importance of maintaining a high degree of suspicion and prompt recognition local anesthetics side-effects and providing appropriate treatment.

CASE: A 75 year old male patient in phase 2 cardiac rehab presents with increasing shortness of breath and recurrence of Afib after bi-Atrial maze procedure. PMHX includes CAD (coronary artery disease); HTN (hypertension); Paroxysmal atrial fibrillation; S/P angioplasty with stent; Aortic valvular stenosis; Hyperlipidemia; DM (diabetes mellitus); CKD (chronic kidney disease) stage 3, GFR 30–59 mL/min; and S/P aortic valve replacement. He is s/p AVR bioprosthetic valve, tricuspid annuloplasty, bi-atrial MAZE procedure with CABG (LIMA to LAD) 6 months ago. Medications: amlodipine, Zaroxyn, Lasix, lisinopril, glipizide, aspirin and carvidolol. Physical Examination: Vitals: BP; 145/90, HR; 105, Temp; 98 °F, RR 18 min, SpO₂; 98 % (before the procedure). General: alert, Ox3, not in distress Neck: JVP 13 cm H2O Lungs: bibasilar rales heart: irregular, S1 & S2 normal. faint systolic murmur Abdomen: liver edge smooth and nontender. Extremities: Bilateral Lower limb edema. Hospitalization Course: Patient was attached to non-invasive hemodynamic and electrophysiological monitoring equipment, TEE was done with local anesthesia and showed no LA thrombi. After achieving an appropriate level of sedation with propofol, a synchronized, biphasic 200 J shock was delivered and converted to NSR. The patient was hypoxic with O2 Saturation in the mid-80s while on a non-rebreather mask and non-sedated, for that he was given Lasix IV and flumazenil, afterward patient became cyanotic, less responsive, respirations slow, Mhemoglobin level was obtained (45 %) and patient given methylene blue and placed on non invasive ventilation, his O2 saturation improved to 90s over an hour and patient recovered.

DISCUSSION: The patient developed an episode of benzocaine induced Methemaglobinemia which was used during preparation for TEE prior to electrical cardioversion. Methemaglobinemia can result in impaired oxygen delivery to tissues as well as a left shift of the oxygen-Hb dissociation curve, it's a potentially life threatening emergency which can result in respiratory depression, altered consciousness, shock, seizures, and death. Mucosal benzocaine spray is used in most local anesthesia procedures i.e. endoscopy, bronchoscopy, awake intubation and TEE and has been associated with methemoglobinemia and its complications. Knowledge of this adverse medication reaction is essential for medical residents and house staff in ICU.

LIFE-THREATENING ARRHYTHMIA IN A HEALTHY YOUNG WOMAN WITH PECTUS EXCAVATUM Naoki Takamatsu; Christine Kwan. Teine Keijinkai Hospital, Sapporo-shi, Japan. (Tracking ID #1929494)

LEARNING OBJECTIVE 1: Recognize that pectus excavatum (PE) may cause life-threatening arrhythmias

LEARNING OBJECTIVE 2: Treat adult PE patients with surgery for reasons other than cosmetic purposes

CASE: A previously healthy, active 35 years old Japanese woman presents with 3 episodes of syncope in the last month. Her first episode occurs during a neck massage; she describes nausea and lightheadedness with urinary incontinence upon awakening. She denies paresthesias, seizures, and cardiovascular symptoms; all other review of systems is within normal limits. The patient does not have any past medical problems and does not take any medications or use tobacco, alcohol, or recreational drugs. Her father has PE, but no family history of sudden cardiac death (SCD). On exam, her vital signs include temperature 36.7°C, heart rate 40, blood pressure 108/55, respiratory rate 14, and O2 saturation 99 % room air. Generally, she initially appears disoriented but quickly becomes alert/oriented ×3. Cardiac exam demonstrates a depressed sternum; otherwise, her exam shows no irregularities. Her labs show complete blood counts and chemistry within normal limits. Electrocardiogram shows pulse 35 with junctional rhythm. Meanwhile, during diagnostic workup, she goes into cardiac arrest with ventricular fibrillation (V-fib) but is successfully resuscitated. Even with the use of a pacemaker, however, she develops delayed pupillary light reflexes and extremity convulsions/rigidity, so she is placed on hypothermia protocol with subsequent recovery, albeit with slight retrograde amnesia. Diagnostic workup continues with chest computed tomography's confirmation of a depressed sternum with pectus severity index (PSI) 6.8 (normal 2.5). Holter monitor records multiple ventricular dysrhythmias, 35 % being premature ventricular contractions with some R on T waves. Echocardiography, coronary angiography, electrophysiological study, and cardiac magnetic resonance imaging demonstrate no abnormality. The patient is treated with amiodarone and carvedilol and is discharged after getting an implantable cardioverter-defibrillator (ICD). Surgical repair is on hold due to having only one (PSI>3.25) of five Nuss criterion.

DISCUSSION: PE, a congenital hereditary deformity of the chest, is often considered a benign condition although this anatomic alteration can result in compression of the heart, thereby decreasing exercise capacity and affecting right ventricular morphology and function. An association with supraventricular dysrhythmia has been well documented while only a few reports of ventricular dysrhythmia

exist. The patient's V-fib arrest occurs without any preceding cardiovascular symptoms or precipitating factors like exercise. In the absence of coronary heart disease and cardiomyopathy, the only suggestive cause remains to be her PE. Ventricular dysrhythmias associated with PE are a rare entity; however, since it remains to be the leading cause of SCD and because V-fib recurs in ~14 % of all V-fib resuscitations, ICDs are a necessity. Furthermore, surgical repair is often performed in children or in adults' wanting cosmetic enhancement. The indications of repair in adults for medical purposes remain unclear due to lack of reports although the Nuss criteria is sometimes used. This case underscores the importance of PE in the recognition of its potentially life-threatening clinical presentation and gives insight into indications for surgical correction of PE in symptomatic adults.

LIFE-THREATENING HYPERSENSITIVITY REACTION TO ACE INHIBITOR USED IN SCLERODERMA RENAL CRISIS Sonja Gill. ¹SUNY Upstate Medical University, Syracuse, NY; ²University of Toronto, Toronto, ON, Canada. (Tracking ID #1938979)

LEARNING OBJECTIVE 1: Identify and treat life threatening drug reactions

LEARNING OBJECTIVE 2: Recognize a rheumatologic emergency encountered in training and practice

CASE: A 68yo female presented to the emergency department after recently being discharged from the hospital for renal crisis in diffuse-type systemic sclerosis. She was discharged on an ACE-inhibitor, captopril, and came back 3 days later for fever, shortness of breath, pruritic rash and facial swelling. Her blood pressure was 215/90 mmHg and her skin diffusely swollen and tender with erythematous confluent patches covering 85 % of total body surface area. Creatinine was 5.8 mg/dL with white blood cell casts on microscopy, and she was diagnosed with acute hypersensitivity reaction secondary to captopril with recurrent renal crisis. Skin biopsy revealed partial necrosis of the epithelium with vacuolar change and spongiosis consistent with major erythema multiforme or Stevens-Johnson syndrome. Treatment with pulse dose steroids was initiated and captopril discontinued, noting the possibility that renal crisis may precipitously worsen. Over 2 days, the patient's symptoms abated and the exfoliative rash was resolving, however, her renal function remained impaired with persistently elevated blood pressures. Preparations were made for hemodialysis. She was started on an inpatient antihypertensive regimen that included losartan, methyldopa and hydralazine. Over several days, her renal function improved, and blood pressure returned to baseline. Hemodialysis was avoided, and the patient was discharged home in hemodynamically stable condition with close rheumatology and nephrology follow-up. She was not started back on ACE inhibitor therapy and continues on ARB monotherapy without any significant adverse effects.

DISCUSSION: Renal crisis in systemic sclerosis is a life-threatening condition, and ACE inhibitors have thus far been the standard pharmacological treatment. In a patient with a serious adverse drug reaction to ACE inhibitor therapy, other modalities such as hemodialysis and renal transplant are usually considered to treat this condition. Prior to subjecting a patient to these lifelong interventions, however, we as internists may consider alternate management strategies to avoid this commitment. While employing the expertise of a rheumatologist and nephrologist, we may begin treatment with systemic steroids with strict blood pressure control. ARB monotherapy took the place of ACE inhibitors for the management of renal crisis in this case and thus, we may also ponder the hypothesis of whether ARB monotherapy may be of use in treating systemic sclerosis renal crisis, especially in those patients with adverse drug reactions to ACE inhibitors.

LISTERIA SEPSIS IN AN IMMUNOCOMPROMISED HOST WITH ADVANCED BREAST CANCER Valida Bajrovic; Christopher Sankey. Yale School of Medicine, New Haven, CT. (Tracking ID #1924459)

LEARNING OBJECTIVE 1: Recognize listeria monocytogenes as an important bacterial pathogen in the immunocompromised host.

LEARNING OBJECTIVE 2: Review clinical characteristics and etiologic factors in listeria monocytogenes infection.

CASE: A 50 year-old Caucasian woman with history of stage IV breast cancer (ER/PR+, HER2/NEU -) with metastasis to liver and bone on hormonal chemotherapy presented with a 4 day history of fever (104 °F), malaise, and anorexia. She denied dysuria, cough, or diarrhea; she had no indwelling central access. On admission, the patient was afebrile but tachycardic and hypotensive (blood pressure 86/58). Her physical examination was most notable for how well she appeared; she had an intact mental status, absence of meningismus, dry mucous membranes, pale conjunctivae and no localizing sign of infection. Laboratory testing revealed hyponatremia (serum Na 120 mmol/L), acute renal failure (creatinine 2.5 mg/dL), and a worsening of her

chronic hypoproliferative anemia (hemoglobin 7.4 mg/dL, down from a baseline of 9 g/dL). She had a no leukocytosis and a normal lactic acid. Admission chest radiography showed no infiltrates and persistence of known bony metastases. The patient was admitted for hemodynamic monitoring as well as correction of her metabolic derangements. Over the first 24 h, she was aggressively volume-resuscitated with intravenous fluids and packed red blood cells. Her blood cultures were quickly positive for gram positive rods, which were initially presumed to be a contaminant and antibiotics were withheld. However, repeat cultures from the following day demonstrated the same organism, which was identified as listeria monocytogenes. Treatment with ampicillin was initiated, and she clinically improved. Her laboratory abnormalities resolved, antibiotics were switched to oral amoxicillin, and she was discharged home. Her subsequent recovery was uncomplicated.

DISCUSSION: Listeria monocytogenes is a pathogen implicated in infection of neonates, immunosuppressed patients, the elderly, and pregnant women. The great majority of listeria infections are sporadic, but outbreaks have been reported in association with unpasteurized milk, soft cheeses and delicatessen meat. Clinical syndromes associated with Listeria monocytogenes infection range from a self-limited gastroenteritis to invasive diseases including meningitis, meningoencephalitis, or bacteremia. Invasive infections most commonly occur in immunosuppressed patients, individuals at the extremes of age and pregnant women. Listeria sepsis occurs in patients of all ages. Adults with Listeria sepsis classically present with fever and chills but can be asymptomatic especially if immunocompromised, as was the case for our patient. Septic shock can develop and there may be seeding of the brain and/or meninges, leading to meningoencephalitis or cerebritis. The diagnosis of listeria bacteremia is best established by obtaining blood cultures. The antibiotic of choice for Listeria infection is ampicillin or penicillin G. Neither antibiotic achieves adequate bactericidal activity in the cerebrospinal fluid; thus, listeria central nervous system infections, endocarditis, and infections in neonates and immunocompromised patients are usually treated with combination therapy, with an aminoglycoside being added for synergy. Penicillin-allergic patients can be desensitized or treated with trimethoprim-sulfamethoxazole.

LITHIUM-INDUCED HYPERTHYROIDISM MIMICKING ACUTE CORONARY SYNDROME Lucas A. Burke; Kiran Mogali; David E. Winchester; Margaret C. Lo. University of Florida, Gainesville, FL. (Tracking ID #1936553)

LEARNING OBJECTIVE 1: Diagnose and treat hyperthyroidism-induced coronary vasospasm in acute chest pain presentation.

LEARNING OBJECTIVE 2: Recognize the various thyroid dysfunctions that can result from lithium use, even at subtherapeutic levels.

CASE: A 50-year-old female with chronic obstructive pulmonary disease, tobacco use and bipolar disorder presented with acute, intense substernal chest pain and heart rate of 170 bpm. She had no previous cardiac history and no similar episodes in the past. She started taking lithium 2 months earlier for bipolar disorder. Her electrocardiogram showed inferior ST depression and an incomplete left bundle branch block (LBBB). Troponin T was elevated at 0.48 ng/mL. An emergent left heart catheterization revealed non-obstructive coronary artery disease and vasospasm of the left main and left anterior descending coronary arteries which resolved with intra-coronary nitroglycerine. She remained tachycardic and the electrocardiogram later showed multifocal atrial tachycardia. A subsequent thyroid-stimulating hormone level came back low (< 0.01 mIU/L) and free T4 elevated (3 ng/dL). Thyroid stimulating antibodies were negative however thyroid peroxidase (TPO) was positive. Thyroid ultrasound was unremarkable. Despite a sub-therapeutic lithium level (0.53 mmol/L), lithium-induced hyperthyroidism was suspected given its narrow therapeutic index. Lithium was discontinued and methimazole was started. After 2 days, she became asymptomatic and converted to normal sinus rhythm; she was discharged with cardiology and endocrinology follow-up.

DISCUSSION: The presentation of severe coronary artery spasm can be similar to acute coronary syndrome (ACS). Unlike ACS, coronary artery spasm is more easily reversible and can be prevented by treating underlying causes. Coronary artery spasm is part of variant angina and if left untreated, can lead to myocardial infarction by promoting coronary thrombus formation. Furthermore, coronary artery spasm can cause life-threatening arrhythmias including heart block (with right coronary artery spasm) or ventricular tachycardia (with left anterior descending coronary involvement). Coronary vasospasm has been reported in patients with overt hyperthyroidism. The management generally includes thionamides (methimazole or propylthiouracil) to treat the hyperthyroid state as well as long-acting nitrates or dihydropyridine calcium channel blockers to decrease spasm of the coronary arteries. Interestingly, lithium itself is also used to treat hyperthyroidism by blocking thyroid hormone release, although its use is certainly not first or second line. There is little in the medical literature regarding coronary vasospasm secondary to hyperthyroidism as evidenced

by a review of 21 case reports describing this clinical scenario. Of these 21 cases, 14 were attributed to Graves' disease (67 %), 2 to toxic multinodular goiter (10 %), 1 to amiodarone-induced hyperthyroidism (5 %) and the remaining cases did not provide the underlying etiology for the hyperthyroidism. This patient may have been in "Hashimototoxicosis" (initial hyperthyroid phase of Hashimoto's disease) as evidenced by positive TPO antibodies and may eventually become hypothyroid due to underlying chronic autoimmune thyroiditis, with a predisposition for autoimmunity secondary to lithium. One study found that 20 % of lithium-treated affective disorder patients had elevated TPO antibodies vs. 7.5 % in non-lithium treated patients and 0 % in controls. Lithium has a narrow therapeutic index and can cause thyroid dysfunction (hypo or hyperthyroidism) even at sub-therapeutic levels. A particular case series showed a 3-fold increase of thyrotoxicosis in patients taking lithium. Lithium use has also been associated with a self-limited destructive thyrotoxicosis (lithium-associated thyroiditis). This particular type of hyperthyroidism falls under the category of subacute painless thyroiditis and typically resolves over the course of months to years with adequate treatment of the hyperthyroid state. In conclusion, this case highlights key points in the diagnostic evaluation of acute chest pain. First, non-ST elevation myocardial infarction or new LBBB do not establish a diagnosis of a type 1 myocardial infarction (secondary to acute plaque rupture) but could be secondary to acute coronary vasospasm (type 2 myocardial infarction; secondary to decreased oxygen delivery or increased oxygen demand). Second, hyperthyroidism must be considered with chest pain presentations, especially in patients with low Framingham risk score and isolated coronary artery vasospasm on heart catheterization. Finally, thyroid function should be evaluated in all patients who take lithium, given its narrow therapeutic index.

LITTLE KNOWN LYMPHOMA: SMALL LYMPHOCYTIC LYMPHOMA PRESENTING AS A PARANEOPLASTIC SYNDROME WITH ACUTE CNS DEMYELINATION Nicholas DeVito, Tufts Medical Center, Boston, MA. (*Tracking ID #1925987*)

LEARNING OBJECTIVE 1: 1. To recognize rare neurological paraneoplastic syndromes, appropriately identify their cause and the cancer of origin.

LEARNING OBJECTIVE 2: 2. To identify other paraneoplastic syndromes in hematologic malignancies and identify possible causes of these syndromes.

CASE: A 72-year-old woman with a past medical history of hyperlipidemia presented with progressive complete ophthalmoplegia, facial diplegia, slurred speech and right-sided ataxia for 6 weeks, preceded by transient monocular vision loss. She was worked up at an outside hospital with negative CT and MRI. She presented to our institution after several falls at home. Her vital signs were stable and she was alert and oriented. She had shotty bilateral axillary lymphadenopathy. Her neurological exam was significant for complete ophthalmoplegia, left eye ptosis, dysarthria, severe finger-nose-finger dysmetria on the right, inability to sit up unsupported, and severe rubral head tremor. Laboratory values were unremarkable. Repeat MRI of the head revealed a well marginated, extensive T2/FLAIR signal abnormality extending from the midbrain to the pons posteriorly with subtle peripheral enhancement, suggestive of a demyelinating disease. CT of the chest, abdomen, and pelvis showed numerous enlarged lymph nodes. CSF revealed 10 white cells (82 % lymphocytic), >5 oligoclonal bands, normal protein/glucose, and elevated CSF IgG index and synthesis rate. This was suggestive of an antibody present in the CSF not present in the blood. Rheumatologic and infectious workup was negative. Axillary lymph node biopsy was consistent with small lymphocytic lymphoma (SLL). She was treated with high dose steroids, five sessions of plasmapheresis, and R-CHOP chemotherapy (Rituximab, Cyclophosphamide, Doxorubicin, Vincristine and Prednisone). Within days of starting treatment, her symptoms resolved. Post-treatment CSF studies and MRI were unremarkable 6 months later.

DISCUSSION: SLL is a mature B cell lymphoma characterized by accumulation of functionally incompetent monoclonal lymphocytes with the same morphologic and immunophenotypic features as chronic lymphocytic leukemia (CLL), but lacks peripheral blood lymphocytosis. Paraneoplastic and autoimmune complications occur in up to 25 % of all patients with CLL/SLL. The most common complications are autoimmune hemolytic anemia or immune thrombocytopenia, both of which were not present in this patient. CNS complications are rare except when there is direct invasion of leukemic cells. This represents the first known case of a demyelinating paraneoplastic syndrome due to SLL. This was a unique case of SLL presenting as paraneoplastic syndrome of brain stem demyelination as determined by imaging, CSF studies and symptoms. Brain stem demyelination is an autoimmune syndrome seen in small cell lung cancer, germ cell cancers or in viral infections. Malignancies can interfere with self-tolerance in the central immune system, resulting in aberrant antigen recognition

and autoimmunity. Unfortunately we were unable to isolate a specific autoantibody in this case; however this highlights the fact that there is a plethora of research to be done in understanding the causes of paraneoplastic autoimmunity in CLL/SLL.

LOSING A BATTLE BUT NOT THE WAR: INSIGHTS INTO AVETERAN'S PREFERENCE FOR AGGRESSIVE MEASURES IN ADVANCED ILLNESS

Neil Gupta¹; John Thomas^{1,2}. ¹Yale University School of Medicine, New Haven, CT;

²Veterans Affairs (VA) Connecticut Healthcare System, West Haven, CT. (*Tracking ID #1936952*)

LEARNING OBJECTIVE 1: Appreciate the potential complexity surrounding goals of care discussions for patients with terminal illness.

LEARNING OBJECTIVE 2: Recognize that a decline in health status may prompt a change in goals of care for such patients.

CASE: A 96-year-old World War II veteran with prostate and bladder cancer with metastases to bone and brain presented to the hospital after an unwitnessed fall at home. Chart review revealed numerous cancer treatments over a span of several years, including a series of radiation treatments and transurethral resection of bladder tumor procedures. The patient's son reported that his father had been living at home independently until a few weeks prior to admission, when his growing forgetfulness and loss of energy prompted the hiring of a home health aid. He had no focal neurologic deficits on exam. CT scan showed subarachnoid hemorrhage of the right frontal lobe. A chest x-ray showed a large right-sided pleural effusion, and CT of the abdomen and pelvis showed a new bladder wall mass, metastatic lesions in his lung, and bilateral hydronephrosis and hydroureter. Urinalysis was consistent with urinary tract infection. Due to intracranial hemorrhage, he was admitted to the intensive care unit for close monitoring. Goals of care discussions initially centered on the patient and family's insistence upon aggressive measures, including full code status, despite the patient's overall poor prognosis. The patient's son confirmed that his father was always a "fighter," and despite multiple prior hospitalizations, he was always able to return to living at home independently and without significant symptom burden, even in the face of metastatic cancer. Within hours of arrival to the hospital, a chest tube and bilateral nephrostomy tubes were placed. The patient tolerated these procedures well and was transferred out of the intensive care unit the next day. While on the medicine floor, he took a turn for the worse, developing delirium and a steady cognitive decline, eventually responding only to voice. In light of this, his family decided to focus on making him comfortable and enrolled him in an inpatient hospice program. He died the next day.

DISCUSSION: Within only a few days, the patient in this case had a dramatic shift in care preferences spanning opposite ends of the treatment spectrum. Such decision making would at first glance make little sense to a medical team fully cognizant of his overall prognosis. However, certain aspects of the patient and family's perspective in initially insisting on aggressive treatment were compelling. The patient proudly identified as a veteran and maintained his "fighting" spirit in approaching chronic illness, not without prior successes, and his quality of life prior to this hospitalization was excellent. In his understanding, he was perhaps "winning the war," but facing a new setback of unclear significance. From the perspective of the medical team, they had inherited a "losing battle" in terms of the seeming futility of aggressive treatment at such a late stage in the patient's illness. Initial discussions about goals of care were awkward, as the team had just met the patient and family and were trying to gingerly reveal bleak prognostic information that perhaps had not been fully discussed previously. Ultimately, the patient's poor prognosis declared itself fully, and with the aid of continued conversations between the medical team and family, a smooth transition to hospice care was made. This case illustrates the vital role of communication in providing compassionate, patient-centered care at the end of life. Preferences for patients with advanced illness have been shown to be highly dynamic, thus necessitating careful, ongoing discussions involving the patient and a family member who can serve as health care proxy when needed. It is unclear whether advance care planning in the outpatient setting for this patient would have altered his care trajectory while hospitalized, but in the least it may have more clearly established his values and better prepared both him and his family for in-the-moment decision making.

LOWER EXTREMITY EDEMA AND JVP ELEVATION: MORE THAN

MEETS THE EYE Ryan Campbell-Massa¹; Anna K. Donovan². ¹University of

Pittsburgh Medical Center, Pittsburgh, PA; ²University of Pittsburgh School of Medicine, Pittsburgh, PA. (*Tracking ID #1940159*)

LEARNING OBJECTIVE 1: Maintain a high index of suspicion for pericardial constriction in the appropriate clinical setting

LEARNING OBJECTIVE 2: Understand the diagnostic work-up and treatment options for chronic pericardial constriction

CASE: A 64 year old man with a history of hypertension and rheumatic fever as a child presented as a new patient to primary care with complaints of lower extremity edema. The lower extremity swelling was present for the preceding 10 years, managed on furosemide and metolazone. He denied exertional chest pain, dyspnea, orthopnea, or paroxysmal nocturnal dyspnea. He denied any history of heart failure or myocardial infarction. He had no history of radiation exposure, tuberculosis, acute pericarditis, or autoimmune disorders. He had a 15 pack year history of tobacco use, and quit 30 years prior to presentation. On physical examination, he was in no acute distress. His cardiac examination was remarkable for a II/VI systolic ejection murmur best appreciated at the right upper sternal border without radiation to the carotids, elevated jugular venous pressure (JVP) to 11 cm, and 1+ pitting edema to mid-shins bilaterally. No rubs or gallops were appreciated on auscultation. There was no pulsus paradoxus. Pulmonary examination demonstrated clear lung fields bilaterally without crackles. EKG demonstrated sinus bradycardia with a heart rate of 60 without ST segment or T wave changes. QRS voltage was within normal limits. On transthoracic echocardiogram (TTE), the pericardium was echobright consistent with possible pericardial thickening. TTE also demonstrated 10–12 % increase in mitral inflow velocity with expiration and 13 % increase in tricuspid inflow velocity with inspiration. The respiratory variation was not diagnostic of pericardial constriction, but the constellation of findings warranted further evaluation. Chest CT with contrast demonstrated focal thickening and calcification of the pericardium along the right heart border. Cardiac catheterization demonstrated equalization of right ventricular end-diastolic pressure (RVEDP) and left ventricular end-diastolic pressure (LVEDP), near-equalization of pulmonary arterial diastolic pressure and LVEDP, and an RVEDP that was greater than one-third of right ventricular systolic pressure. An early diastolic dip followed by a plateau (the “square root sign”) was also noted on hemodynamic tracing. Cardiothoracic surgery was consulted and recommended pericardectomy. Given the patient’s lack of obvious risk factors, his constrictive pericarditis was presumably due to idiopathic or viral causes.

DISCUSSION: When seeing a new patient in clinic, it is essential to pause to consider the rationale for the prior management of a patient. Our patient was requiring two diuretics to appropriately manage his peripheral edema without a clear explanation of why. Given this patient’s unexplained elevated JVP and peripheral edema, especially in the absence of any history or electrocardiographic evidence of prior myocardial infarction, further workup was pursued. Heart failure is common in a primary care clinic, and its presentation can be similar to that of constrictive pericarditis. Patients with constrictive pericarditis often report a history of peripheral edema and decreased functional capacity. Physical examination commonly reveals elevated JVP but may also more rarely include pulsus paradoxus, Kussmaul’s sign, and a pericardial knock. Constrictive pericarditis is an uncommon entity. The etiology in a particular case is often not identified, and is most commonly attributed to idiopathic or viral causes. Other associated conditions include cardiac surgery, radiation exposure, infection of pericardium, and connective tissue disorders. Current guidelines recommend echocardiography for the initial evaluation of patients suspected to have pericardial constriction. Echocardiography may be diagnostic in some cases, especially with the use of Doppler assessment of hemodynamic changes in the respiratory cycle, which has been reported to have sensitivity and specificity of 85 % to 90 % in this setting. Imaging with CT scan and cardiac MRI can evaluate for pericardial thickening. Cardiac catheterization is a useful modality to definitively establish a diagnosis, and is typically performed prior to operative intervention. Hemodynamic findings frequently seen in constrictive pericarditis include increased right atrial pressure, elevated RVEDP to greater than one-third of RV systolic pressure, equalization of RVEDP and LVEDP, and an early diastolic dip followed by a plateau on hemodynamic tracing. Note that these findings were seen in our patient. Pericardectomy is the definitive treatment for chronic constrictive pericarditis, but must be timed optimally. Early disease may not warrant surgical correction and can sometimes be temporized with diuretic therapy. Conversely, patients with late disease (NYHA Class IV) rarely benefit from surgery, which is associated with a 30–40 % mortality in that population.

LUNG HERNIATION POST CARDIO-PULMONARY RESUSCITATION
Sourabh Aggarwal; Shrey Velani; Mark Loehrke. Western Michigan University School of Medicine, Kalamazoo, MI. (Tracking ID #1941459)

LEARNING OBJECTIVE 1: To understand rare complication of lung hernia post resuscitation

LEARNING OBJECTIVE 2: To know management of lung hernia

CASE: Chest compressions during cardiopulmonary resuscitation (CPR) can be traumatic to patients resulting in ribs/sternum fractures. Sternal fractures occur in 1

out of 5 and costal fracture in 1 out of 3 patients with resuscitation attempts. We report a rare complication of lung parenchymal herniation post-CPR. Fifty-six-year-old, previously healthy male, had Ventricular Fibrillation cardiac arrest and return of spontaneous circulation after 10 min of CPR. He was intubated and hemodynamically stabilized in the intensive care unit. Therapeutic hypothermia was initiated and rewarming done after 24 h. His neurological and cardio-respiratory status gradually improved over next 7 days. He was eventually extubated and placed on BiLevel positive air pressure (BiPAP). However, he started having respiratory distress with decelerating oxygen saturation. He had asymmetric chest wall movements with right side expanding more than left side. He was re-intubated and CT scan revealed displaced fracture from 3rd-6th ribs and herniated right-sided upper and middle lobe of lung tissue outside of the rib cage into pectoralis muscle. He was immediately taken to operating room where emergency repair of a large right lung hernia with a right pectoralis major muscle flap, open reduction and internal fixation of multiple right-sided rib fractures and drainage of the right pleural effusion was done followed by chest tube placement. He had an uneventful recovery, re-extubated and was transferred to floor.

DISCUSSION: Lung herniation post CPR has been very rarely described. A study of 705 post-CPR autopsies did not report even a single case of lung herniation. The rib fractures our patient received during CPR caused patient’s lung parenchyma to herniate which was complicated by initiation of BiPAP therapy. Most patients with lung herniation remain asymptomatic and a soft, reducible bulging mass may be noted in chest wall or neck fluctuating with the respiratory cycle, coughing or straining. Lung parenchymal hernias may appear as loculated subcutaneous air pockets on chest X-ray, however CT scan is the diagnostic modality of choice. Management is largely conservative in asymptomatic patients with careful monitoring of the respiratory function. Surgical intervention may be chosen in appropriate patients, especially those symptomatic with intractable pain, dyspnea, incarceration or ongoing effusion. Lung herniation should be considered as a differential in patients with a bulging mass in the anterior thorax, intractable pain at the site of potential fracture, ongoing dyspnea with no definite etiology, subcutaneous emphysema or pneumothorax after CPR.

LUNG HERNIATION—A UNIQUE CASE OF CHEST PAIN Chirag D. Patel; Van Holden. Rutgers—Robert Wood Johnson Medical School, New Brunswick, NJ. (Tracking ID #1938128)

LEARNING OBJECTIVE 1: Reviewing clinical and radiologic findings of lung herniation

LEARNING OBJECTIVE 2: Considering lung herniation as part of the differential diagnosis in a patient with atypical chest pain and associated risk factors.

CASE: A 57 year-old woman with a past medical history of morbid obesity, coronary artery disease status post coronary artery bypass surgery (CABG) with left internal mammary artery harvesting more than 5 years ago, hypertension, diabetes mellitus type II, and intermittent asthma presents with progressively worsening dyspnea over a month. It was associated with increased lower extremity edema, increased abdominal girth, paroxysmal nocturnal dyspnea, 3-pillow orthopnea, productive cough, and a “squeezing”, non-radiating, pleuritic chest pain. At baseline, she uses her nebulizer once a week and gets shortness of breath after walking up one flight of stairs. On admission, patient had dyspnea at rest despite using her nebulizers four times a day and medication compliance with furosemide and metoprolol. Her presentation was not characteristic of her asthma or anginal symptoms. The patient was hemodynamically stable except for 90 % oxygen saturation on 100 % non-rebreather. She was in respiratory distress with accessory muscle use; she had jugular venous distention, bilateral apical wheezing, decreased breath sounds at the bases, and bilateral lower extremity pitting edema. She was treated for presumed CHF exacerbation and started on BiPAP and intravenous furosemide. Her condition did not improve despite diuresis of more than four liters; thus, she was started on intravenous methylprednisolone for severe asthma exacerbation. The patient continued to have vigorous coughing spells despite antitussives. On hospital day five, she reported having sharp, pleuritic, left-sided chest pain radiating to the back after a violent coughing fit. She also had a focal bulge around the left parasternal area that was non-tender to palpation but had paradoxical movement with respirations. It was associated with a 30 mmHg systolic blood pressure difference in the arms. A CT angiography of the chest was obtained to evaluate for aortic dissection. It unexpectedly showed a diastasis between the 4th and 5th ribs where a 5.2×2.6 cm section of left upper lobe herniated. Adjacent to the defect was a metal clip from her cardiac surgery, suggestive of an intercostal muscle defect. Pulmonary and thoracic surgery recommended conservative management with observation in the acute setting because the patient’s pain was resolved gradually with local lidocaine and NSAIDS. She was discharged on oral furosemide and a prednisone taper with the plan for future surgical intervention. Our theory is that the patient’s previous cardiac surgery and parasternal clipping resulted in intercostal

muscle weakness. Concurrently, her violent coughing spells causing increased abdominal pressure, and her periodic steroid use for asthma exacerbations prevented wound healing. All of these factors contributed to the patient's lung herniation.

DISCUSSION: Lung herniation is an uncommon cause of chest pain with approximately 300 cases reported in the literature. The incidence may be even higher since many are asymptomatic. Herniation of the lung is usually classified as either congenital or acquired. Causes of acquired lung herniation include trauma, pathologic or spontaneous. Spontaneous herniations are a consequence of body habitus, COPD and hyperinflation; however, the majority of causes are a result of trauma or after surgery where the rib cage has been violated. Authors have reported intercostal lung hernias after numerous procedures interfering with the integrity of the thoracic wall (i.e. video-assisted thorascopic surgery, tube removal, minimally invasive direct coronary artery bypass grafting surgery, harvesting of internal mammary artery and thoracotomy). Specifically, harvesting left internal mammary artery for coronary bypass grafting along with the use of parasternal steel wires may interfere and damage the intercostal arteries leading to local ischemia. Consequently, thoracic wall integrity is compromised, increasing the risk of herniation, especially during vigorous coughing spells. Unique to our case is the fact that the lung herniation occurred years after her CABG. Most lung herniations due to surgical intervention described in the literature occurred weeks to months in the post-operative period. Numerous factors including body habitus, respiratory disease, and previous cardiac surgery contributed to her condition. This case illustrates the importance of understanding the clinical and radiologic findings of lung herniation also the risk factors associated with such an entity.

LYMPHADENOPATHY AND FEVERS AND TACHYCARDIA, OH MY!

Chaitanya Madamanchi; Mukhtar Adem. University of North Carolina, Chapel Hill, NC. (Tracking ID #1923942)

LEARNING OBJECTIVE 1: To recognize clinical manifestations of Castleman's disease

LEARNING OBJECTIVE 2: To recognize the importance of promptly initiating treatment

CASE: A 32 year-old woman with a history of asthma presented with 1 week of pleuritic chest pain. She also noted intermittent fevers, fatigue, and a dry cough. She denied weight loss, rash, or myalgias. She had a 15 pack-year smoking history and a family history of Systemic Lupus Erythematosus. Physical exam was notable for tachycardia and decreased breath sounds at the lung bases bilaterally without wheezing or rhonchi. There were bilateral, nontender, palpable, one-centimeter lymph nodes in the inguinal region. Labwork revealed eosinophilia and ANA 1:160. Chest X-ray revealed bilateral ground glass opacities and pleural effusions. CT Chest/Abdomen/Pelvis revealed bulky mediastinal and cervical lymphadenopathy and anterior mediastinal soft tissue mass, in addition to small pericardial and pleural effusions, tree-in-bud opacities, and ascites. PET scan showed FDG (tracer) avid lymphadenopathy with a dominant conglomerate 6×4 cm anterior mediastinal nodal mass. Thoracentesis revealed exudative effusions. Bronchoscopy was unrevealing. Blood, urine, pleural fluid, and bronchial wash cultures were negative. Hospital course was complicated by daily fevers up to 102 F, tachycardia up to 150 s, and hypoxic respiratory failure requiring mechanical ventilation despite empiric treatment with broad-spectrum antibiotics. Biopsy of the anterior mediastinal lymph node revealed interfollicular and paracortical expansion of polyclonal plasma cells. Pathology was consistent with a plasma cell variant of Castleman's Disease. Patient was started on solumedrol and tocilizumab, an IL-6 monoclonal antibody, with improvement in symptoms.

DISCUSSION: Castleman's Disease, also known as angiofollicular lymph node hyperplasia, is a rare, lymphoproliferative disorder that can be found in nodal and extra nodal sites. It is encountered infrequently and thus is difficult to diagnose. The plasma cell variant is characterized by the presence of hyperplastic germinal centers in lymph nodes. These enlarged lymph nodes can cause local symptoms such as pain from tissue expansion, dyspnea, and cough from compression of trachea. This disease has been linked to excessive release of IL-6, which leads to excess lymphocyte proliferation. This immune response helps explain other manifestations including high fevers, weakness, and fatigue. It is important to recognize Castleman's disease and obtain tissue diagnosis early, so that pharmacotherapy with glucocorticoids and IL-6 antibody can be initiated promptly. Failure to do so can result in death from fulminant infection, progressive disease with multi-organ failure, and conversion to lymphomas or uncontrolled HHV-8 infection.

LYMPHOMA TRAPPED IN BLOOD VESSELS: A RARE CASE OF INTRAVASCULAR B-CELL LYMPHOMA

Gagan Preet; Sreenivasa Chandana; Christine Dugan. WMU, Kalamazoo, MI. (Tracking ID #1936973)

LEARNING OBJECTIVE 1: To understand the pathology, clinical presentation, diagnosis and prognosis of intravascular B-cell lymphoma.

CASE: A 52-year-old Caucasian female presented with fatigue and diffuse abdominal pain for 4 weeks accompanied by 30-pound unintentional weight loss over 2 months duration. Her past medical, social and family history were non-contributory. On examination, she had hypotension (BP 70/50 mmHg), tachycardia (100 beats/min) and hypoxia (94 % oxygen saturation on 4 L/min oxygen). She was cachectic, had decreased breath sounds in lung bases and generalized abdominal tenderness. Initial labs revealed hemoglobin 11.6 mg/dL, WBC 5,000/mm³, platelets 15,000/ μ L, anion gap of 23 with lactic acidosis (9.1 mmol/L), LDH 2147 U/L, haptoglobin 98 mg/dL (normal 41–165 mg/dL) and ferritin 5127 ng/ml (Normal 13–300 ng/mL). She had worsening respiratory distress which required intubation. Fluid resuscitation was initiated, empiric broad spectrum antibiotics given and vasopressors started for hemodynamic support. CT scan of chest, abdomen and pelvis revealed bilateral pleural effusion, ascites and splenomegaly. An exhaustive work up including pan-culture, fungal serology, broncho-alveolar lavage, hepatitis panel, HIV, DIC panel, rheumatological workup (ANA, anti-dsDNA), transthoracic echocardiogram, colonoscopy, peripheral smear and flow cytometry were unremarkable. Despite all supportive measures, her clinical condition deteriorated fairly rapidly. She developed multi-organ failure and died within 7 days from the day of admission. Autopsy revealed extensive infiltration of small and medium sized vessels with large malignant lymphocytes. The lymph nodes were largely unremarkable. Immunohistochemistry was strongly positive for CD20, consistent with the diagnosis of intravascular B-cell lymphoma (IBCL).

DISCUSSION: IBCL is an extremely rare type of NHL characterized by selective clonal proliferation of lymphocytes, within the lumina of small blood vessels, particularly capillaries, without an extra-vascular tumor or nodal involvement. These lymphocytes lack CD29 and CD54 cell-surface proteins which are required for trans-vascular migration, hence malignant cells remain trapped in small-vessel lumina. Patients present with varied symptoms and are challenging to diagnose. Based on the presence of severe thrombocytopenia, anemia, elevated LDH, our patient did fit in to the category of IBCL associated with hemophagocytosis which is very rarely described in Caucasian population. Peripheral blood smears and flow cytometry can be normal as in our patient. Biopsy of the involved organ is the diagnostic test of choice with literature supporting random biopsy of even normal skin to confirm diagnose if no obvious lesions are present and suspicion is high. IBCL is a very aggressive tumor with grave prognosis and early diagnosis with intensive chemotherapy is crucial for better outcomes. Clinicians should be aware of this entity and should have high index of suspicion in appropriate patients.

MANAGEMENT OF HEPATITIS C VIRUS-INDUCED CRYOGLOBULINEMIC VASCULITIS IN THE PRESENCE OF COEXISTING DISEASES AFFECTED BY IMMUNOSUPPRESSANTS

Esther Hwang; Madan R. Aryal; Kaiming Wu; Benjamin Lloyd. The Reading Hospital and Medical Center, West Reading, PA. (Tracking ID #1926781)

LEARNING OBJECTIVE 1: Recognize the challenges of treating hepatitis C-induced cryoglobulinemic vasculitis in the presence of coexisting diseases affected by immunosuppressants

CASE: A 57-year-old Hispanic male with past medical history of untreated hepatitis C, chronic pulmonary Mycobacterium Avium Complex (MAC) newly started on clarithromycin, incompletely treated latent tuberculosis (TB), and chronic bronchiectasis presented with a 3-month history of intermittent severe pain, discoloration, and swelling of his lower extremities. On physical examination, the patient had tender palpable purpura with brown copper deposits and punctate satellite lesions, significant pitting edema from ankles to knees, previously identified as leukocytoclastic vasculitis by skin biopsy. Positive lab results included serum cryoglobulins, rheumatoid factor, low C4, hepatitis C genotype 1 with viral load >23.5 million, and sputum culture growing Pseudomonas. ANA, ANCA, HIV, sputum acid-fast bacillus, and urinalysis were negative. CT chest revealed stable bronchiectasis. A multidisciplinary meeting was called with GI, ID, and pulmonary to discuss the impact of all possible treatments. The team decided to pursue symptom-based treatment with steroids, antihistamines, colchicine, diuretic, wound care, and conservative measures, such as leg elevation and fluid restriction. Over the next few days, the patient's leg swelling improved. He was discharged on levofloxacin and the same inpatient regimen for cryoglobulinemic cutaneous vasculitis with steroid taper and wound care. The decision was made to start anti-virals after 6 months of clarithromycin therapy.

DISCUSSION: Creating this patient's treatment plan was a balancing act requiring management of multiple diseases as well as many potential complications of different therapies. Immunosuppressant therapy for cryoglobulinemic vasculitis could worsen hepatitis C viremia, MAC, and bronchiectasis; interferon therapy for hepatitis could

re-activate TB; latent TB could not be treated due to hepatic intolerance. Since there was no literature for this patient's specific constellation of diseases and there were risks with every treatment option, decision-making was based on the principles of prioritizing treatment of diseases that cause definite harm while maximizing benefit and minimizing potential harm in the management of coexisting diseases.

MANAGEMENT OF METABOLIC ACIDOSIS IN PRE-EXISTING PROXIMAL RTA Guillermo E. Espinoza, NYPH-WCMC, New York, NY. (*Tracking ID #1938719*)

LEARNING OBJECTIVE 1: To understand the mechanisms underlying the electrolyte imbalances present in patients with proximal RTA.

LEARNING OBJECTIVE 2: To learn how an understanding of this pathophysiology impacts the treatment of critically ill patients with proximal RTA.

CASE: Patient is a 27 year old male with a past medical history significant for vertically transmitted HIV/AIDS, diffuse large B-cell lymphoma with intestinal involvement status post sigmoidectomy with end colostomy and proximal renal tubular acidosis secondary to tenofovir therapy. He presented to the hospital with complaints of increased ostomy output, decreased oral intake, generalized weakness and fatigue. He was noted to have C. diff positive ostomy output as well as a marked hyperchloremic hypokalemic metabolic acidosis with a bicarbonate less than 5, potassium of 2.2 and chloride of 122. At first, management and electrolyte repletion focused primarily on correcting a profound metabolic acidosis, for which the patient was briefly placed on a bicarbonate drip. Efforts were also made to correct the patient's other concomitant electrolyte abnormalities, in particular his hypokalemia, which proved to be difficult to manage with replacement equating to 220 mEq of KCl daily. Repletion efforts eventually shifted to consolidation of supplementation in order to optimize his repletion regimen (e.g. KPO4 for phosphorus repletion and LR for volume repletion). Most notably, the patient's potassium repletion changed from a KCl based regimen to a CH3CO2K based regimen. With this change the patient's high potassium requirements decreased to 80 mEq of potassium daily as did his sodium bicarbonate requirements, though to a lesser extent, despite continued high ostomy output.

DISCUSSION: The treatment of acidemia in proximal RTA is complicated by the fact that alkali therapy can result in a HCO3 diuresis and increased urinary K+ losses. In order to avoid a refractory and persistent hypokalemia, efforts should be made to ensure a portion of the alkali replacement is in the form of a potassium salt such as potassium citrate or potassium acetate. This physiologic perturbation in patients with proximal renal tubular acidosis is illustrated by the fact that this patient's potassium repletion requirements were markedly reduced once concomitant alkali therapy was added to his potassium repletion substrate, rather than addressing each of his electrolyte deficits individually.

MAY THURNER SYNDROME Manisha Bhude; Kandace Shepherd. University of Colorado Denver, Aurora, CO. (*Tracking ID #1923475*)

LEARNING OBJECTIVE 1: Discuss how a common anatomic variant can increase risk of left leg deep vein thrombosis.

LEARNING OBJECTIVE 2: Increase the awareness of this vital problem that causes morbidity in young adults and needs more aggressive management.

CASE: 53 years old, previously healthy, male presented to clinic for left leg pain, new unilateral varicose veins, purple discoloration, leg swelling and unable to bear weight. He denies any recent travel, trauma, illness, fever or chills. Past history significant for former smoker 15 pack years quit 10 year ago, hereditary spherocytosis, s/p splenectomy. Age appropriate cancer screening up to date, including normal colonoscopy. Exam revealed normal Ankle brachial index, but dusky, blue edematous leg with varicose veins. Systemic exam was normal. Ultrasound of the leg showed left common iliac vein occlusion, extending into Inferior Vena Cava (IVC), partial thrombus in external iliac and femoral veins. CT of abdomen pelvis noted- Extensive left lower extremity thrombus and thrombophlebitis. Non occlusive thrombus in the IVC beginning 6 cm below the right main renal vein with occlusive thrombus in the left common iliac left external and internal iliac, common femoral, femoral and deep femoral veins. CT chest confirmed moderate burden of pulmonary emboli to both lungs with small wedge lung infarction. Vascular surgery was contacted and TPA directed thrombolysis with left iliac vein stent was done. He was found positive for Factor V Leiden mutation. He was discharged on chronic anticoagulation. Course- 2 months later, he developed iliac vein stent thrombosis on INR 1.7 and needed re stenting Case 2-35 year female nonsmoker presented with extensive left leg DVT. CT abdomen diagnosed MTS. She underwent iliac vein stenting and 6 month anticoagulation. Her stent remains patent for >5 year

DISCUSSION: In 1851, Virchow noted increased incidence of left sided DVT (deep vein thrombosis). In 1957, May and Thurner noted hemodynamically significant compression of the left common iliac vein between the overlying right common iliac artery and the underlying vertebral body causing a venous spur. This was termed May-Thurner syndrome (MTS) or iliac vein compression syndrome. Venous spur develops due to collagen and elastin deposition and intimal fibrosis due to chronic arterial pulsations. Incidence of MTS is 20 % and accounts for 2-5 % of venous disorders in leg. It is more common in young women in 2nd-3rd decade. When accompanied by postpartum state, contraceptive use, immobility, hypercoagulable states it can precipitate a left leg DVT. Diagnosis is made based on clinical suspicion, venous ultrasound and CT or MR venography. Advanced techniques like intravascular ultrasound is sensitive in detecting the pathognomonic venous spur and helps to calibrate vessels before stenting. Long term anticoagulation alone may not prevent recurrence; hence more aggressive approach like intravascular stent placement is needed. Society of Vascular surgery 2012 guidelines do not recommend IVC filter placement, but do recommend catheter directed thrombolysis and mechanical thrombectomy to prevent post thrombotic syndrome. Usually anticoagulation is needed for at least 6 months post stenting. Longer duration of anticoagulation is recommended for pulmonary embolism. Literature review shows average post stent patency is about 70-80 % over 2 years. Thus it is important to know and identify this anatomic variant, since it affects management, prognosis and morbidity.

MELANOMA MASQUERADE AS HEMORRHOID Fumi Ito¹; Hidenori Oguchi¹; Mitsunori Iwase¹; Masataka Shinoda²; Shinichi Mizuno¹; Takahisa Suzuki¹.

¹Toysa Memorial Hospital, Toyota, Aichi, Japan; ²Toysa Memorial Hospital, Toyota, Aichi, Japan. (*Tracking ID #1930588*)

LEARNING OBJECTIVE 1: Recognize the possibility of malignancy even in patients with hemorrhoid.

LEARNING OBJECTIVE 2: Assess the need for pathological diagnosis in hemorrhoid.

CASE: A 63-year-old woman with a past medical history of internal hemorrhoid was admitted to our hospital for gradually developing edema of lower extremities. Her internal hemorrhoid had been followed by a practitioner who was specialized in anal diseases, and excised three times during 4 months prior to admission. She denied dyspnea, orthopnea, fatigue, nausea, weight loss, headache, cough, any pain throughout her body. She had no history of medication, smoking or drinking alcohol. Vital signs showed the blood pressure of 103/60 mmHg, the pulse of 80 beats per minute, and the body temperature of 36.5 °C, the respiratory rate of 14 per minute, and the oxygen saturation of 96 % while breathing ambient air. Physical examination revealed slightly swollen abdomen without tenderness, and also severe edema in her lower bilateral extremities. Laboratory results including complete blood cell counts, basic metabolic panel were normal, but liver enzymes prominently elevated. Abdominal ultrasound showed ascites and multiple high-echoic lesions in the liver. Plain chest and abdominal CT scans revealed several small masses in the bilateral lungs and liver, and a tumor in the rectum. Colonoscopy revealed a melanotic tumor in anorectal region. Accordingly, malignant melanoma with metastasis was highly suspected. Biopsy was performed, and indicating positivity for malignant melanoma specific in Human melanoma black 45 (HMB45) immunostaining. The patient was diagnosed with malignant melanoma stage 4 and anorectal lesion was suspected of the primary site from imaging results. MRI and PET findings revealed multiple metastasis not only in both side lungs and liver, but also in iliac and femoral bones. At first, the standard chemotherapy with DAV (dacarbazine, nimustine hydrochloride and vincristine) was considered. However, the mono-therapy with dacarbazine was chosen, because her condition was seriously exacerbating with increasing ascites and emergence of dyspnea and appetite loss. After the mono-therapy with dacarbazine, her symptoms were substantially improved. Accordingly, DAV therapy was added once. Inspite of these chemotherapies, the patient passed away 2 months after admission.

DISCUSSION: Melanomas may stem from the mucosal epithelium lining in the respiratory, alimentary, and genitourinary tracts, all of which contain melanocytes, as well as from the skin. Anorectal mucosal melanoma accounts for approximately 0.05 % of all colorectal malignancies and only 1 % of all anal canal cancers. Importantly, mucosal melanomas generally carry a worse prognosis than those arising from cutaneous sites, with most patients developing recurrent and disseminated disease. The standard initial management for locoregionally confined mucosal melanoma is a complete wide local resection, which offers the best chance for long-term survival. Actually, some studies have shown early resection of primary mucosal lesions considerably improve the patient's prognosis. The approach to the

management of systemic metastases from a mucosal melanoma is based upon the treatment of metastatic cutaneous melanoma, and is limited. Anorectal mucosal melanoma is a very rare disease and likely to be missed at the time of resection, though its prognosis is dismal especially in advanced metastases. Once we recognize that some hemorrhoid may be malignant tumor, we should assess the excised hemorrhoid pathologically to prevent the tumor spread systemically. That will allow patients survive longer with more options for treatment including resection.

METRONIDAZOLE-INDUCED ENCEPHALOPATHY Yuichiro Suzuki; Christine Kwan. Teine Keijinkai Medical Center, Sapporo, Japan. (*Tracking ID #1932143*)

LEARNING OBJECTIVE 1: Recognize that encephalopathy may be caused by the commonly used antibiotic, metronidazole

CASE: A 22 years old Japanese man presents with 12 days' history of altered mental status while hospitalized. He is noted to have behavioral changes, disinhibition, dysarthria, and decreased response to external stimuli. At the time, he has no constitutional symptoms or other neurological changes. Of note, he has been hospitalized 2 weeks prior for fevers (39 °C), headache, left arm/leg weakness, and vomiting for which he has been diagnosed with *Streptococcus constellatus* right putamen brain abscess and prescribed ceftriaxone 2 g Q12H and metronidazole 500 mg Q6H in addition to stereotactic drainage. He has been clinically improving until now with new-onset encephalopathy not improved by sulpiride (anti-psychotic). Physical exam at this time shows vital signs of temperature:35.8C, blood pressure:108/59, heart rate:61, respiratory rate:10–15, and O₂ saturation:92–98 % room air. Generally, he is awake but has depressed affect and psychomotor retardation. Neuro exam shows intact cranial nerves, motor strength 4/5 on his right extremities and 3/5 on his left, continued decreased sensation to light touch and position on his left extremities, 2+ reflexes bilaterally, (+) muscle rigidity, and unstable gait. Labs, including complete blood counts and chemistry, are within normal limits except for gamma-glutyl transpeptidase:184U/L, alkaline phosphatase:350U/L, aspartate aminotransferase:44U/L, alanine aminotransferase:73U/L, and creatine kinase:38U/L. Repeat head computed tomography (CT) 1 week after the first one shows no worsening of the abscess. Head magnetic resonance imaging (MRI), however, reveals high intensity areas in the retrosplenial region and bilateral cerebellar dentate nucleus. Given these imaging results consistent with metronidazole-induced encephalopathy, his metronidazole is switched to clindamycin with behavioral improvement the following day. Repeat MRI 1 week after shows a decrease of the high intensity signals with continued clinical improvement although still with some residual numbness, albeit improving, in his extremities.

DISCUSSION: Metronidazole is one of the mainstay drugs for the treatment of anaerobic infections, including brain abscesses, and *Clostridium difficile* diarrhea. Resistance remains rare, which is probably one of the reasons why this drug is commonly used worldwide. It can also reach high concentrations when taken orally, and its tissue penetration is excellent. Metronidazole can even effectively penetrate the blood brain barrier, hence why it is often used for brain abscesses. While the most common side effects of the drug is usually in the gastrointestinal tract, neurotoxicity can occur, usually when the dose exceeds the range of 21–135 g; the above patient has taken a total of 2000 mg/day × 41 days=82 g. Metronidazole-induced encephalopathy, however, has only been reported in 21 case reports in 2011. Key radiologic findings on diffusion weighted MRI include bilateral, symmetric high intensity areas in the cerebellar dentate nuclei and corpus callosum, like the above patient. Most patients improve within 3–6 weeks after discontinuation of metronidazole, but some are left with irreversible severe neurologic disabilities. Given the possibility of encephalopathy, therefore, one should recognize the potential adverse effects of the commonly used antibiotic, metronidazole.

METRONIDAZOLE-INDUCED PSYCHOSIS: A CASE REPORT AND BRIEF REVIEW OF THE LITERATURE Margaret Park¹; Christopher P. Redgate²; Estebes Hernandez¹. ¹UCLA Medical Center, Los Angeles, CA; ²David Geffen School of Medicine at UCLA, Los Angeles, CA. (*Tracking ID #1938516*)

LEARNING OBJECTIVE 1: Recognize the neuropsychiatric side effect of metronidazole.

CASE: A 42 year old male with a history of end-stage renal disease, type 2 diabetes mellitus, and stroke presented with a 2 week history of acute episodes of altered mental status. The first episode occurred at the end of a hemodialysis session during a recent hospitalization for catheter-associated bacteremia and *Clostridium difficile* colitis. He became acutely agitated and repeatedly endorsed suicidal ideation. The

episode lasted 20–30 min then resolved with the patient having no recollection of the event. Psychiatry attributed the episode to acute delirium in the setting of multiple medical issues. He was monitored for 24 h without a recurrent episode and discharged home. Upon discharge, he subsequently had multiple episodes similar to the first. Over the course of a week, the episodes increased in duration and frequency. Several emergency room visits failed to reveal a metabolic or organic cause. Subsequently, a persistent episode required inpatient admission for management of his symptoms and search for etiology. Initial testing for reversible causes of delirium were negative including blood cultures, thyroid function, liver function, blood chemistry, vitamin B1, and urinary drug toxin screen. A CT and MRI of the brain noted encephalomalacia in the right MCA territory consistent with prior stroke. Review of current medications revealed a long list of stable medications. The only medications over the past several weeks were antibiotics prescribed to treat bacteremia and colitis. He completed his course of ciprofloxacin on the day of admission and metronidazole was switched to oral vancomycin. He continued to have daily acute episodes of agitation and hallucinations requiring 24-hour supervision and intermittent use of restraints. Psychiatry again felt the episodes were more likely delirium versus a new underlying psychiatric condition. He was medically managed with risperidone twice daily and clinically improved over the course of 5–7 days. Patient was discharged with Psychiatry follow-up. Patient has been followed closely since discharge without recurrence of symptoms for greater than 6 months since hospitalization.

DISCUSSION: Previous cases of metronidazole-induced psychiatric side effects described in the literature often involved healthy, young patients. The low number of reported cases of psychiatric side effects, despite widespread use of metronidazole, may speak to the difficulty in confirming drug-related psychiatric adverse reactions in general but particularly in more medically complex patients in which this drug is often used. The exact mechanism of metronidazole neurotoxicity remains unknown. Metronidazole reaches near 100 % bioavailability, with a large volume of distribution and low serum protein binding. The drug undergoes extensive hepatic metabolism and rapidly and effectively crosses the blood brain barrier in concentrations that approximate serum levels, which could explain its potent albeit rare neurologic side effects. This drug reaction may have been confounded by his renal dysfunction despite appropriate dose reduction. That being said, after evaluation of the case reports collectively, a consistent dose or duration relationship with metronidazole and neuropsychiatric side effects has not been confirmed. Both direct and indirect neurotoxic effects have been hypothesized for metronidazole-induced neuropsychiatric side effects. Direct toxicity appears to occur through inhibition of neuronal protein synthesis and temporary axonal swelling or neuronal injury with subsequent death of Purkinje-fibers. The proposed indirect toxicity is thought to be due to oxidation of catecholamines to their corresponding semiquinone radicals when exposed to metronidazole or impaired thiamine utilization. This case highlights the importance of maintaining a broad and thorough differential when determining the cause of psychiatric symptoms. A detailed account of current medications with start and stop dates is a critical component in the assessment of new-onset psychiatric complaints and should be conducted upon presentation, particularly in the setting of polypharmacy and a medically complex patient. Delay in diagnosis can result not only in severe impairment, impacting the patient's mental and physical well-being, but also in increased healthcare utilization as in this case.

MICROSCOPIC POLYANGIITIS Christina M. Cruz; Darlene LeFrancois. Montefiore Medical Center, Bronx, NY. (*Tracking ID #1940703*)

LEARNING OBJECTIVE 1: Distinguish non-infectious from infectious causes of pulmonary consolidation

LEARNING OBJECTIVE 2: Recognize the clinical manifestations and diagnostic criteria of microscopic polyangiitis

CASE: Mr. M is a 70 year old man with prostate cancer treated with radiation therapy 3 years prior and a former smoker with significant emphysematous disease who presented with progressively decreasing exercise tolerance × 6 weeks. He initially presented 5 weeks previously with decreased exercise tolerance, cough, malaise, and subjective fever. He was treated for community acquired pneumonia, which was seen on CXR, and superimposed COPD exacerbation. Two weeks later, without interim improvement, he again presented with similar symptoms. Repeat CXR and CT thorax revealed multilobate consolidations. He was then treated for hospital acquired pneumonia. But 3 weeks thereafter, he again presented with progressively worsening dyspnea. His initial cough had persisted, productive of some white sputum, however fevers did not continue. He had also developed pleuritic pain significant weight loss and 1 week of painful paresthesias of his right foot. He did not note any lower extremity edema, palpitations, arthralgias, myalgias, rashes nor muscle weakness. On exam he had focal areas of decreased breath sounds but a normal heart exam. He had decreased sensation to light touch of right lateral and plantar foot, strength preserved.

Initial laboratory studies were significant for a leukocytosis of 24,000 (increased from 12,000 5 weeks prior, 16,700 3 weeks ago and 18,800 1 week ago) with a neutrophilic predominance, no immature cells. Hemacrit was 29 % from a baseline of 40 % 6 weeks to this presentation. Stable creatinine with GFR >60 but urinalysis with 22 RBCs/hpf, 35 WBCs/hpf, 30 protein, no casts sent (microscopic hematuria on urinalysis apparent for months). ESR of 95 mm/h and AST 133, ALT 135 (previously normal). CXR demonstrated stable multifocal consolidations. During his hospital course he also developed rapidly progressive renal failure and labs significant for positive ANA titer at <1:40, Rheumatoid factor 770, positive ANCA (P3-at >8.0 U but negative MPO) normal hepatitis serologies, negative anti-GBM, normal C3 and C4. Renal biopsy results showed diffuse segmental glomerulonephritis, pauci-immune, consistent with ANCA-mediated renal disease. He was diagnosed microscopic polyangiitis and treated with high dose steroids and cyclophosphamide, along with plasmapheresis for rapidly progressive glomerulonephritis. Although he required hemodialysis, his renal function and other symptoms improved and did not require subsequent renal replacement therapy.

DISCUSSION: Microscopic polyangiitis (MPA) is a small vessel vasculitis. It is an ANCA positive vasculitis characterized by pauci-immune necrotizing small-vessel vasculitis without clinical or pathological evidence of necrotizing granulomatous inflammation. Clinical manifestations include constitutional symptoms, including fever and weight loss, as well as renal, pulmonary, gastrointestinal, skin and neurologic manifestations. Renal involvement is a primary feature and seen 80–100 % of reported cases. It is typically characterized as rapidly progressive glomerulonephritis. Pulmonary manifestations include hemoptysis and alveolar hemorrhage, infiltrates, pleural effusion, pulmonary edema, pleuritis, and interstitial fibrosis. It remains one of the most common causes of pulmonary-renal syndromes. Growing evidence indicates a role for ANCA in the pathogenesis of MPA, with over 80 % of patients having associated ANCA positive serologies, although they are not included in the diagnostic criteria. Diagnostic criteria, like the Chapel Hill Consensus Conference criteria, primarily define MPA based on pathologic findings. Treatment for MPA includes an induction phase with high dose steroids and usually cyclophosphamide, with maintenance prolonged maintenance therapy. Alternative regimens are being explored given the substantial toxicity of cyclophosphamide.

MOLLARET'S MESS: THE HEADACHE YOU JUST CAN'T SHAKE

Catherine Firestein; Cady (Blackey) Brown. Tulane University Health Sciences Center, New Orleans, LA. (*Tracking ID #1926145*)

LEARNING OBJECTIVE 1: Explore the differential diagnosis for aseptic meningitis

LEARNING OBJECTIVE 2: Review definition, diagnosis, and treatment of Mollaret's meningitis

CASE: A 40 year-old woman with a history of meningitis and migraines presented with complaints of a frontal headache with associated photophobia, nausea, vomiting, and neck stiffness. She denied altered mental status and endorsed subjective fever and chills. On exam, the patient was found to be afebrile and demonstrated mild photophobia and neck stiffness. Basic laboratory studies were only significant for white blood cell (WBC) count of 11400/microL. CT of the head was within normal limits. Cerebrospinal fluid (CSF) studies were as follows: protein 62 mg/dL, glucose 66 mg/dL, zero red blood cells, WBC 716 with 8 % polymorphonuclear cells, 74 % lymphocytes, 2 % monocytes, 1 % eosinophils, and 5 % basophils. As the lymphocytic predominance was more consistent with viral meningitis and the Gram stain and routine culture of the CSF fluid were negative, empiric antibiotics were discontinued. The patient continued to improve and was ultimately discharged from the hospital with no further treatment indicated. Four days later, the patient re-presented to the emergency room with similar complaints of headache, photophobia, nausea, vomiting, and neck pain. She remained afebrile with only mild photophobia and neck stiffness noted on physical exam. HSV-2 PCR from her prior CSF studies had returned positive and she was admitted for treatment of HSV meningitis. The infectious disease service was consulted and recommended treatment with acyclovir until her discharge date, at which time she was transitioned to oral antivirals and treated with valacyclovir for 7 days.

DISCUSSION: Based on clinical signs and symptoms, this case was concerning for aseptic meningitis. Aseptic meningitis is commonly encountered by the general internist; it is important to be familiar with an appropriate differential diagnosis. This includes infectious causes, such as viruses, parasites, spirochetes, fungi or mycobacteria, as well as non-infectious causes such as medications, Bechet's disease, sarcoidosis and lupus. Mollaret's meningitis, or recurrent aseptic meningitis, was named for the French physician who first wrote about cases of recurrent aseptic meningitis. Today, diagnosis of Mollaret's meningitis is based on clinical findings and cerebrospinal fluid results. The disease is characterized by multiple episodes of meningitis, with symptom-free periods between episodes. Lymphocytosis is seen in the CSF and characteristic mononuclear (Mollaret

cells may be seen early on. For many decades, the etiology of this disease was unclear, though a viral etiology has long been suspected. Since the advent of polymerase chain reaction testing, Herpes simplex virus has been found to be the cause of the majority of cases of Mollaret's meningitis. Treatment for this entity is still being debated. Case studies have shown benefit of antiviral medications in both treatment of acute illness and prevention of recurrence. However, acute episodes usually resolve spontaneously and many patients have long symptom-free intervals. Until more clear evidence exists, treatment decisions should be made individually for each patient, based on the severity and frequency of his or her symptoms.

MOTHER NATURE TO THE RESCUE? AN UNUSUAL RASH

Jane Andrews; A Dominica Fotino. Tulane University Health Sciences Center, New Orleans, LA. (*Tracking ID #1926245*)

LEARNING OBJECTIVE 1: Recognize the treatment potential of omega-3 fatty acids for skin conditions

LEARNING OBJECTIVE 2: Understand the workup of urticaria

CASE: A 64-year-old woman presented with a two-day pruritic rash that began on her scalp and progressed diffusely. She had no past medical history of rashes, allergies, recent sick contacts, fevers, chills, new exposures, medications or foods. She noted worsening GERD symptoms and dysphagia in the days leading up to admission, to the point that she could not swallow, but denied other symptoms or triggers. She has a history of severe GERD, depression, celiac disease though compliant with a gluten-free diet, and multiple family members with Sjogren's, systemic lupus erythematosus and rheumatoid arthritis. Home medications include Paxil 20 mg daily, ranitidine 150 mg po twice a day, and albuterol q6h prn for shortness of breath. Patient had all childhood vaccines including measles, mumps and rubella. Her vital signs were within normal limits. Her skin was dry and erythematous, with coalescing, papular patches throughout the abdomen, back, and extremities. No scaling or vesicles were present. The rash appeared uniform, with no predilection for sun-exposed areas or extensor surfaces. Genital and oral membranes were pink and without ulceration. No oral ulcerations or joint abnormalities noted. Lab work demonstrated comprehensive metabolic panel notable for elevated BUN and creatinine of 29 mg/dL and 2.54 mg/dL, which normalized over 48 h with intravenous fluids, and elevated total protein to albumin ratio (8.8 g/dL to 3.8 g/dL), elevated erythrocyte sedimentation of 58, elevated C-reactive protein of 1.31 mg/dL, positive anti-neutrophil antibody (unknown titer), negative anti-neutrophil cytoplasmic antibody, and negative HIV-1/2 antibodies and normal complete blood count. Manual differential showed 52 % neutrophils, 42 % lymphocytes, 6 % monocytes, and 0 % eosinophils. The patient's urticarial reaction appeared 4 days after starting Benadryl and prednisone, however the rash slowly reappeared after discharge when patient had stopped taking the Benadryl and prednisone. An outpatient physician suggested adding omega-3 fatty acids to her diet, and upon starting flax seed oil (a rich source of omega-3) the rash went away. She stopped taking the flaxseed oil months later and the rash reappeared. This cycle repeated itself two more times with the rash disappearing each time she restarted the flax seed oil.

DISCUSSION: Rashes frequently challenge general internists. When pattern recognition fails to identify the cause, lab work may be helpful. Elevated serum IgE levels can point towards atopic dermatitis, skin scrapings may point towards fungal infections or scabies, ESR, CRP and antibody testing can point towards autoimmune disease, and flow cytometry and immunophenotyping are useful if B or T cell lymphoma is on the differential. HIV testing (particularly PCR testing) is important, since exfoliative dermatitis is predictive of seroconversion and can point to HIV-associated infectious agents. Differential diagnosis of this patient's urticarial rash included contact dermatitis, atopic dermatitis, shingles, dermatitis herpetiformis, bacterial or fungal infection, scabies and DRESS. However, the distribution and characteristics of the rash were not consistent with these diagnoses. The patient denied having started any new medications, making Drug-Reaction with Eosinophilia and Systemic Symptoms less likely. In this particular case, anti-inflammatories were used to treat a presumed inflammatory process. This case study demonstrates one patient's experience with using flax seed to treat this condition. Flaxseed's likely benefits derive from its anti-inflammatory effects. In fact, several dermatologic conditions can be treated with omega-3 fatty acid supplementation such as atopic dermatitis, atopic eczema, alopecia, psoriasis, dandruff, ichthyosis, follicular hyperkeratosis and photosensitivity. The omega-3 fatty acids present in flax seed have been shown to inhibit cyclooxygenase, a precursor to arachidonic acid and to lower multiple inflammatory markers such as white blood cell count, C-reactive protein, and serum amyloid A. Physicians may rely on medications to offer symptomatic relief in urticaria, such as anti-histamines and steroids, however these may be accompanied by side effects such as drowsiness, skin changes and weight gain. Flaxseed oil offers a non-pharmacologic anti-inflammatory alternative.

MULTIPLE CHIEF COMPLAINTS: CAN THERE BE 1 UNIFYING DIAGNOSIS? Theresa Poulos¹; Marisa Hernandez-Morgan²; Marcia Glass³. ¹University of California, San Francisco, San Francisco, CA; ²University of California, San Francisco, San Francisco, CA; ³University of California, San Francisco, San Francisco, CA. (*Tracking ID #1898051*)

LEARNING OBJECTIVE 1: Recognize the clinical presentation of high-output heart failure due to severe thiamine deficiency (wet beriberi).

LEARNING OBJECTIVE 2: Understand the pathophysiology of wet beriberi and identify individuals at highest risk of developing thiamine deficiency.

CASE: A 48 year-old woman presented with 5 days of abdominal pain and difficulty breathing, a week of hemoptysis, and painful swelling of her left lower extremity. Her history was notable for alcohol dependency with delirium tremens, COPD, and hepatitis C. She was afebrile and tender to palpation in the epigastric area, with erythema and induration of the left abdomen. She had two-plus pitting edema to the mid-thigh bilaterally; both lower extremities showed marked erythema and were warm and tender to touch. She had a tremor of the upper extremities bilaterally. Her toxicology screen was positive for alcohol, and lactate was elevated at 2.6 mmol/L. Lower extremity Doppler was negative for deep vein thrombosis. CT of the abdomen was only remarkable for diffuse subcutaneous edema. Transthoracic echocardiogram findings were consistent with a high cardiac output.

DISCUSSION: Fluid accumulation resulting in edema is a common presentation. Distinguishing between dependent and diffuse soft tissue edema can help to narrow the differential and result in more timely diagnosis and treatment. The underlying cause of this patient's anasarca is high-output heart failure due to severe thiamine deficiency. Thiamine deficiency can manifest as a peripheral neuropathy (dry beriberi), or with predominantly cardiac symptoms (wet beriberi). Initially in wet beriberi, peripheral vasodilation results in a decreased SVR and increased venous return. Continued deficiency leads to impaired myocardial function because thiamine acts as a coenzyme in carbohydrate metabolism. Specifically, thiamine deficiency results in impaired utilization of lactate, which then accumulates in the blood causing elevated serum lactate, as was seen in this patient. While elevated blood lactate is nonspecific, it has been used in the diagnosis of beriberi. With continued vasodilation, the kidneys detect a relative volume loss and respond by conserving salt. Fluid is reabsorbed, leading to diffuse edema, consistent with this patient's otherwise odd pattern of fluid retention. The body cannot produce thiamine, and is only able to store up to 30 mg in tissue. The half-life is 9 to 18 days, so individuals who lack thiamine in their diet will become deficient within a month. Thiamine deficiency is rare in developed countries because most foods are fortified, however the WHO has documented outbreaks of beriberi among refugees and in developing countries—particularly Thailand and in sub-Saharan African—where diets are based on thiamine-poor staples such as polished rice and cassava. This patient was deficient as a consequence of poor nutrition associated with her chronic alcoholism. Gastric bypass patients and individuals on “fad” diets are also at risk. Physicians need to consider thiamine deficiency when evaluating a patient with diffuse anasarca. The diagnosis is largely clinical, because blood thiamine levels may not accurately represent the amount in tissue. IV thiamine should be administered whenever deficiency is suspected.

MY HUSBAND ATE MOTH BALLS: METHEMOGLOBINEMIA AND HEMOLYTIC ANEMIA ASSOCIATED WITH NAPHTHALENE INGESTION
Ameera J. Ahmed. Baylor College of Medicine, Houston, TX. (*Tracking ID #1939468*)

LEARNING OBJECTIVE 1: – Recognize that elderly patients with dementia may be at increased risk of ingestion of common household items

LEARNING OBJECTIVE 2: – Identify that naphthalene moth balls may cause both hemolytic anemia and methemoglobinemia. Diagnose early signs of methemoglobinemia

CASE: Naphthalene based compounds were widely used as household deodorizers and repellents for moth larvae in the past. Their use has been phased out but not banned given the toxic side effects associated with accidental ingestion. There have been numerous cases of naphthalene toxicity in children reported in literature before the 1970's but recent cases have been rare. Now naphthalene has been replaced with 1,4-dichlorobenzene which tends to be safer. A 74 year old African-American male with advanced vascular dementia was brought to the clinic with complaints of lethargy, confusion and dark colored urine. The patient's wife reported that she had found the patient with mothballs in his hand 2 days prior to presentation and suspected that he had ingested them. On exam the patient was somnolent. Labs showed profound anemia, indirect hyperbilirubinemia and elevated reticulocyte count.

On the second day of admission the patient's oxygen saturation was found to be 70 % with no signs of respiratory distress. Co-oximetry of an arterial blood gas sample showed elevated methemoglobin levels (9.5 %). He was managed conservatively with IV hydration and packed red blood cell transfusions.

DISCUSSION: Naphthalene has been well known to cause oxidative stress to red blood cells and cause hemolysis. The degree of hemolysis is greater in people with glucose-6-phosphate dehydrogenase deficiency, which is important to consider in African American patients. The hemolysis tends to resolve once the offending agent is removed. Conservative management with transfusions is recommended. Methemoglobinemia occurs by the oxidation of ferrous (Fe²⁺) to ferric (Fe³⁺) hemoglobin. This causes the hemoglobin to become incapable of carrying oxygen and shifts the oxyhemoglobin curve to the left. If MethHb levels are >20 % treatment with intravenous methylene blue and/or oral ascorbic acid is recommended. The caveat to this being avoidance of intravenous methylene blue if glucose-6-phosphate dehydrogenase deficiency is suspected since methylene blue may cause oxidant stress leading to further hemolysis. Clinicians should have a high index of suspicion for ingestion in elderly patients with dementia presenting with confusion and lethargy. Although the use of naphthalene moth balls has decreased in recent years there are still cases of ingestions leading to hemolytic anemia and methemoglobinemia. It is important to suspect methemoglobinemia in patients with hypoxia detected on pulse oximetry with no signs of respiratory distress. Early recognition may be life saving for the patient.

MYCOTIC ANEURYSM RUPTURE ASSOCIATED WITH ENTEROCOCAL ENDOCARDITIS Melissa Lyle¹; Christopher Akre¹; Jae Yoon Park¹; Peter C. Spittel². ¹Mayo Clinic, Rochester, MN; ²Mayo Clinic, Rochester, MN. (*Tracking ID #1927596*)

LEARNING OBJECTIVE 1: Using diagnostic criteria to recognize a mycotic aneurysm in patients with infective endocarditis

LEARNING OBJECTIVE 2: Understanding the importance of early detection of mycotic aneurysms

CASE: A 33-year-old male with history of intravenous drug abuse and chronic hepatitis C presented to an outside hospital with fatigue, anorexia, myalgias, and general malaise. Blood cultures indicated enterococcal bacteremia, and he was subsequently transferred to our institution. He had mitral valve enterococcal endocarditis 2 years prior, which resulted in severe mitral regurgitation. He underwent mitral valve annuloplasty with neochordae placement. He experienced an episode of MSSA endocarditis 1 year afterwards. On admission, physical examination was notable for a grade 2/6 apical systolic murmur and splinter hemorrhages on his fingernails. Transesophageal echocardiogram demonstrated severe mitral valve regurgitation with new masses on the P2 scallop and an estimated ejection fraction of 60–65 %. He was initiated on a 6 week course of IV Penicillin G and Gentamicin for treatment of enterococcal mitral valve endocarditis. Cardiovascular surgery recommended mitral valve replacement following completion of the antibiotics. On hospital day ten, he developed a progressive unilateral headache. At onset, he had no focal neurologic findings, but suddenly became unresponsive 20 min later. Examination revealed a fixed and dilated right pupil and no spontaneous movements. He was urgently intubated, and a head CT scan illustrated a large right intracerebral intraparenchymal hemorrhage measuring 6.4×6.9×5 cm with intraventricular extension into the frontal and posterior horns of the right lateral ventricle, and herniation with a 2 cm midline shift. Emergent neurosurgical evacuation was performed. After evacuation, he remained comatose with extensor posturing and showed no improvement over the next 3 weeks. He was subsequently dismissed to a long-term care facility.

DISCUSSION: Intracranial mycotic aneurysms are relatively rare, accounting for only 10 % of neurologic complications associated with infective endocarditis. Aneurysmal degeneration of an arterial wall can result from bacteremia or septic embolization. Septic emboli from infective endocarditis have a predilection for the distal branches of the middle cerebral artery. The emboli can lead to inflammatory changes of the adventitia and can destroy the intima, ultimately resulting in aneurysmal formation. Diagnostic criteria assist in determining if an intracranial mycotic aneurysm is definite, probable, or possible. Mandatory criteria include demonstration of intracranial aneurysm by neuroimaging, and supportive criteria include a recent history of a predisposing infection, particularly infective endocarditis, any angiographic features, or age less than 45 years. Early detection of mycotic aneurysms with either magnetic resonance angiography or computed tomography can prove vital in regards to early aggressive treatment with antibiotics and surgery to possibly prevent rupture. Clinicians must keep in mind mycotic aneurysm formation in patients with infective endocarditis, particularly in those who develop new neurologic symptoms.

NATURAL KILLER/T-CELL LYMPHOMA: A CANCER THAT HIDES IN PLAIN SIGHT Nayiri Gharibian; Jeffrey Miller. University of California, Los Angeles Olive View Medical Center, Sylmar, CA. (Tracking ID #1934890)

LEARNING OBJECTIVE 1: Recognize the unique clinical features associated with natural killer/T-cell lymphoma

LEARNING OBJECTIVE 2: Diagnose natural killer/T-cell lymphoma in the setting of challenging pathologic and radiographic findings

CASE: A 33-year-old female without significant PMhx was evaluated in Ophthalmology clinic for 1 month history of "dacryocystitis with nasolacrimal duct obstruction of left eye" after a cooking injury. She was started on antibiotics and had an I&D 1 month later given no improvement. After failing conservative management, her antibiotics were broadened and she underwent a left dacryocystorhinostomy (DCR) with stent placement. She returned to the ED twice after DCR with persistent facial pain and swelling. Four months after initial presentation, she was referred to ENT clinic with complaints of a new ulcer on the roof of her mouth. Biopsies were obtained and sent for culture. Several days later, CT imaging showed a "hypodense rim-enhancing collection" of the anterior septum most consistent with an abscess. Meanwhile, biopsy pathology returned showing "extensively inflamed and partially necrotic tissue with bacterial colonization." She was then referred to ID clinic and placed on different antibiotics. On-going documentation notes "an unusual infection in a patient with no medical history." Eight months after initial presentation, new biopsies demonstrated atypical T-cells consistent with NKTCL. Repeat imaging showed "significant progression of facial lymphoma" with extension of the mass to the entire upper lip and left buccal space. Staging CT showed mild splenomegaly but was otherwise unremarkable. Chemo and radiation therapy were started. In the following months, the patient had multiple hospitalizations for issues related to her lymphoma and developed progressive pulmonary involvement by her NKTCL. Four months after diagnosis, she was admitted with sepsis. CT chest showed worsened adenopathy, parenchymal abnormalities and bilateral pleural effusions. Given such rapid progression of her disease and poor prognosis, she was placed on comfort care measures and died 4 days later.

DISCUSSION: Natural killer/T-cell lymphomas (NKTCL) are aggressive malignancies occurring worldwide, with a strong predilection for Asian and South American populations. They are usually extra-nodal with initial sites involving the naso/oropharynx. Compared with other lymphomas, NKTCL portends a much higher mortality rate. This case highlights the challenges in diagnosing NKTCL, and the vigilance needed when faced with an "unusual infection" of the naso/oropharynx. Physicians should specifically consider NKTCL when confronted with a mass or ulceration of the naso/oropharyngeal space. Retrospectively, this patient's hard palate ulcer was characteristic of NKTCL invasion of the nasal cavity floor which was not recognized. On radiographic imaging, NKTCL can easily be mistaken for an infection or abscess. In addition, biopsies often only reveal necrotic tissue. The treating physician should alert the pathologist of the consideration of NKTCL and surgeons should take care to adequately sample soft tissue adjacent to necrotic tissue. If initial biopsy results are inconclusive but clinical suspicion remains high, repeat biopsies should be pursued. As demonstrated in this case, timely diagnosis of NKTCL is typically elusive though essential. There is no surgical cure. Standard therapies include chemotherapy and radiation, however, clinical outcomes for most patients remain poor. Complete response to primary treatment is reported in about half of all patients. Studies estimate that 5-year overall survival for NKTCL is 42 %. Still, Stage I (limited) disease can be cured, but stage IV (more invasive) disease is much less likely to be cured.

NAUSEA, VOMITING AND DIARRHEA: COMMON SYMPTOMS WITH AN UNCOMMON ETIOLOGY Arvind Kalyan Sundaram^{1,2}; Julie Grimes^{1,2}; Saira Samani^{1,2}; Christopher Roy^{1,2}. ¹Mount Auburn Hospital, Cambridge, MA; ²Harvard Medical School, Boston, MA. (Tracking ID #1939208)

LEARNING OBJECTIVE 1: To recognize the signs and symptoms of Ciguatera poisoning.

LEARNING OBJECTIVE 2: To emphasize the importance of detailed history taking to overcome the anchoring heuristics while treating patients.

CASE: A healthy 34-year-old female presented to the emergency department after two episodes of syncope in a week's time. The patient had returned from Haiti a day before where a few days ago, she had developed nausea, vomiting, diarrhea along with generalized pruritus. At Haiti she was given intravenous fluids and anti-histamines. Upon arrival to the US, her symptoms persisted. She experienced two syncopal events, leading her to seek medical attention. While in the emergency department she developed excruciating right leg pain. On review of symptoms, she reported reversal of hot/cold sensation in her hands, as well as generalized weakness.

She was asked whether she had any exotic fish while on her trip at Haiti, which she replied to positively for red snappers. The patient's cardiovascular and neurological examination was within normal limits. However, she was positive for orthostatic hypotension. Her complete blood count, basic metabolic profile, and electrocardiogram were unremarkable. Beta-HCG was negative. The patient was admitted on a telemetry floor to watch for bradycardia. It was decided to withhold Mannitol administration. Neurology recommended Gabapentin for the patient's right leg pain that was thought to be neuropathic, and Duloxetine for the increased generalized weakness experienced by the patient. Despite aggressive fluid resuscitation, she continued to have orthostatic hypotension. She was then started on Fludrocortisone, following which her symptoms improved. Ondansetron and Diphenhydramine were continued for nausea and pruritus respectively. She improved and was discharged after being counseled on avoiding fish, alcohol, caffeine and nuts for 6 months.

DISCUSSION: Ciguatera poisoning is a food borne disease commonly noticed in the tropical and subtropical regions, accounting for 20 % of the fish related food borne diseases in the US. Nausea, vomiting, diarrhea, tingling, numbness, temperature relate dyesthesia, orthostatic hypotension are some of the presentations of Ciguatera poisoning. There are no clinical tests to diagnose Ciguatera poisoning. Gastrointestinal symptoms usually resolve earlier while neurological symptoms take longer time. Treatment is largely symptomatic. Use of Mannitol is controversial. Some trials have advocated for its use within the first 48 h, while another randomized control trial showed no benefit with Mannitol versus Normal saline administration. The case illustrates the importance of obtaining a complete history and the danger of anchoring heuristics. Presenting with symptoms of gastrointestinal upset has a broad differential. However, obtaining a careful history provided a diagnosis that tied in the entire patient's presenting features, and most importantly counseled on prevention, as recurrent symptoms could be worse than the initial illness. This would have otherwise been a lost opportunity.

NECROLYTIC ERYTHEMA ASSOCIATED WITH HEPATITIS C Priyanka Yaramada¹; Shannon Miller²; Huy Au^{2,1}. ¹University of California, Riverside, Riverside, CA; ²Riverside County Regional Medical Center, Moreno Valley, CA. (Tracking ID #1923606)

LEARNING OBJECTIVE 1: A good clinical examination is necessary for evaluation of diseases. This case is to remind physicians to recognize a pathognomonic rash for the diagnosis of an indolent but common disease. In this case, a good skin examination led us to diagnose a dangerous but treatable systemic disease that has been progressing undiagnosed and untreated for several years.

LEARNING OBJECTIVE 2: Awareness of necrolytic acral erythema is important not only for accurate dermatologic diagnosis but also because of the potential for earlier diagnosis and treatment of hepatitis C infection. The appearance is similar to psoriasis or lichen planus and is often misdiagnosed as these alternate conditions.

CASE: A 42 y/o Hispanic female with a history of IV drug abuse and dermatitis since 2005 with recurrent episodes of cellulitis presented to the hospital with severe edema, erythema and pain of the right lower extremity for 3 days. She had been treated with topical steroids and steroid injections intermittently for her dermatitis since 2005. She denied Hepatitis C stating she was last tested in 2003. She was found to have cracked demarcated and pigmented skin lesions with extensive scaling on the dorsal aspect of both feet from the toes extending across the dorsum of the foot, advancing 4 cm up the anterior portion of the bilateral lower extremities. The lesions were also noted on the dorsal aspect of both hands from just below the nail beds to the wrist. There was fluid drainage from the lesions on her feet. A CT scan of the legs showed soft tissue inflammation. Labs revealed elevated INR (1.6), PTT (43), bilirubin (2.4) and low albumin (1.4). Abdominal CT was unremarkable. A hepatitis panel was positive for hepatitis C virus with the 1a genotype. A punch biopsy of one of the lesions showed mild hyperkeratosis, minimal acanthosis and slight psoriasiform hyperplasia with mild superficial dermal chronic inflammation with post-inflammatory hyperpigmentation. She was diagnosed with Necrolytic acral erythema (NAE). Her cellulitis improved with IV antibiotics (vancomycin and zosyn) and zinc supplementation. She was discharged to follow up with Dermatology and Hepatology.

DISCUSSION: Necrolytic acral erythema (NAE) is a rare condition, first described in 1996. It is a cutaneous manifestation of hepatitis C viral infection (considered an early cutaneous marker of hepatitis C) with onset typically between 35 and 55 years old. It is described as a well-defined, pruritic or burning, hyperkeratotic erythematous eruption that most often affects the acral surfaces. The pathogenesis of NAE is thought to be related to zinc dysregulation, which can occur as a result of hepatitis C induced metabolic alteration. Histopathologically, it closely resembles psoriasis. Treatment for NAE is to treat the underlying hepatitis C infection. Oral zinc replacement has also been successful in some cases.

NEISSERIA SICCA ENDOCARDITIS PRESENTING AS MULTIPLE EMBOLIC BRAIN INFARCTS Jorge L. Salinas; Kobina Wilmot; Christine L. Kirlew; Mark Mulligan. Emory University School of Medicine, Atlanta, GA. (*Tracking ID #1938692*)

LEARNING OBJECTIVE 1: Learn about the typical presentation of *Neisseria sicca* endocarditis

LEARNING OBJECTIVE 2: Learn how to appropriately treat *Neisseria sicca* endocarditis

CASE: The patient was a 58 year-old man with a history of HIV infection (CD4 191/22 %; viral load <20 copies/cm³ on antiretroviral therapy), ischemic cardiomyopathy, and a myxomatous mitral valve status post mitral valve replacement in 2006 who presented with a 14-day history of worsening encephalopathy. He had become progressively more aggressive, forgetful, and disoriented and was lethargic and somnolent on the day of admission. On presentation, the patient had a temperature of 37.8°, was tachycardic, and had a blood pressure of 105/66. Physical exam revealed a Glasgow comma scale of 14 and a muffled valvular click and 3/6 systolic murmur heard best at the apex. He did not have splinter hemorrhages, conjunctival petechiae, Osler nodes, nor Janeway lesions. White blood cell count was 15,000 (85 % neutrophils) and INR 5.54. Of note, the patient was on coumadin due to presence of St. Jude's mechanical mitral valve. A non-contrast computer tomography of the brain revealed a left frontal hemorrhage (Figure 1) as well as a right temporal and right cerebellar hemorrhage, scattered subarachnoid hemorrhages, and an intraventricular hemorrhage with rightward midline shift. The patient was admitted to the neurological intensive care unit (ICU). Anticoagulation was discontinued and fresh frozen plasma and prothrombin complex concentrate were administered to reverse prolonged INR. The initial gram stain from blood cultures indicated presence of gram positive cocci, but the organism was later determined to be a gram negative diplococcus that was identified as *Neisseria sicca*. Transesophageal echocardiography performed on day 3 of admission revealed mild mitral regurgitation and two small vegetations. CT surgery evaluated the patient and opted not to perform surgery due to preserved mitral valve functionality and concern for further intracranial hemorrhage in the setting of heparin administration during surgery. The patient was initially started on vancomycin, rifampin, gentamicin, and ceftriaxone. Blood cultures cleared within in 3 days. Antibiotic coverage was narrowed to ceftriaxone after final sensitivities (MIC 0.25) were determined. After a 9 day Neurological ICU stay and stability on multiple head computed tomography (CT) scans, his mental status had improved significantly. He was discharged to subacute rehab after 30 days of inpatient care and received ceftriaxone for a total of 12 weeks. Anticoagulation was held for the duration of antibiotic treatment due to risk of recurrent intracranial hemorrhage.

DISCUSSION: *Neisseria sicca* is a gram negative diplococcus (Figure 2) found commonly in the upper respiratory tract [1]. It is typically a commensal organism. To our knowledge, there only 21 reports of *Neisseria sicca* endocarditis in the existent literature. Immunosuppression and the presence of an artificial valve were two risk factors which predisposed our patient to infection with the organism [1–17]. Other risk factors include poor dentition and intravenous drug abuse [1–17]. *N. Sicca* grows easily on blood culture. The organism is usually susceptible to beta-lactams [1, 2, 12, 15, 16] but obtaining sensitivities is highly recommended. In the literature, >90 % of cases present with embolic events [16], and the brain is involved in at least 65 % of cases. Due to the high rates of embolism early surgery may be an important consideration in patients with *Neisseria sicca* endocarditis. Current endocarditis guidelines recommend surgery in cases of prior embolism and large remaining vegetation [18]. However, it may be reasonable to argue for early surgery in patients with *Neisseria sicca* endocarditis even in the absence of prior embolism due to the high rates of embolism associated with the organism. In this case, the patient had already experienced embolic events but the remaining vegetations were small. The patient also had significant risk of bleed if heparin were administered during surgery. Surgery was, therefore, not performed. Conclusion *Neisseria sicca* is a rare cause of endocarditis which is highly prone to embolic events.

NEVER TRUST THE GOLD STANDARD: A DIFFICULT DIAGNOSIS OF IGA DOMINANT ACUTE POST-STAPHYLOCOCCAL GLOMERULONEPHRITIS Vikram Balakumar; Jodie Bryk. University of Pittsburgh, Pittsburgh, PA. (*Tracking ID #1940173*)

LEARNING OBJECTIVE 1: Integrate history, physical examination, laboratories and biopsies into the diagnosis of glomerulonephritis (GN) sub-types

LEARNING OBJECTIVE 2: Recognize IgA Dominant Acute Post-staphylococcal Glomerulonephritis (APSGN) as an emerging etiology of GN.

CASE: A 76 year old male with hypertension, diabetes mellitus II, and bilateral Charcot's foot deformity presented with oliguria, cola-colored urine, and anasarca following completion of therapy for a non-healing methicillin-resistant staph aureus (MRSA) left toe ulcer status-post 2 months of amoxicillin, 1 week of trimethoprim-sulfamethoxazole and recovery course complicated by osteomyelitis for which he underwent left toe amputation and treatment with parenteral daptomycin. Upon admission, the patient was found to have BUN of 140 mg/dL and Cr of 5.2 mg/dL (baseline of 1.0 mg/dL 3 months prior to admission). An initial urinalysis revealed 3+ protein, positive urine eosinophils, gross hematuria, and urine protein/creatinine ratio of 12 mg/g. Urine microscopy was positive for dysmorphic red blood cells. His presentation was felt to be consistent with a diagnosis of glomerulonephritis (GN). The differential included ANCA-vasculitis associated GN, anti-GBM GN, and immune complex GN. ANCA and anti-GBM laboratories returned non-elevated. He was found to have decreased C3 with normal C4. Given the decreased C3 and history of MRSA infection, APSGN was felt to be the most likely etiology of GN. A renal biopsy was performed for definitive diagnosis and showed pauci-immune cellular crescents with no immune complex deposits on immunofluorescence. Hence, it was concluded that an ANCA-associated GN was the more likely diagnosis and APSGN less likely despite our clinical suspicions. During his hospital course, the patient developed worsening anasarca and renal failure, requiring the initiation of hemodialysis. Empiric initiation of plasmapheresis with cyclophosphamide was recommended for management of ANCA-associated GN. Although the biopsy results were considered the gold standard to diagnose GN, clinical suspicion for APSGN prompted a repeat biopsy. The repeat biopsy revealed proliferative glomerulonephritis with presence of IgA and C3 deposits consistent with a diagnosis of IgA dominant APSGN, as history and laboratories predicted. After the second biopsy, plasmapheresis and cyclophosphamide were not started. The patient showed marginal improvement in his renal function without medical intervention, but remained oliguric and ultimately was discharged on long-term intermittent hemodialysis.

DISCUSSION: Although renal biopsy is considered the gold standard in the diagnosis of etiology of GN, this case demonstrates the importance of the history and supplemental laboratories in interpretation of even supposedly definitive data. The importance of making a diagnosis based upon all available data in this case cannot be overemphasized, as the treatment would have been a cytotoxic medication and plasmapheresis, an intervention not without harm. Earliest cases of MRSA related APSGN were reported in 1995 in Japan. Given the global increase in incidence of MRSA, it is likely that the incidence APSGN will increase as well. IgA dominant acute post-staphylococcal glomerulonephritis (APSGN) is more common amongst the elderly following staphylococcal skin infections developing up to 16 weeks after the initial infection. Overall, the prognosis of APSGN is poor; existing data suggest that an important predictor in renal recovery in APSGN is the absence of chronic renal parenchymal changes. Although there have been no systematic evaluations of treatment options, there is currently no available evidence to support corticosteroids in addition to appropriate anti-staphylococcal therapy.

NEW ONSET HYPOGLYCEMIA IN A PATIENT WITH SEVERE DIARRHEA: EVALUATING THE CAUSES Rebecca Koransky; Manuela Calvo. Montefiore Medical Center, Bronx, NY. (*Tracking ID #1939272*)

LEARNING OBJECTIVE 1: Identify the most common causes of new onset hypoglycemia and prioritize an appropriate work up.

LEARNING OBJECTIVE 2: Identify some less common causes of hypoglycemia.

CASE: A 33 year-old man with AIDS presented with 1 week of watery diarrhea. Home medications included anti-retrovirals and Bactrim. The patient reported having 8–9 bowel movements a day, a 15 lb weight loss over 1 week and abdominal pain worsened by food. Vital signs were significant for hypotension and fever. On exam, abdomen was diffusely tender but non-distended, with no guarding or rebound tenderness. Laboratory data was significant for potassium of 2.4 meq/L, chloride of 116 meq/L, CO₂ of 12 meq/L and glucose of 75 mg/dL. An infectious work-up of the diarrhea was done, and patient was found to have positive cryptosporidium Ag in his stool, for which he was treated with aggressive electrolyte replacement, anti-diarrheal agents and anti-retroviral therapy. On day 2 of hospitalization the patient reported that he was feeling dizzy and weak with palpitations and diaphoresis, glucose level was found to be 20 mg/dL. Patient was given D50 IV injections, but hypoglycemia did not significantly improve, and he was then started on a D10 drip at 125 cm³/h. Glucose levels did not tolerate any decrease in the rate of the drip and patient continued to be symptomatic from the low blood glucose. He had never had similar episodes of hypoglycemia in the past, and liver function was normal. Insulin, C peptide, and cortisol levels drawn with each hypoglycemic episode were unrevealing. ACTH stimulation test was performed, and results demonstrated appropriate adrenal response. Bactrim was held as potential cause of hypoglycemia and replaced with

Atovoquone, with no improvement in hypoglycemic episodes. After 1 week of supportive treatment, diarrhea slowly began to improve and patient began to eat his meals. With this improvement in diarrhea, symptomatic episodes of hypoglycemia decreased, glucose levels remained stable and patient was weaned from D10 drip. On the day of discharge 3 weeks later, abdominal pain had resolved, patient was having only one to two bowel movements a day, and glucose levels were normal without any supplementation.

DISCUSSION: Severe infectious diarrhea is often seen in immunocompromised patients. As seen in this patient, severe diarrhea in the setting of malnourishment can lead to symptomatic hypoglycemia. Common causes of hypoglycemia include medications, sepsis, renal insufficiency, cortisol deficiency, and nonislet cell tumors. In this patient, differential diagnoses should also include bactrim-induced hypoglycemia and decreased production of endogenous glucose. The standard of care for hypoglycemia work up includes close review of medications and medical history and laboratory testing of glucose, insulin, C-peptide, beta-hydroxybutyrate, pro-insulin, sulfonylurea and meglitinide during hypoglycemic episode. ACTH stimulation test can be performed to rule out adrenal insufficiency. If endogenous insulin production is found from laboratory values, radiologic studies can be performed. Once these common causes of hypoglycemia have been ruled out, as they were in this patient, other less common causes of hypoglycemia should be considered. Bactrim has been shown to cause hypoglycemia, and was initially considered as a cause in our patient. Medication was stopped and replaced with Atovoquone but hypoglycemia did not resolve. In children, there have been studies of hypoglycemia during episodes of severe diarrhea, with failure of gluconeogenesis found to be most common cause of hypoglycemia. Other case reports have shown hypoglycemia in patients with severe diarrhea correlated with low glycogen stores. We believe this impaired gluconeogenesis in the setting of severe diarrhea and malnourishment to be the cause of the patient's hypoglycemia. It is important for clinicians to recognize this process in patients with severe diarrhea in order to maintain good nutritional intake even with diarrhea and to prevent symptomatic and dangerous episodes of hypoglycemia.

NEWFOUND ASSOCIATION OF ERYTHEMA NODOSUM WITH RARE SCALP DISEASE Karl Kirschke; Robby Singh; Diane L. Levine. Wayne State University School of Medicine, Detroit, MI. (*Tracking ID #1938659*)

LEARNING OBJECTIVE 1: Recognize the clinical features of dissecting cellulitis of the scalp

LEARNING OBJECTIVE 2: Assess the current treatment modalities for dissecting cellulitis of the scalp

CASE: A 23-year-old male with a past medical history of dissecting cellulitis of the scalp (DCS) presented to the Emergency Department with a 1 month history of bilateral leg desquamation with hyperpigmentation and tenderness and chronic scalp lesions. The patient was diagnosed with DCS 1 year ago. He had a complicated course and was treated with multiple medications including doxycycline, clindamycin, TMP-sulfa, isotretinoin, intralesional corticosteroids and an incision and drainage; all with minor improvement. One month ago, the patient developed painful bruises on his legs and was diagnosed with erythema nodosum (EN). Shortly, thereafter he began to have well demarcated desquamation over his legs as well as increased tenderness. On admission, he was afebrile. Exam of the scalp revealed diffuse weeping lesions with crusting and moderate diffuse alopecia. Multiple 1–2 cm tender erythematous nodules were present over both shins with significant desquamation of the overlying skin. The remainder of the exam was normal. He was treated with vancomycin, fluconazole and terbinafine for suspected refractory cellulitis. Cultures were taken from his legs and scalp, which were negative. The leg biopsy showed spongiosis with features of cellulitis and abscess formation. Chest radiographs and urinalysis were negative. CRP and ESR were elevated. HIV, GC and RPR were all negative. ANA was positive with a titer of 1:320 and a speckled pattern. Anti-dsDNA antibody was negative. Over the course of the hospital stay, his pain improved, and the desquamation and hyperpigmentation began to resolve. However, the DCS showed little to no improvement during the course of his stay. He was discharged 1 week after admission with a diagnosis of dissecting cellulitis of the scalp with cellulitis NOS of the legs and given TMP-sulfa for 3 weeks and terbinafine for a total of 6 weeks. One week later, his leg swelling and desquamation had improved and his scalp showed mild improvement. Etiology of leg involvement was suspected to be autoimmune in nature though medication related EN could not be ruled out.

DISCUSSION: DCS is a rare chronic inflammatory disease affecting the hair follicles of the scalp. It begins with multiple painful nodules forming abscesses on the scalp and often progresses to disfiguring scarring alopecia. It most commonly affects African American males between 20 and 40 years of age. The etiology remains unknown but is thought to represent a follicular occlusion disorder. While many treatments have been attempted, few have yielded promising long-term results. There

are no large trials for DCS but many treatments have been tried in small series. Rifampicin and isotretinoin have yielded positive results in treating DCS but are often found to be unsuccessful in severe disease. In these instances, adalimumab and IV infliximab have had success in decreasing discharge, inflammation and pain. Laser therapy has also been effective in the treatment of DCS leading to reduced reliance on systemic treatments. Surgical approaches including skin grafting have been successful in the most refractory cases of DCS. Koshelev et. al. recently reported the first case of DCS with associated pyoderma gangrenosum lesions but there have not been any DCS cases associated with EN. We believe this is the first report of dissecting cellulitis of the scalp with concurrent EN. However, we must also allow for the possibility that the multitude of antibiotics our patient received over the last 6 months, specifically sulfa antibiotics, may have caused EN. While a rare disease, DCS has a characteristic course which if recognized early can be treated more effectively using the alternative modalities discussed here.

NIFEDIPINE INDUCED GINGIVAL HYPERPLASIA Roshni Naik; Alan Tso. Beth Israel Medical Center, New York, NY. (*Tracking ID #1939130*)

LEARNING OBJECTIVE 1: Recognize the risk of gingival hyperplasia with nifedipine use.

LEARNING OBJECTIVE 2: Review the management of nifedipine induced gingival growth.

CASE: A 68 year old male with history of hemorrhagic stroke and hypertension on nifedipine was seen for complaint of gum swelling for the past year. The patient started taking nifedipine at the time of his stroke 1 year prior. His medication list included nifedipine 60 mg daily, losartan 25 mg daily and aspirin 81 mg daily. Patient was not on any antiepileptic drugs. The patient saw the dentist over the past year with reports of poor oral hygiene. There was improvement in gum swelling after one dental hygiene cleaning visit. Oral cavity examination revealed gingival growth in between teeth in anterior maxilla teeth and anterior mandibular teeth with multiple posterior molar cavities. The patient was seeking alternative blood pressure medication as his symptoms started since his stroke. Nifedipine was stopped because of the known side effect of gingival hyperplasia. The patient was seen 11 days later and was reporting decreased symptoms of gum growth.

DISCUSSION: We present a case in which a patient developed gum swelling with nifedipine use. Gum hyperplasia can be very distressing as it can result in difficulties in mastication and speaking as well as troublesome breath odor. The mechanism of gingival hyperplasia is thought to be a result of metabolic byproducts from the medication or alterations in calcium metabolism. Initially there is an enlargement of interdental papillae of the gingiva that develop into a lobulated mass or nodule. The gingiva can extend over the teeth and crowns. Trials have shown that the prevalence of nifedipine induced gum hyperplasia ranges from 0.5 to 83 %. Gum overgrowth is generally seen within 1 to 9 months of starting nifedipine. Factors that increase risk of gum hyperplasia include young age, dosage of nifedipine, and poor oral hygiene. Younger patients are at higher risk because they have higher fibroblast metabolism and hormonal changes. Also, increasing dosages of nifedipine may result in increased risk of gum growth. Doses of 30 mg/day to 100 mg/day have been shown to result in gum growth. Patients with poor oral hygiene with high plaque index also are at greater risk of gum hypertrophy. Treatment generally consists of meticulous hygienic dental cleaning and plaque control. In addition, reduction of nifedipine dose or discontinuation of drug is advised. Regression can occur after 1 week of stopping the medication, and complete regression can happen within 15 days. Gingival growth may recur if nifedipine is resumed. Also, switching to another calcium channel blocker may not result in resolution of gum growth as gingival hyperplasia has been associated with other calcium channel blockers in both dihydropyridines (i.e. felodipine, nitrendipine, amlodipine) and nondihydropyridines (i.e. diltiazem and verapamil). In severe cases, gingival resection may be needed, but nifedipine must be stopped as gum growth generally recurs if nifedipine is resumed.

NITROUS OXIDE ABUSE LEADING TO HYPERHOMOCYSTEINEMIA AND PULMONARY EMBOLI Eiran A. Warner¹; Yamin Shwe²; Leonard Amoruso¹; Erica Grabscheid¹. ¹Beth Israel Medical Center, New York, NY; ²Beth Israel Medical Center, New York, NY. (*Tracking ID #1939770*)

LEARNING OBJECTIVE 1: Understanding The Complications Of Nitrous Oxide Abuse

LEARNING OBJECTIVE 2: Understanding The Complications of Vitamin B12 Deficiency

CASE: A 23 year old Caucasian man was admitted to the hospital with a 5 day history of progressively worsening paresthesias and numbness of the feet which

spread to his legs, arms and hands. The patient admitted to nitrous oxide (whippets) abuse over the previous 6 months. PMH included migraines, anxiety, bipolar disorder and heroin abuse. There was no history of alcohol abuse, vegetarianism or pancreatic/small bowel/gastric disease. On physical exam neurological abnormalities included: proximal weakness in the lower limbs, diffuse hyporeflexia, bilateral impairment of vibration and positional sense at the toes, a wide-based stance and truncal ataxia. Labs: Vitamin B12 303 pg/mL (normal 211–911), folate 12.9 ng/mL (normal 4.1–22.0), homocysteine 83.7 μ mol/L (normal 5–15), methylmalonic acid 6144 nmol/L (normal 87–318) and Hgb 11.4 g/dL (normal 13.5–17.5) with an MCV of 104.8 fL (normal 80–100). MRI of the c-spine showed T2 signal hyperintensity within the bilateral posterior columns, extending from the cervicomедullary junction to mid C5. The patient began treatment with Vitamin B12 1000 mcg IM daily. After 1 week of treatment, Vitamin B12 was changed to weekly dosing. Prophylactic sq heparin 5000 units three times daily was also started on the day of admission. Five days after admission pt developed fevers, shortness of breath and pleuritic chest pain. CT angiogram showed bilateral pulmonary emboli. No DVT's noted on US. Pt was started on Lovenox 1 mg/kg q12 h with a bridge to warfarin. At time of discharge 2 weeks after admission, his neurological deficits were resolving.

DISCUSSION: Nitrous oxide (N2O), because of its euphoric effects, is often a drug of abuse—especially among young adults. Nitrous oxide is generally administered as ‘whippets’, small canisters that contain a pressurized form of the gas (similar to whipped cream aerosol containers). One of N2O’s harmful effects is its ability to cause Vitamin B12 (cobalamin) deficiency by oxidizing Cob (I) alamin to Cob (III) alamin. B12 deficiency can lead to ineffective erythropoiesis (and ultimately megaloblastic anemia) as well as demyelination of the brain and spinal cord. A consequence of Vitamin B12 deficiency is elevated homocysteine levels. Hyperhomocysteinemia causes an increased risk for thrombosis and atherogenesis. This risk likely explains why the patient, despite thrombo-embolic prophylaxis, developed bilateral pulmonary emboli. Nitrous oxide use leads to Vitamin B12 deficiency which begets hyperhomocysteinemia, a risk factor for thrombi. Due to the high prevalence of nitrous oxide abuse in young adults, it is important to screen for B12 deficiency in any individual presenting with unexplained neurologic abnormalities or thrombosis in this age group. To the best of our knowledge, there have been no other case reports of symptomatic pulmonary emboli in the context of Vitamin B12 deficiency secondary to nitrous oxide abuse.

NO BULGING DISK Patrick Quinlan; Ronald Herb. Reading Hospital, Wyomissing, PA. (*Tracking ID #1933080*)

LEARNING OBJECTIVE 1: Consider Neuralgic Amyotrophy in the differential of unilateral arm pain and weakness

LEARNING OBJECTIVE 2: Recognize the classic presentation and diagnostic workup for Neuralgic Amyotrophy

CASE: A 56yo M with a remote past medical history of radiculopathy secondary to a bulging disk at C6 presented as an outpatient for evaluation of numbness on the tips of the first and second digits and severe, “knife-like” neck pain. His pain was constant when lying down. He also noted numbness on the posterior aspect of the ipsilateral forearm. The patient stated that he had similar symptoms in the contralateral arm about 10 years prior when he was diagnosed with cervical radiculopathy. At that time, he was successfully treated with a course of oral prednisone and physical therapy. On exam, he was noted to have decreased range of motion of the left upper extremity with weakness with arm flexion, wrist extension and hand grip. Decreased sensation to light touch was also appreciated. The patient was referred to neurosurgery, and an MRI of the spine was performed which revealed no significant cord compression or bulging disk. Upon follow up, the patient had no improvement of his symptoms and had developed “obvious atrophy of the left bicep”. EMG was performed and was notable for findings consistent with Neuralgic Amyotrophy. With two - seven day courses of oral prednisone the patient had relief of his neck pain but only had minimal improvement of his neurologic symptoms. He did have pertussis 7 months earlier which may have been an autoimmune trigger leading the his Neuralgic Amyotrophy.

DISCUSSION: Neuralgic Amyotrophy, also called Parsonage-Turner syndrome, idiopathic brachial plexopathy, brachial plexus neuropathy, acute brachial radiculitis, and paralytic brachial neuritis is an inflammatory disorder of the brachial plexus classically presenting with pain, sensory abnormalities, and eventual paresis. The pathophysiology is assumed to be autoimmune in origin, but the precise mechanism is unknown. The differential diagnosis may include cervical radiculopathy, peripheral nervous system vasculitis, or pancoast tumor. Imaging studies may be warranted to rule out these other possible etiologies as was done in this case. It is also important to obtain accurate history to rule out any potential preceding brachial plexus trauma (accidents, surgery, radiation). When no cause is apparent, and the onset of symptoms is rapid and painful, Neuralgic Amyotrophy is the most likely diagnosis. EMG will confirm the diagnosis. Those patients treated with corticosteroids early in their disease course have earlier recovery from their paresis. In summary, recognize Neuralgic Amyotrophy as a possible cause of neck and arm pain followed by paresis and sensory deficits.

NO MONOPOLY ON MONO: A CURIOUS CASE OF AVIRAL SYNDROME

Chelsea Bowman¹; Marion Stanley¹; Harry Lampiris^{2,1}; Meg Pearson^{2,1}. ¹University of California, San Francisco, San Francisco, CA; ²Veterans Affairs Medical Center, San Francisco, CA. (*Tracking ID #1928138*)

LEARNING OBJECTIVE 1: Assess for acute Ebstein Barr virus (EBV) infection with a negative heterophile antibody

LEARNING OBJECTIVE 2: Recognize diagnostic considerations in heterophile-negative mononucleosis syndromes

CASE: 32-year-old healthy man presents with 2 weeks of malaise and diffuse myalgias after returning from a bachelor party. He also noted low-grade fevers and mild diffuse arthralgias. He denied sore throat, nasal congestion, cough, abdominal pain, dysuria and penile discharge. He is monogamous with his wife. Exposure history was significant for ticks and fresh water swimming near his home in Northern California. He had no exposures to farm animals, household pets, international travel, or mushroom ingestion. His exam showed a clear oral pharynx, no lymphadenopathy or rash, and liver edge was palpable 3 cm below costal margin. Initial labs were significant for a mild transaminitis with AST of 43 U/L and ALT of 56 U/L. Other labs revealed prior hepatitis B infection, negative HIV antibody, and a negative monospot (heterophile antibody). One week after initial presentation, persistent symptoms and development of right upper quadrant pain resulted in repeat evaluation which was significant for a white blood cell count of 6 K/cmm with lymphocytosis (54 % lymphs), mild anemia and thrombocytopenia (hemoglobin of 12.5 g/dl, platelets of 124 K/cmm), and acute hepatitis without evidence of liver failure (AST of 255 U/L, ALT of 416 U/L, total bilirubin of 0.8 mg/dl, alkaline phosphatase of 54 U/L and INR of 1.2). Further work up included negative Hepatitis C RNA, Hepatitis B core antibody IgM, RPR, EBV viral capsid antigen IgM, and HIV PCR. Both EBV viral capsid antigen IgG and EBV nuclear antigen IgG were positive consistent with prior EBV infection. Abdominal ultrasound revealed mild hepatosplenomegaly (both liver and spleen measured 18 cm). Cytomegalovirus (CMV) antibody IgM and IgG returned positive at 2.1 and 3.95 respectively (Normal <0.9). The patient’s symptoms were treated with supportive care. Transaminases downtrended to AST of 89 U/L and ALT of 177 U/L, and symptoms resolved by week 6 of illness.

DISCUSSION: General internists commonly evaluate patients with infectious syndromes likely due to viral pathogens. Our patient’s constellation of symptoms and lab findings, including subacute fevers, malaise, fatigue, diffuse myalgias, lymphocytosis, transaminitis and splenomegaly, were strongly suggestive of infectious mononucleosis. EBV is the primary etiology of infectious mononucleosis with around 80 % of patients having a positive monospot. A negative monospot can occur in acute EBV within the first 2 weeks of symptom onset. As our suspicion for EBV remained high and the monospot was negative, additional testing with EBV specific antibodies was taken as the next diagnostic step. The presence of EBV nuclear antigen IgG within the first 4 weeks of symptom onset excludes acute EBV as a diagnostic consideration. CMV is the most common etiology of EBV-negative mononucleosis. Primary CMV infection presents as symptomatic in less than 10 % of immunocompetent patients. CMV is less likely than EBV to have features such as lymphadenopathy, splenomegaly and exudative tonsillopharyngitis but is more likely to present with significant transaminitis, typically affecting ALT more than AST. Secondary syphilis and acute toxoplasmosis are important bacterial and protozoal causes of acute mononucleosis-like illness, respectively. Patients presenting with symptoms compatible with a mononucleosis syndrome should have an evaluation for EBV with a monospot and, if negative, EBV-specific antibodies. If testing for EBV is unrevealing, CMV, secondary syphilis and acute HIV infection should be highly considered in the differential diagnosis.

NON-ALCOHOLIC BEER: A UNIQUE CASE OF ACUTE ALCOHOLIC HEPATITIS Ankita Tandon¹; Neal Fitzpatrick¹; Karen Krok². ¹Penn State University Hershey Medical Center, Hershey, PA; ²Penn State University Hershey Medical Center, Hershey, PA. (*Tracking ID #1934352*)

LEARNING OBJECTIVE 1: Recognize that patients who are to abstain from alcohol should also abstain from non-alcoholic beer.

CASE: Acute alcoholic hepatitis (AAH) can develop in patients with chronic alcohol abuse or recent heavy intake. Patients who go untreated with severe acute alcoholic hepatitis (defined as Maddrey discriminant function (DF) >32) have mortality rates as high as 25–35 % within 1 month. Patients substitute non-alcoholic beer (NAB) for alcohol-containing beer, however, NAB is a misnomer as it also contains alcohol. Most brands contain 0.5–1 % alcohol by volume (ABV) compared to regular beer that contains approximately 4 % ABV. We describe a patient with severe AAH after drinking NAB. Sixty-nine-year-old woman presents with worsening abdominal pain

and fullness, confusion and jaundice for the past week. She has a history of alcohol abuse but stopped drinking alcohol 3 years ago because she developed AAH. Since then she has been consuming 7–8 NABs per day and denies any other alcohol consumption (corroborated by her supportive family). Physical exam revealed icteric sclera, jaundiced skin and 3+ pitting edema. Labs revealed a creatinine of 4.1 mg/dL, ALT of 33u/L, AST of 107u/L, total bilirubin of 23.6 mg/dL, albumin of 2.6 g/dL, platelet count of 208 and INR of 1.8. CMV IgM, HSV IgM, hepatitis A, B, C serologies and EBV PCR were all negative. ASMA, ANA and AMA were also negative. Abdominal MRI without contrast did not show signs of liver cirrhosis, splenomegaly or varices, however, it did show ascites and a fatty liver. Within 4 days, her liver function worsened and she had a DF of 39. Given her anuric acute renal failure, she was started on pentoxifylline, prednisone and treated with octreotide, midodrine and albumin for hepatorenal syndrome. Ultimately she required a week of hemodialysis. Subsequently, her total bilirubin started trending down and eventually her kidney function improved as well. Two weeks later, the patient was back to her baseline at which point her creatinine was 0.8 mg/dL, INR was 1.3 and total bilirubin was 6.4 mg/dL. Given her MELD score of 39, she was evaluated for a liver transplant. She underwent extensive psychosocial evaluation of her alcohol consumption by a transplant psychiatrist, social worker, and transplant hepatologist. These specialists all agreed that she was honest about her consumption of only NAB. Ultimately no transplant was required as her liver function continued to improve.

DISCUSSION: The patient was drinking eight NABs everyday for 3 years. With 0.5–1 % ABV per NAB, her total alcohol consumption per day exceeded the amount consumed from one regular beer. The 2010 dietary guidelines for alcohol consumption recommend drinking no more than 1 drink per day for women. If not treated appropriately, AAH carries a high morbidity and mortality. AAH in association with low alcohol content beer has previously not been described in the literature. Patients with cirrhosis, on medications that should be avoided with alcohol, or with chronic liver disease are advised not to drink alcohol. These patients may gravitate towards NAB without realizing these drinks still contain alcohol. It is imperative to educate physicians and patients about the existence of alcohol in NAB. The amount of NAB that patients can consume remains unclear, and it is our recommendations that they avoid all NAB.

NON-ARTICULAR FELTY'S SYNDROME: AN UNCOMMON DIAGNOSIS

Tarun Jain; Chetan Mittal; Bernard R. Rubin. Henry Ford Hospital, Detroit, MI.
(Tracking ID #1936228)

LEARNING OBJECTIVE 1: Appropriately rule out alternate causes of neutropenia with splenomegaly.

LEARNING OBJECTIVE 2: Recognize an uncommon presentation of Felty's syndrome

CASE: 73 year old caucasian female with past medical history of chronic kidney disease, essential hypertension, ischemic cardiomyopathy status post implantable cardioverter defibrillator and ventricular tachycardia on amiodarone. She was found to have leukopenia (1800 cells/ μ l) and neutropenia (700 cells/ μ l) on routine blood work which persisted despite discontinuation of amiodarone. Review of systems was negative for morning stiffness, joint pains, swelling, oral or anal ulcers, rash and family history of rheumatological diseases. Physical examination was unremarkable except for splenomegaly. There was no obvious synovitis or limited range of motion in any joint. Imaging confirmed splenomegaly (18 cm) but was otherwise unremarkable. She subsequently underwent bone marrow biopsy and multiple peripheral smears which were negative for alternate causes of neutropenia. Autoimmune work-up revealed negative direct antiglobulin test, anti-nuclear antibody, C-3, C4, c-ANCA, p-ANCA and monoclonal protein evaluation. However, rheumatoid factor (RF) 180 IU/ml, cyclic citrullinated peptide (CCP) 35 IU/ml and erythrocyte sedimentation rate 65 mm/h were significantly elevated. X-ray of the hands revealed diffuse osteopenia but no joint erosions. Ultrasound of hands was performed. Final diagnosis of Non-articular Felty's Syndrome (FS) was proposed and she was started on daily prednisone 20 mg with subsequent improvement in leukocyte (4100 cells/ μ l) and neutrophil (1700/ μ l) count gradually. It is now planned to start her on Azathioprine.

DISCUSSION: FS is characterized by neutropenia and splenomegaly in patients with seropositive (RF+, anti-CCP+) rheumatoid arthritis (RA). As a result of neutropenia, affected patients are increasingly susceptible to certain infections like *Staphylococcus aureus*, *Pseudomonas aeruginosa*, *Escherichia coli*, herpes and fungi. Differential diagnoses in our case vignette include myeloproliferative syndromes, amyloidosis, systemic lupus erythematosus, large granular lymphocyte syndrome, tuberculosis, HIV infection, sarcoidosis and cirrhosis; all of which were ruled out by appropriate

testing. The articular disease in FS is usually severe in terms of both erosions and deformity. In some affected individuals, FS may develop during a period when the symptoms and physical findings associated with RA have subsided or are not present. In such scenario, it may remain undiagnosed. Manifestations of FS without clinical but only with laboratory features of rheumatoid arthritis are extremely rare. We present a case of severe neutropenia and mild splenomegaly in a patient with high titers of RF and anti-CCP with no signs of synovitis. The current vignette highlights the importance of recognizing Non-articular FS without much delay to initiate appropriate management.

NON-KETOTIC HYPERGLYCEMIC CHOREA

Mahmoud Abdelghany; Andrea Fritz; Samuel Massoud. Conemaugh Memorial Medical Center, Temple University, Johnstown, PA. (Tracking ID #1923595)

LEARNING OBJECTIVE 1: Non-ketotic hyperglycemic chorea might be the first presentation of hyperglycemia, or it might be secondary to poorly controlled DM.

LEARNING OBJECTIVE 2: Non-ketotic hyperglycemic chorea is a benign disorder that could completely reversible if diagnosed early and treatment properly.

CASE: A 34-year-old white male presented to our hospital complaining of flailing-like movements of the right side of the body, polyuria, polydipsia and 20 lb weight loss in 1 month. He denied any other symptoms or history of drug abuse. The past history was significant for type II DM for which he was on insulin therapy but had not been taking it for a year because of financial problems. Laboratory investigations were only significant for fasting blood sugar of 230 mg/dl, with no anion gap, and glycated hemoglobin (HbA1c) of 13.6 %. CT scan of the head did not show any abnormalities. MRI of the brain showed high T2-weighted signal in the both putamina of the basal ganglia, with low T1-weighted signal in the left putamen. Physical exam showed mild hypotonia on the right side but no weakness. The patient was started on insulin and clonazepam. After 3 days; the patient's abnormal movements markedly decreased. Two weeks later, the abnormal movements disappeared completely. The patient refused to have a repeat MRI of the brain after 6 months, but he continued to be completely asymptomatic.

DISCUSSION: NKH chorea is a rare disorder with unclear etiology. The prevalence in the Asian females increases the possibilities of genetic or environmental predisposing factors. Cerebral vascular insufficiency, petechial hemorrhage, hyperviscosity, depletion of both gamma-aminobutyric acid and acetylcholine secondary to metabolic changes have been suggested as possible mechanisms of the NKH chorea. Infection could be a trigger factor. NKH chorea might be the first presentation of hyperglycemia, or it might be secondary to poorly controlled DM. Rapid correction of hyperglycemia might cause NKH chorea. Typically in patients with NKH chorea, there is high T1- and low T2-weighted signal in the contralateral putamen and high density on CT of the brain. Absence of putamen abnormalities on the MRI or the CT of the brain was previously reported. Here, we report a case with high T2-weighted and low T1-weighted signals in the contralateral basal ganglion. A follow up brain MRI after 6 months usually shows disappearance of the initial findings. The prognosis of NKH chorea is good. It depends on early diagnosis and proper management of the blood glucose. Additionally, typical neuroleptic drugs and benzodiazepines are helpful in controlling choreic movements. DM should be highly suspected in older patients with newly diagnosed chorea.

NON-OCCCLUSIVE MESENTERIC ISCHEMIA IN A PATIENT WITH NO CARDIOVASCULAR DISEASE

Takeomi Nakamura; Christine Kwan. Teine Keijinkai Hospital, Sapporo, Japan. (Tracking ID #1934046)

LEARNING OBJECTIVE 1: Recognize that patients with no cardiovascular (CV) disease may still have non-occlusive mesenteric ischemia (NOMI)

LEARNING OBJECTIVE 2: Recognize that type 1 diabetes mellitus (DM-I) may be associated with NOMI

CASE: A 49 year-old Asian man presents with sudden onset, witnessed syncope and fall from a standing position. He loses consciousness for several seconds with spontaneous recovery and no residual confusion. Soon after, he has diaphoresis, fatigue, and watery diarrhea $\times 3$. He reports eating oysters 24 h ago, but no other gastrointestinal/CV/ neurological symptoms, pre-syncope, tunnel vision, or recent travel. Besides his DM-I, he has constipation and takes insulin, senna, and telmisartan. He smokes 1.5 packs/day and drinks 1 beer/day for 29 years but uses no recreational drugs. Family history is unremarkable. Physical examination shows temperature = 37.5C, pulse = 90, blood pressure = 50/38, respiratory rate = 20, and O2 saturation >95 % room air. He generally appears in no acute distress; alert/oriented $\times 3$. CV, abdominal, and neurological exams demonstrate no abnormalities, as does the rest of the exam. Laboratory testing, including complete blood counts, chemistry, and arterial blood gas, is normal except for BUN=37.4 mg/dL, creatinine=2.72 mg/dL, glucose=174 mg/dL, HbA1c=7.6 %, creatine

kinase=210 IU/L, lactate=34 mg/dL (3.3–14.9), pH=7.23, HCO₃=13 mmHg, pO₂=78 mmHg, and PCO₂=33 mmHg. Electrocardiogram reveals no abnormalities. Several hours later, he starts shivering with diffuse abdominal pain, so given a presumptive diagnosis of acute gastroenteritis, he is administered IV fluids, scopolamine, and pentazocine with continuation of his symptoms in addition to development of hematochezia, decreased urine output, and abdomen's becoming flat, hard, and diffusely tender with peritoneal signs and decreased bowel sounds. Non-contrasted computed tomography shows pneumonosis cystoids intestinalis and gas in the portal vein consistent with mesenteric ischemia and colonic necrosis. He thus undergoes enterostomy without any complications. After the operation, he clinically improves. Pathology confirms the above diagnosis of NOMI.

DISCUSSION: NOMI occurs when either the small/large intestine undergoes partial- or full-thickness necrosis in the absence of an overt organic vascular occlusion. It starts with non-specific symptoms of mild abdominal pain that gradually progresses although abdominal pain is absent in up to 25 % of patients. Abdominal exam may initially, therefore, be normal or reveal only mild abdominal distension or fecal occult blood. Typical risk factors for NOMI include medications, such as vasoconstrictors (digoxin, dopamine, or norepinephrine) and diuretics, dialysis, severe CV disease, dehydration, or cardiopulmonary bypass. In the above case, however, the patient has none of the above risk factors except for dehydration. Instead, he has a long history of DM-I, which may have contributed to some arteriosclerosis around the NOMI lesion. It and the diarrhea may also have contributed to his dehydration. One case report has shown acute inferior mesenteric arterial occlusive disease associated with diabetic ketoacidosis although no other cases have specifically reported an association between DM-I and NOMI. One should recognize, therefore, that NOMI may still occur in patients with DM-I and without known CV disease.

NON-UREMIC CALCIPHYLAXIS IN PATIENT WITH PROGRESSIVE ISCHEMIC ACRAL LESIONS Gladys Rodriguez; Robert L. Fogerty. Yale School of Medicine, New Haven, CT. (*Tracking ID #1940115*)

LEARNING OBJECTIVE 1: Diagnosing non-uremic calciphylaxis in patients with acral lesions.

LEARNING OBJECTIVE 2: Review management of non-uremic calciphylaxis.
CASE: A 47-year-old gentleman with a PMH of diabetes, hypertension, and chronic renal insufficiency presented to our hospital with progressive, ischemic acral lesions. He had an episode of acute kidney injury 2 months prior to presentation where he was noticed to have hypercalcemia to 14 with normal PTH. Around that time he had noted cracks in his fingers that subsequently progressed to blackened tissue. He was empirically started on prednisone and underwent a renal biopsy consistent with diabetic nephropathy. He was discharged on a prednisone taper and had stable lesions. Two months later he presented with progression of necrosis of his fingertips and wet gangrene on his right foot. He underwent ray resection of his second to fourth digits of the right foot and was restarted on steroids and empiric antibiotics, and transferred to our hospital. On physical exam he had multiple black necrotic lesions on his fingers and toes. On genital exam, he had a necrotic lesion on the glans of his penis with fibrinous material present around the corona. Labs showed WBC of 11, Hct 21.3, plt of 111, INR 2.3, BUN 43, Cr of 2.5. LFT's showed elevated alkaline phosphatase of 143 and GGT of 210. LDH, Vit D, intact PTH, PTH-RP, ACE level, and alpha-1 antitrypsin levels were all normal. His haptoglobin was elevated at 341. SPEP and cryoglobulins were negative. He had a positive phospholipid neutralization test, and his dilute Russell viper venom test was elevated at 1.35. Urine CTX was positive at over 1000 suggesting high bone turnover. On imaging he had a CT abdomen that showed para-aortic adenopathy and splenomegaly. Chest CT was consistent with multiple unchanged pulmonary nodules bilaterally. Upper angiogram showed widespread vascular calcifications. Dermato-pathology showed right medial calf consistent with calciphylaxis. Left upper lobe bronchial alveolar lavage and FNA of lymph nodes were negative for malignant cells. Bone marrow aspirate was not indicative of leukemia or lymphoma. A mediastinoscopy with lymph node biopsy showed markedly hyalinized lymph nodes with bland necrosis, focal calcification, and scattered small non-caseating granulomas consistent with sarcoidosis. Surgically he underwent several bilateral digit amputations and right foot MTA for wet gangrene. He was started on sodium thiosulfate and trialed on bisphosphonates with a notable drop in both calcium and phosphate. Because of the response to therapy, sodium thiosulfate was discontinued and he was started on a steroid taper again with a plan to discontinue as outpatient.

DISCUSSION: This case is of interest to General Internists and Nephrologists due to the severe morbidity and high cost ramifications of this diagnosis. Calciphylaxis is a well-described entity in patients with end-stage kidney disease and renal transplant. Sodium thiosulfate has been used in patients with uremic calciphylaxis undergoing dialysis. However, non-uremic calciphylaxis (NUC) is well less characterized. Patients with NUC usually have a normal or low values of calcium, phosphate and

PTH. NUC is associated with high mortality with no known specific effective treatment. Thus, calciphylaxis should be considered while evaluating skin lesions in patients even in the absence of end-stage kidney disease and renal transplantation.

NONTUBERCULOSIS MYCOBACTERIAL INFECTION IN AN IMMUNOCOMPETENT HOST WITH UNDERLYING LUNG DISEASE Emily H. Miller¹; Geeta Laud². ¹Albert Einstein College of Medicine, Bronx, NY; ²Montefiore Medical Center at Albert Einstein College of Medicine, Bronx, NY. (*Tracking ID #1938672*)

LEARNING OBJECTIVE 1: Recognize mycobacterium avium-intracellulare as an important pathogen in immunocompetent elderly men with chronic pulmonary disease

CASE: An 83 year-old former smoker with COPD on home oxygen, recently hospitalized and treated for community-acquired pneumonia presented with ongoing symptoms of dizziness, dyspnea and failure to thrive culminating in syncope. He revealed generalized weakness, subjective fevers, and an unintentional weight loss of 20 lb over 2 months with a cough productive of white sputum without hemoptysis. The patient was a cachectic elderly white male with clubbed digits, crackles and dullness to percussion in the left lower lung fields. A chest CT showed dense consolidation and nodular opacities of the left lower and upper lobes without appreciable improvement from his previous admission. The patient was suspected to have chronic aspiration pneumonia and was treated with antibiotics for both aspiration and nosocomial pneumonia, given his recent hospitalization. He improved with this treatment regimen, but further workup was pursued given the indolent nature of his symptoms. Sputum cultures were positive for rare acid-fast bacilli by fluorochrome stain as well as mycobacterium avium-intracellulare (MAI) by DNA probe. He tested negative for HIV. The patient was started on MAI therapy and was discharged home with close follow-up in the pulmonary clinic. Eventually, his sputum cultures grew MAI. He improved significantly on this treatment, reporting increased exercise tolerance and weight gain.

DISCUSSION: MAI is perhaps best known as an opportunistic infection in the immunocompromised host. However, nontuberculosis mycobacterial infections can present in immunocompetent patients, and should be considered in the differential diagnosis of indolent nonresolving pneumonia. The exact number of MAI infections in the United States is not known, because reporting of the disease is not mandatory. Current data suggests that the rate of nontuberculosis mycobacterial pulmonary infection is 47/100,000 in people over the age of 65 in the U.S., and is thought to be on the rise. It is thought that about 2/3 of sputum samples which test positive for mycobacterium contain nontuberculosis mycobacterium, while only 1/3 are M. tuberculosis, suggesting that MAI may be a more common infection than previously thought. Pulmonary MAI often presents in middle age or elderly immunocompetent white men who have pre-existing lung disease, such as COPD. Common symptoms include fever, weight loss, and fatigue and these patients are often treated for recurrent lung infections with little resolution of their symptoms. The underlying lung disease present in these patients can make diagnosis of MAI very challenging. CT findings such as lung nodules in a tree-and-bud pattern are suggestive of MAI in a patient with the previously described symptoms. The gold standard for diagnosis is sputum culture, but a DNA probe for MAI can also be useful in diagnosis as cultures take weeks to result. Indications for the treatment of MAI include clinical symptoms consistent with the disease, radiographic findings and isolation of MAI from multiple sputum samples. Treatment of MAI requires a lengthy multi-drug regimen, consisting of a macrolide (azithromycin or clarithromycin), rifampin and ethambutol taken three times a week. This regimen should be continued until sputum cultures are persistently negative for MAI for at least 1 year. Close follow-up during this treatment course is important to monitor for medication side effects and clinical improvement. This patient had a significant improvement in his symptoms and quality of life with MAI treatment, highlighting the importance of including atypical organisms in the differential diagnosis for male smokers with chronic or unresolving symptoms such as persistent cough or weight loss.

NORMOLIPEMIC XANTHOMAS; A RARE CUTANEOUS FINDING LEADING TO DIAGNOSIS OF MULTIPLE MYELOMA Devin B. Malik; Sourabh Aggarwal. Western Michigan University School of Medicine, Kalamazoo, MI. (*Tracking ID #1939102*)

LEARNING OBJECTIVE 1: Recognize that the presence of xanthomas, especially when a patient is normolipemic, may represent an underlying systemic disease such as malignancy and may warrant further investigation.

CASE: We describe a 66 years old gentleman with a history of cutaneous lupus well controlled by topical steroid cream, who presented to primary care office for a new rash of 3 months duration. The patient denied any pruritus or pain from the rash. He denied any fever, sick contacts or recent travel. There was no personal or familial

history of hyperlipidemia or xanthoma. Exam revealed flat, yellowish plaques in bilateral axillae as well as inguinal fold without any adenopathy, xanthelasma palpebrarum, or tendon involvement. Laboratory investigation revealed total cholesterol of 172 mg/dL, triglycerides of 37 mg/dL, HDL of 70 mg/dL and LDL of 95 mg/dL. Complete blood count, complete metabolic profile including kidney function test, liver function test and thyroid profile were normal. Erythrocyte sedimentation rate was elevated at 63 mm/h. C reactive protein, complement level and cryoglobulins were unremarkable. A punch biopsy of the skin lesion revealed mononuclear cell infiltrate with numerous foamy histiocytic cells consistent with xanthoma. Further testing with immunofixation demonstrated an IgG monoclonal protein with lambda light chains. Patient was referred to oncology where a bone marrow biopsy showed 20 % plasma cells with no signs of end organ damage present, therefore a diagnosis smouldering multiple myeloma was made.

DISCUSSION: DPNX is a very rare entity and presents as a yellowish maculo-papular lesion symmetrically found in flexural folds of skin. It is usually associated with hematological disorders, mainly leukemias and paraproteinemias and rarely can be first sign of an underlying malignancy. The novelty that surrounds the diagnosis is the absence of hyperlipidemia. It is postulated that there is an interaction between paraproteins and lipoproteins which are cleared by macrophages to form complexes and deposit in the skin. The monoclonal antibody interacts with LDL forming an abnormal Ig-LDL complex that is scavenged by macrophages and are deposited in skin, causing xanthomas. Macrophages are believed to have predilection for abnormal LDL complex as opposed to normal LDL allowing the latter to be degraded as per the usual metabolic pathway resulting in normal lipid profile in these patients. Therefore, in a patient with xanthomas and normal lipids, a serum protein electrophoresis should be done to exclude an underlying myeloma, with close monitoring for overt disease manifestations such as renal failure, and bone lesions. This case demonstrates the importance of investigating xanthomas in the absence of hyperlipidemia, as it can often be the first manifestation of hematological disease, therefore physicians should be aware this entity.

NOT ENOUGH OF A GOOD THING Devika Nair; Deepa Bhatnagar. Tulane University Health Sciences Center, New Orleans, LA. (*Tracking ID #1924913*)

LEARNING OBJECTIVE 1: Recognize pericardial effusions as a complication of renal failure

LEARNING OBJECTIVE 2: Distinguish uremic pericarditis from dialysis-associated pericarditis

CASE: A 63-year-old woman with end-stage renal disease due to long-standing hypertension presented with dyspnea and pleuritic chest pain that had been present for weeks. She denied fevers, cough, recent surgeries or recent hospitalizations. Outside records indicated that many of her dialysis sessions had been terminated prematurely due to fatigue. Vital signs revealed a temperature of 98 F, pulse of 89 beats/min, blood pressure of 153/68, mm Hg and oxygen saturations of 94 % on 2 l nasal cannula. She had a pericardial friction rub, and pulmonary examination revealed no abnormalities. Laboratory studies were significant for a BUN of 30 mg/dL and a creatinine of 4 mg/dL. An electrocardiogram showed normal sinus rhythm, but an echocardiogram revealed a 2.4 cm pericardial effusion. The patient underwent daily hemodialysis sessions for 1 week without a change in her symptoms. It was thus determined that she was suffering from dialysis-associated pericarditis. After she received a pericardial window, her symptoms resolved.

DISCUSSION: Internists must be aware of cardiovascular complications seen in patients with end-stage renal disease. Two such complications are uremic pericarditis and dialysis-associated pericarditis. In both cases, the pathophysiology appears to be related to the accumulation of nitrogen residues and chemical irritants in the pericardial space. However, it is important to distinguish between the two, as management differs significantly. Uremic pericarditis occurs when the visceral and parietal membranes of the pericardium are inflamed. Such patients usually present with an acute rise in BUN, with values being greater than 60 mg/dL. Unlike the diffuse ST elevations seen in pericarditis from other causes, uremic pericarditis shows a normal ECG. This is because uremic pericarditis is a result of fibrin and uremic toxin deposition into the pericardium, rather than acute inflammation. There is less epicardial electric injury in uremic pericarditis, resulting in less noticeable ECG changes. Our patient was likely suffering from dialysis-associated pericarditis, which occurs over a more extended period of time. This should be suspected in end-stage renal patients who present with a BUN that is not significantly elevated despite multiple missed dialysis sessions. Unlike patients with uremic pericarditis, these patients often do not respond to extended hemodialysis sessions. The underlying pathophysiology is less understood, but the phenomenon may be due to increased fibrosis and adhesions of the pericardial fluid necessitating surgical intervention for adequate fluid removal. Any patient with renal failure who presents with a pericardial effusion should be monitored with serial echocardiograms to assess for resolution with dialysis. If the effusion does not resolve after 7 to 10 days of daily

dialysis, current practice suggests the patient be treated for dialysis-associated pericarditis with pericardiotomy and window placement. Our case highlights this important, albeit less common, manifestation of pericardial disease in end-stage renal patients.

NOT EVERYTHING THAT LOOKS LIKE IS A CELLULITIS Subodh Pandey; Subhas Saitala; Swagatam Mookherjee; Bhaskara Madhira. SUNY Upstate Medical University, Syracuse, NY. (*Tracking ID #1939141*)

LEARNING OBJECTIVE 1: Differentiate cellulitis from vasculitic rash

LEARNING OBJECTIVE 2: Recognize unusual presentation of adult onset Henoch-Schonlein purpura (HSP) and importance of immunofluorescence study

CASE: A 43 year-old man with no medical history, presented with a 2 month history of worsening bilateral lower extremity rash, ulcers and painful swelling. These symptoms started 2 week after taking celecoxib for suspected tendinitis. He had failed outpatient treatment with 1 week of Augmentin given by primary care and with Prednisone 60 mg with rapid taper given by a dermatologist. At the time of ER presentation, he had unbearable neuropathic pain with intense burning and pins and needle sensation and he received a dose of Vancomycin and Zosyn for suspected cellulitis and admitted to our service. On examination he was afebrile, with diffuse palpable purpuric rash on bilateral feet extending up to upper leg, some blisters with serosanguinous discharge and many ulcers with black eschar. Other review of system was completely normal including no eye, oral, lung, abdomen, renal or joint affliction. His lab work revealed normal renal and hepatic function, leukocytosis of 15,000 with normal differential and no signs of infectious source, presumably secondary to steroids. An extensive rheumatologic workup was completely normal and failed to reveal a possible etiology. A skin biopsy was done and immunofluorescence revealed granular deposition of IgA, C3 and fibrin around scattered small dermal vessels pathognomonic for HSP. Patient's pain was adequately controlled and continued on Prednisone at 50 mg. No new skin lesions were noticed in his three-day of hospital stay and he was discharged with rheumatology follow up.

DISCUSSION: With the incidence of skin and soft tissue infection 24.6/1000 person-years, cellulitis is a common anchoring bias for an inflamed rash. The wide array of vasculitides, with its systemic involvement and often-fatal course, should always be in the differential. More than 10 % of patients labeled as having cellulitis do not have it. Because the internists and the hospitalists usually take care of cellulitis, they should be able to differentiate other dermatologic conditions. HSP, also termed as IgA Vasculitis, is a primarily pediatric disease of small vessel with more than 90 % cases in less than 17 years age, with peak in 4–6 years of age. Although a variety of infectious and chemical triggers are recognized, the underlying cause of HSP remains unknown. At presentation in adults, clinical findings included palpable purpura (96 %), arthritis (61 %), and gastrointestinal symptoms (48 %) and renal insufficiency (30 %). In adults, renal involvement tends to be more severe in adults than in children as manifested by a higher frequency of nephrotic syndrome, hypertension, and an elevated serum creatinine. Biopsy commonly shows Leukocytoclastic vasculitis, but the immunofluorescence showing IgA deposition is pathognomonic. We present this case as an unusual presentation in adults without any systemic manifestation. Many a times, the classic purpuric lesions are marred by advanced ulcers and with significant edema and inflammation, commonly misdiagnosed and managed as cellulitis. Leukocytoclastic vasculitis, also known as hypersensitivity vasculitis, is a term used for small vessel vasculitis and not a diagnosis in itself. Other differential are cryoglobulinaemic, urticarial, ANCA-associated vasculitis, as well as vasculopathy and coagulopathy in SLE or in bacteremia/sepsis. Along with formalin specimen a second specimen in Michelle solution should also be sent to detect autoantibody deposition.

NOT JUST A SIMPLE PNEUMONIA Rachel Solomon; Jenny J. Lin. Icahn School of Medicine at Mount Sinai, New York, NY. (*Tracking ID #1935178*)

LEARNING OBJECTIVE 1: Identify unusual causes of pneumonia in immunosuppressed patients

LEARNING OBJECTIVE 2: Recognize symptoms associated with Mycobacterium Avium Complex-related pneumonia

CASE: A 53 year-old woman with history of orthotopic liver transplant 20 years ago for chronic hepatitis B and hepatocellular carcinoma presented to her PCP with a two-week history of nasal congestion and cough. She was an active yoga instructor and had been doing well on minimal immunosuppression with sirolimus. She was afebrile and her clinical exam was normal so robitussin and a steroid nasal spray were prescribed for a likely viral URI. Two weeks later, she returned with persistent symptoms and fevers to 101 F. On exam, her lungs were clear and she was given

Bacitracin for presumed bacterial sinusitis. Two days later, the patient returned because she had persistent fevers. Even though her lungs remained clear, a chest x-ray was performed and revealed a left upper lobe infiltrate. She was started on a 14-day course of levofloxacin for presumed community-acquired pneumonia and her fevers and symptoms resolved. Six weeks later, however, the patient returned with recurrent cough and fatigue. She was afebrile, had a normal oxygen saturation, and her lungs remained clear. Repeat CXR showed a dense rounded opacity in the lingula concerning for possible abscess. A chest CT confirmed the lingular consolidation and showed left upper-lobe and right-sided bronchiectatic changes. She was referred to a pulmonologist and a week later, underwent bronchoscopy and thoracentesis for a new, left-sided pleural effusion. Cultures from the lingular biopsy and lavage grew Methicillin-sensitive *Staphylococcus aureus*. Pleural fluid studies suggested a hemorrhagic effusion. Clinically, the patient appeared well and remained afebrile. But a repeat chest CT revealed new left upper lobe lesions and worsening lingular consolidation with cavitation. The patient was hospitalized with concern for necrotizing Staphylococcal pneumonia. She received 3 days of intravenous ceftriaxone and in light of her clinical stability, was discharged home to complete 4 weeks of Bacitracin. Post-discharge, tissue and fluid cultures from her bronchoscopy grew *Mycobacterium Avium Complex* (MAC).

DISCUSSION: Community-acquired pneumonia (CAP) is common and usually due to common pathogens such as *Streptococcus pneumoniae* or *Haemophilus influenzae*. Atypical pathogens such as *Mycoplasma* or *Legionella* can also cause CAP but often present more subacutely and sometimes with extrapulmonary symptoms (such as diarrhea or headache). In solid-organ transplant patients who are immunosuppressed, unusual or opportunistic infections must also be considered. Both *Staphylococcus* and MAC are less common culprits in the spectrum of pulmonary infections. Necrotizing *Staphylococcus* pneumonia typically affects older adults with underlying comorbidities. It is generally acute in onset and rapid in its progression to septic shock, ARDS, and frequently death despite treatment with appropriate antibiotics. Consistent with our patient's presentation, pathologic MAC generally has a more indolent course with a variable symptom profile including chronic or recurring cough, sputum production, dyspnea, malaise, fatigue, chest pain, and hemoptysis. Notably, fever and weight loss may be absent. Although historically MAC-related illness was rare and generally isolated to middle-aged women ("Lady Windermere"), those with underlying lung disease, and AIDS/HIV patients, non-tubercular mycobacterium has been implicated more frequently in the past two decades in pulmonary disease in both immunocompetent and immunocompromised hosts. While overall numbers remain low and data scarce, the incidence of mycobacterial disease in solid-organ transplant recipients appears to be increasing as well. Of the eight cases reported in liver transplant recipients, two were pulmonary specific and four were disseminated. Non-tubercular mycobacterium pulmonary infections generally arise late in the post-transplant course. Radiography may show predominantly fibrocavitory disease or more nodular/bronchiectatic disease. As in our patient, the latter typically manifests as dense airspace disease localized to the mid- and lower-lung fields accompanied by multifocal bronchiectasis, clustered sub-centimeter nodules, and some cavitation. Our patient improved both clinically and radiographically on single-agent therapy. Her cavitary pneumonia was likely pathologic MAC revealed in the setting of an exacerbating MSSA superinfection. Her (albeit mild) immunosuppression may have protected her from the usual severe inflammatory response to an MSSA driven process. She has initiated treatment for MAC with rifabutin, moxifloxacin and azithromycin. As patients with solid-organ transplants are living longer and more likely to be followed by primary care physicians, clinicians should be aware of unusual presentations and causes of pneumonia, even among those who are minimally immunosuppressed.

NOT JUST ANOTHER DAY AT THE SPA Camille M. Webb; Peter D. Bulova; University of Pittsburgh Medical Center, Pittsburgh, PA. (*Tracking ID #1937540*)

LEARNING OBJECTIVE 1: Recognize that chronic schistosomiasis can remain relatively asymptomatic in the granulomatous form.

LEARNING OBJECTIVE 2: Identify previous travels as an important component of history taking.

CASE: A previously healthy 40-year-old female originally from Brazil presented to the Emergency Department complaining of 3 days of dark tarry stools and one episode of bloody diarrhea, associated with palpitations and lightheadedness. Review of systems was positive for a 14-pound unintentional weight loss over the past 4 months, and was negative for fever, abdominal pain, nausea or vomiting. Travel history was positive for yearly visits to Brazil, including a visit to a local hot springs spa 3 years prior. On presentation, temperature was 37.2, heart rate was 87 and blood pressure was 106/69. Physical exam showed a thin female in no acute distress and was positive only for conjunctival pallor. Rectal exam showed melanocytic heme

positive stool. Laboratory studies revealed hemoglobin of 8.2, white blood cell count of 6.3, platelet count of 255, and albumin of 2.8. The patient was admitted to the medical floor where her hemoglobin continued to drop and she received two units of packed red blood cells and fluid resuscitation. An upper endoscopy showed gastritis without active bleeding. Colonoscopy showed small hemorrhoids with normal rectal and colonic mucosa, no evidence of blood. A biopsy from the terminal ileum revealed granulomas. The patient was discharged home, and the biopsy came back positive for *Schistosoma* organisms. She received praziquantel 40 mg/kg in two separate doses separated by 6 h with no recurrence of gastrointestinal bleed. Her hemoglobin at a follow up office visit was 13.6.

DISCUSSION: *Schistosoma* is a trematode worm responsible for Schistosomiasis (bilharzias), a neglected tropical disease that affects more than 200 million people worldwide. It is endemic in more than 70 countries: throughout most of Africa, as well as Brazil, Venezuela, and the Caribbean, where it causes significant morbidity and mortality. *S. japonicum* and *S. mansoni* are responsible for most GI manifestations worldwide, while *S. haematobium* predominantly causes urinary manifestations. *Schistosoma* eggs are released from human urine or feces into fresh water. They then make their way in the form of mirasidia to snails, their intermediate hosts, mature and are released into fresh water, where they penetrate human skin and reside in mesenteric veins. Schistosomiasis is commonly obtained when swimming in fresh water in endemic areas, and in this case the disease was likely obtained during this patient's visit to hot springs in Brazil. The disease can present in either its acute form (Katayama fever) or chronic form, as in this patient. Gastrointestinal and hepatic manifestations are common and include both upper and lower GI bleeding, polyposis, and microabscess formation, caused by host's immune reaction to parasite eggs. Finding eggs in stool or urine is diagnostic but requires high suspicion for the disease, and treatment is 70 to 90 % effective with praziquantel, 20 mg/kg in two doses taken 6 h apart.

NOT JUST SKIN DEEP: PARANEOPLASTIC PEMPHIGUS DUE TO THYMOMA Josh H. Bukowski; Kaumakaokalan Shimatsu; Paul Aronowitz; University of California Davis, Sacramento, CA. (*Tracking ID #1936741*)

LEARNING OBJECTIVE 1: Understanding initial serologic evaluation of pemphigus

LEARNING OBJECTIVE 2: To learn about causes of paraneoplastic pemphigus
CASE: Pemphigus is a dermatological disorder characterized by acantholysis (loss of intrakeratinocyte adhesion), which leads to intraepithelial blisters in the skin and mucous membranes. Pemphigus is usually idiopathic, but in rare circumstances can be paraneoplastic in origin. When evaluating a patient with blistering skin lesions serologic studies can be useful in helping to narrow the differential diagnosis. Our case illustrates that despite the use of serologic markers, further work up should be pursued to rule out other rare etiologies such as neoplastic processes. A 49 year-old man with a history of diabetes mellitus, herpes simplex keratitis, and methamphetamine abuse presented from dermatology clinic with a two-month history of progressively worsening blistering rash that began on his fingers and hands, and spread to his torso, all extremities, face, oral mucosa, and groin. A skin biopsy was performed and he was begun on corticosteroids for what was believed to be pemphigus vulgaris. He was admitted to the hospital for concurrent management of his steroid-induced hyperglycemia and wound care. Biopsy results revealed intracellular epithelial deposition of IgG and C3 consistent with pemphigus. Though paraneoplastic pemphigus antibody serologies were obtained in an attempt to rule out paraneoplastic pemphigus, these studies came back negative. However, a chest radiograph revealed a retrosternal clear space that computed tomographic (CT) imaging of the chest found to be an anterior mediastinal mass. CT-guided biopsy of the mass revealed spindle cell thymoma. His skin lesions markedly improved with the addition of mycophenolate mofetil and clobetasol to his corticosteroid regimen. He was discharged with follow-up for surgical resection of the thymoma.

DISCUSSION: Pemphigus, is an organ-specific human autoimmune disease that is known to be associated with various tumors, autoimmune disorders and some viral infections. The types of pemphigus are normally characterized by their clinical features and the identification of autoantibodies. These autoantibodies can be used to differentiate between paraneoplastic pemphigus and pemphigus vulgaris. Paraneoplastic pemphigus is characterized by antibodies against desmoplakins or desmosomal antigens in the setting of an identified neoplastic disorder. More than half of these neoplastic disorders are lymphoreticular in origin (thymoma, lymphoma, leukemia), with most remaining cases caused by Castleman disease, Kaposi sarcoma and other sarcomas. The pathophysiology of paraneoplastic pemphigus occurring with thymoma is not well understood but it is believed that damage induced by tumor growth within the thymus diminishes its ability to maintain self-tolerance and allows for development of autoimmune diseases such as pemphigus. This hypothesis is supported by case reports in which regression of bullous dermatoses occurred after resection of the thymoma. Our case illustrates that in the setting of pemphigus, serologic testing alone may not be adequate to rule out underlying malignancy as the etiology for bullous dermatoses and

that further investigation looking for tumors commonly associated with pemphigus is warranted.

NOT YOUR TYPICAL “LUMPY JAW”: A CASE OF ACTINOMYCOSIS OSTEONECROSIS OF THE MANDIBLE Prasanna Durairaj; Mihaela S. Stefan; Armando Paez. Baystate Medical Center/Tufts University School of Medicine, Springfield, MA. (*Tracking ID #1940124*)

LEARNING OBJECTIVE 1: Recognize the role of Actinomyces in osteonecrosis

LEARNING OBJECTIVE 2: Identify the histological features that distinguish Actinomyces related osteonecrosis from bisphosphonate related osteonecrosis (BRONJ) of the jaw

CASE: A 51 year old female consulted her primary care physician (PCP) for persistent 5 months left jaw pain, in the absence of preceding dental procedures. Past medical history includes: severe pulmonary hypertension on chronic oxygen supplementation, type II diabetes mellitus, and osteoporosis on weekly dose of Alendronate since 2007. The PCP diagnosed a dental infection; she was started on oral amoxicillin and also referred to the dentist. When seen by the dentist, she was noted to have trismus and facial swelling; hence, she was immediately referred to an oral maxillofacial surgeon for further assessment. The surgeon performed a sequestrectomy, where a fragment of necrotic bone was isolated from areas of healthy bone and sent for biopsy. Swab of the area was initially consistent with *Streptococcus viridans* and oral Clindamycin was prescribed. Four days later, she was admitted with fever and worsening jaw pain. She was noted to have SIRS criteria and appeared to be in moderate distress. Exam revealed left cervical lymphadenopathy, swelling with palpable lump of the mandible, and trismus. Oral exam did not show any exposed bone. Pathology report of the outpatient bone biopsy revealed extensive osteonecrosis with neutrophilic micro abscesses and bacteria with morphology suggestive of actinomyces. In the hospital, she was started on Penicillin 2 million units IV every 6 h and Alendronate was discontinued. The patient was not considered a surgical candidate for margin or segmental resection given poor vascularity of the region and her oxygen dependence. Penicillin dose was increased to 3 million units IV every 4 h for a 6 week course, to be followed by 6 months of oral antibiotics and possible debridement. Her symptoms improved in 48 h after antibiotics were adjusted and she was discharged home. At 2 week follow-up, she was tolerating the antibiotics well with almost total resolution of her jaw pain.

DISCUSSION: This case suggests that Actinomyces may have a role in the pathogenesis of BRONJ as the bacteria can instigate bone resorption by infecting living osteocytes. Bisphosphonates perpetuate mucosal breakdown by inhibiting keratinocyte life cycle and predispose the bone to entry of Actinomyces which form ‘sulfur granules’ (clumps formed during tissue invasion) at the site of the osteonecrotic bone. Previous reports suggest that 43/45 (93.5 %) patients with mandibular BRONJ were found to have direct association of Actinomyces colonies with bone. Although the estimated incidence of osteonecrosis of the jaw in those taking oral bisphosphonates is less than 1 case/100,000 person-years of exposure, long-term bisphosphonate use has to be periodically reevaluated to avoid this uncommon but serious complication. Additionally, once the presence of Actinomyces is recognized, prompt treatment of the infection is crucial for successful resolution of the symptoms.

ONCOGENIC OSTEOMALACIA: A CHALLENGING DIAGNOSIS Dietlind L. Wahner-Roedler. Mayo Clinic, Rochester, MN. (*Tracking ID #1924460*)

LEARNING OBJECTIVE 1: Recognize the clinical and laboratory features of oncogenic osteomalacia

LEARNING OBJECTIVE 2: Reinforce treatment plan for oncogenic osteomalacia

CASE: A 62 year old male patient presented to our institution in October of 2013 requesting a second opinion regarding the possible diagnosis of tumor induced osteomalacia. The patient was doing well until March 2012 when he developed upper back pain, which was treated with physical therapy. In October 2012 his back pain became progressively worse and he developed rib pain. He was seen by a local orthopedic surgeon where a whole body bone scan identified areas of increased uptake in the ribs raising concern of a possible underlying malignancy. However malignancy evaluation by laboratory testing was unremarkable. A repeat whole body bone scan in March 2013 showed some resolution of his previous lesions but new lesions specifically in the ribs which corresponded to rib fractures. There was further multilevel linear uptake in the vertebral column, most marked in the mid thoracic area, consistent with compression fractures. Increased uptake in the bilateral distal medial femoral condyles and the distal aspects of the tibia bilaterally was felt to be related to stress fractures. Irregular uptake in the upper left sacrum was interpreted as

indicating a healing pelvic insufficiency fracture. Because of multiple bone fractures he had an extensive work up for malignancy including multiple myeloma. His serum protein electrophoresis was normal, alkaline phosphatase was markedly elevated ranging between 257 U/L in October 2012 to 400U/L in 2013. In the spring of 2013 he developed right hearing loss. His local ENT physician identified a growth in the right middle ear. A MRI of the head revealed a destructive enhancing lesion centered in the right jugular foramen with extension into the middle ear. He was further noted to have marked hypophosphatemia (phosphorus 1.8 mg/dL). He underwent a bone biopsy which showed significant osteomalacia. A biopsy of his right ear mass was consistent with a mesenchymal tumor. On presentation to our institution he had marked weakness and was in severe pain. He had difficulties rising from sitting to standing position, weakness with ambulation requiring the use of a cane for support. On physical examination there was no lymphadenopathy or organomegaly. ENT exam revealed some dried blood in the right ear canal and a middle ear mass inferiorly and posteriorly. Laboratory tests were remarkable for a markedly elevated alkaline phosphatase of 658U/L. Phosphate level was normal on Neutra-Phos. His outside bone scans were reviewed as were bone x-rays revealing multiple fractures due to his osteomalacia. Tissue from the right ear mass was obtained and stained for fibroblast growth factor 23 (FGF 23). Pathology was consistent with a non-calcifying phosphaturic mesenchymal tumor, positive for FGF23 expression by chromogenic in situ hybridization. Blood FGF-23 was elevated at 140 RU/ml ($n < 100$ RU/ml). At this point the diagnosis of “oncogenic osteomalacia caused by a phosphaturic mesenchymal tumor of the skull base (oncogenic osteomalacia)” was made. The diagnosis was discussed with the patient and an attempt to remove the underlying tumor was advised. The patient preferred to have this procedure done closer to home and returned to his LMD. During a follow-up conversation in December 2013 the patient stated that the tumor had been completely removed and his phosphorus levels were back to normal without replacement therapy.

DISCUSSION: Osteomalacia, a metabolic disorder of decreased mineralization of mature bone, has many causes including inborn errors of metabolism, insufficient levels of vitamin D or calcium, and even common disorders such as chronic kidney disease. Tumor-induced osteomalacia, also known as oncogenic osteomalacia, although relatively uncommon is an important cause of osteomalacia. This paraneoplastic syndrome, characterized by renal phosphate wasting due to increased urinary phosphate excretion caused by excessive synthesis and secretion of FGF23 by the tumor, is unique in that it can be cured by surgical resection of the tumor. Clinical characteristics include bone pain, pathologic fractures due to osteomalacia, and musculoskeletal weakness. Such vague symptoms often lead to a delayed diagnosis with subsequently delayed medical and surgical treatment as in the case presented. The diagnosis of a phosphaturic mesenchymal tumor (oncogenic osteomalacia) should be considered in any patient who presents with multiple bone fractures and hypophosphatemia. FGF 23 measurement helps to establish the diagnosis. Finding the tumor can be challenging, and may involve total body imaging (MRI); scintigraphy using octreotide or PET/CT. Phosphorus supplementation should be continued until the causative tumor can be removed. Follow up FGF 23 measurements may serve as a biomarker of tumor burden and the efficacy of the therapeutic interventions.

ONE HEART, TWO HEART, RED HEART, GREEN HEART: A CAUSE TO CONSIDER IN A PATIENT WITH UNEXPLAINED HEART FAILURE Diego F. Alcivar Franco^{1,2}; Kristy Deep¹. ¹University of Kentucky Medical Center, Lexington, KY; ²VAMC, Lexington, KY. (*Tracking ID #1940126*)

LEARNING OBJECTIVE 1: Recognize the clues that should lead a physician to consider cardiac amyloidosis as a cause of unexplained heart failure

LEARNING OBJECTIVE 2: Review the pathophysiology, diagnosis, and management of amyloid heart disease

CASE: A 68 year-old male presented with a 2 day history of progressive fatigue, palpitations, dyspnea on exertion, and two syncopal episodes. The syncopal episodes were preceded by lightheadedness, lasted only 1–2 min, and spontaneously resolved. The patient had recently received a diagnosis of heart failure with no known etiology. His medications included metoprolol, digoxin, aspirin, atorvastatin and furosemide. Vital signs showed a pulse of 53, blood pressure of 110/71 mmHg, and normal oxygen saturation. Physical examination revealed clear lung sounds, no murmur, and trace lower extremity edema. The serum creatinine was 1.42 mg/dL and N-terminal proB-Natriuretic peptide was 18,474. Chest radiography showed cardiomegaly. An electrocardiogram demonstrated an atrial rate of 180 with a 3:1 conduction block and a wide QRS. Echocardiogram showed an ejection fraction of 40 %, bi-atrial enlargement, concentric left ventricular hypertrophy with small ventricular cavity. His presentation and imaging were concerning for cardiac amyloidosis. Cardiac catheterization demonstrated non-obstructive coronary artery disease with elevated left and right-sided filling pressures and low cardiac output. Right ventricular

endomyocardial biopsy was performed with Congo red stain positive for amyloid. Genetic testing showed wild-type transthyretin (TTR). The patient was treated with intravenous milrinone. Extensive evaluation for extra-cardiac amyloid deposition was negative. The patient underwent successful cardiac transplantation 3 months after presentation.

DISCUSSION: Cardiac amyloidosis is caused by accumulation of abnormally structured proteins which decrease mechanical compliance and disrupt cardiomyocytes. Three main types of primary amyloid protein can affect the heart: monoclonal light-chain amyloidosis (AL), mutated transthyretin in familial amyloidosis, and wild-type transthyretin. The wild-type TTR, often referred to as senile cardiac amyloidosis, typically presents as localized cardiac disease as in this patient. The severity can vary tremendously with many patients having only patchy amyloid deposits and little burden of disease. Cardiac symptoms are related to conduction abnormalities and restrictive physiology which can manifest as syncope, congestive heart failure, and less likely, pericardial disease. Clinicians should consider cardiac amyloidosis in a patient with unexplained heart failure and an echocardiogram with increased wall thickness and non-dilated left ventricular cavity who has no history of hypertension. Electrocardiographic evidence of heart block or conduction delays and low voltage are additional clues. Definitive diagnosis requires tissue biopsy. Loop diuretics and spironolactone are a mainstay of treatment to control symptoms of volume overload. Beta blockers and digoxin are often not tolerated due to exacerbation of conduction defects. ACE inhibitors are often not tolerated due to hypotension and calcium channel blockers are contraindicated due to their negative inotropic effect. Advanced heart disease may require transplantation. Investigational agents to stabilize the TTR molecule and prevent breakdown product accumulation are in active clinical trials.

ONE MAN'S TOE PAIN Mariam Majd; Ahmed Mohiuddin. Tulane University Health Sciences Center, New Orleans, LA. (*Tracking ID #1926238*)

LEARNING OBJECTIVE 1: Identify the patients at risk for atypical presentations of endocarditis

LEARNING OBJECTIVE 2: Recognize the clinical manifestations of a rare gram positive coccus.

CASE: A 64 year-old man with end stage AIDS presented with 1 day of toe pain. He had a recent urinary tract infection 2 months prior that had been treated with trimethoprim/sulfamethoxazole. On exam, he had a low-grade fever and tachycardia. His left great toe was exquisitely tender with mild warmth and erythema over the toe. Cardiovascular exam revealed a grade 2/6 holosystolic murmur, heard loudest at the base of the heart. While undergoing MRI for further evaluation of the toe pain, the patient became hypotensive. His mental status quickly deteriorated. He developed septic shock and transferred to the ICU. Broad-spectrum antibiotics were begun. Within 24 h, gram stain of peripheral blood showed gram-positive cocci suggestive of streptococcus. His hemodynamic status worsened; despite attempts at resuscitation, he died of worsening sepsis. Autopsy and post-mortem blood cultures demonstrated Aerococcal mitral valve endocarditis and an infectious embolus to the toe. His prior urinary tract infection with Aerococcus Urinae led to hematologic seeding of the mitral valve, an embolus to his toe, and fatal bacteremia.

DISCUSSION: Endocarditis is a problem commonly encountered by the internist. When the bacterial culprit is a rarely identified species, as in this case, the challenge of determining both the diagnosis and proper treatment is difficult. In infectious endocarditis, clinical manifestations are the result of both the direct effects of the nidus on the heart's structure and function as well as end organ ischemia produced from embolic events. Patients do not always present with an array of typical physical exam findings; rather they may have only one or two signs of endocarditis. In addition, immunosuppression clouds the picture further with the variety of opportunistic infections to which they are susceptible. Aerococcus urinae is a rarely reported gram-positive coccus that can appear as pairs, tetrads, or clusters on gram stain. It is absent from the databases of many commercial identification systems and is frequently misidentified as a streptococcus, enterococcus, or staphylococcus, as was the case in our patient. Thus, the organism is thought to be drastically under-reported. Its sister species, *A. Viridans*, is a more common cause of endocarditis, but both organisms are known culprits. Patients at risk for this infection are elderly and institutionalized females, males with prostate disease, and the immunosuppressed. This organism should be considered in patients with these factors and those who are unresponsive to sulfonamide therapy like our patient. Aerococcus is susceptible to a variety of both β -lactam and non β -lactam antibiotics in vitro; despite this susceptibility, the prognosis is poor for elderly patients, especially those suffering from endocarditis. It is important for the physician to consider Aerococcus as a potential pathogen in both endocarditis and urinary infections. With the number of immunosuppressed and elderly patients on the rise, internists should be adept in identifying aerococcal infection and its symptomatology.

ONE OF THESE THINGS IS NOT LIKE THE OTHER Skylar Souyoul; Edmond Fomunung; Michelle M. Guidry. Tulane University Health Sciences Center, New Orleans, LA. (*Tracking ID #1927093*)

LEARNING OBJECTIVE 1: Understand causes of cytopenia in rheumatoid arthritis

LEARNING OBJECTIVE 2: Recognize the adverse effects of methotrexate use
CASE: A 56-year-old woman presented with nausea, vomiting, weakness and fatigue. She was diagnosed with rheumatoid arthritis 6 years prior, and treated with methotrexate. On admission she had tachycardia, pancytopenia, acute kidney injury, elevated liver enzymes, and metabolic acidosis. Splenomegaly was not appreciated on exam. A methotrexate level was <0.02 uM/L. We diagnosed her with methotrexate toxicity and this medication was discontinued as we treated her with bicarbonate to correct the acidosis.

DISCUSSION: Rheumatoid arthritis (RA) is the most common form of chronic inflammatory arthritis. It is a systemic disease of unknown etiology that often results in joint damage and physical disability. Though joint symptoms predominate, RA frequently presents with extra-articular manifestations; hematologic abnormalities are common. Hematological involvement is most often manifested as a normochromic and normocytic anemia. Infrequently, neutropenia is encountered and raises several possibilities. Myelosuppression from methotrexate, Felty Syndrome, and T cell large granular lymphocyte leukemia (T-LGL) are possible diagnoses and share many features. Felty Syndrome is classically associated with the clinical triad of leukopenia, splenomegaly and deforming arthritis. It is seen in approximately 1 % of patients with RA, making it relatively rare. It tends to occur later in the disease process, as opposed to T-LGL which may occur early in the course of RA. T-LGL similarly presents with leukopenia and splenomegaly in the patient with RA, and is characterized by chronic indolent clonal growth of LGL cells. In our patient, the absence of splenomegaly, worsening renal insufficiency and presence of thrombocytopenia reflecting more global bone marrow involvement pointed away from these disorders towards methotrexate toxicity. Methotrexate is a folate antagonist recognized for its versatility in the treatment of a wide spectrum of disorders. It represents the first line among the disease-modifying anti-rheumatic drugs (DMARDs) in the treatment of RA. Myelosuppression and gastrointestinal toxicity are among the most common side effects of methotrexate toxicity. It is important to note that some of these adverse effects have been noted in patients taking therapeutic doses of methotrexate, as was our patient. In our patient, an exacerbating factor was the presence of renal insufficiency. Methotrexate is primarily excreted unchanged by the kidney and as such, should be used with caution in patients with renal impairment.

ONE TOUGH MUDDER Thomas Cascino¹; Kanako McKee²; Jeff Kohlwes².

¹University of California, San Francisco, San Francisco, CA; ²San Francisco Veterans Administration Medical Center, San Francisco, CA. (*Tracking ID #1939524*)

LEARNING OBJECTIVE 1: Recognize primary coccidioidal infection after treatment failure for community acquired pneumonia.

LEARNING OBJECTIVE 2: Awareness of the anchoring heuristic.

CASE: A 31-year-old man presented with 1 day of left-sided pleuritic chest pain. Lungs were clear to auscultation without wheezes, rales, or rhonchi. On chest x-ray the patient had a left lower lung airspace consolidation, and he was given doxycycline for treatment of community-acquired pneumonia (CAP). The patient subsequently developed cough, fevers, and chills despite taking the doxycycline. He returned 1 week later and chest CT revealed a consolidation with a confluent focus in the lingula with scattered groundglass and centrilobular nodules, a small left pleural effusion, left hilar lymphadenopathy, and no pulmonary embolism. The patient was diagnosed with a non-resolving pneumonia and started on levofloxacin. He returned 4 days later with continued pleuritic chest pain, cough, malaise, and night sweats. The patient declined hospital admission citing a personal obligation. He was given one dose of ertapenem with the plan to follow-up the next day. On follow-up, he had multiple painful nodules on the right shin consistent with erythema nodosum. Upon further questioning, he revealed that he had participated in a "Tough Mudder" endurance race near San Diego 1 week prior to symptom onset. He was admitted, started on fluconazole for presumed primary coccidioidal infection, and discharged after a brief hospital stay. Cocci antibody complement fixation was eventually positive with a titer of 1:4 and cocci ELISA was also positive, confirming the diagnosis. The patient was seen in follow-up 1 week after initiation of therapy with much improvement in symptoms.

DISCUSSION: Pleuritic chest pain, cough, and fevers are common problems encountered in outpatient medicine. The presence of an infiltrate on chest x-ray is the gold standard for diagnosis of pneumonia. The decision to treat with antibiotics as an outpatient is based on a multitude of factors including the history, physical exam,

laboratory values, and psychosocial situation. It is important to be aware of the anchoring heuristic, the clinging to an original diagnosis despite evidence to the contrary, when treating common, nonspecific symptoms as an outpatient. One should consider alternative diagnoses when a patient fails to respond to treatment as expected. Primary coccidioidal infection is a common cause of CAP in endemic areas. There is a spectrum of presentations, many of which do not require treatment. In our patient, alternative diagnoses were pursued when the patient failed appropriate therapy for a bacterial pneumonia and developed erythema nodosum. Careful attention to the patient's social, travel, and exposure history revealed clues about exposure to cocci during the outdoor race in an endemic area, which if elicited during a prior visit, may have led to an earlier diagnosis. The consideration of non-bacterial causes of pneumonia coupled with the compelling exposure history enabled a diagnosis of primary coccidioidal infection. The decision to treat was based on symptom severity (debilitating enough to keep patient out of work) and proximity to meeting two treatment criteria (>3 weeks of night sweats and prominent hilar lymphadenopathy). Initiation of therapy with fluconazole resulted in improvement in the patient's symptoms. Coccidiomycosis is a common cause of CAP in endemic areas. Physicians should be mindful of the anchoring heuristic and actively seek out alternative diagnoses when patients do not respond to empiric therapy for a presumed bacterial pneumonia.

OPENING PANDORA'S BOX: AN UNFORTUNATE CASE OF INFIDELITY
Sara Turbow²; Cameron Lambert¹. ¹Emory University, Atlanta, GA; ²Emory University School of Medicine, Atlanta, GA. (Tracking ID #1937404)

LEARNING OBJECTIVE 1: Illustrate the neurologic manifestations of syphilis
LEARNING OBJECTIVE 2: Review the challenges of diagnosing HIV and syphilis co-infection

CASE: A 38 year-old man presented to the hospital complaining of a one-month history of rash. The painful, intensely pruritic rash started on his torso and spread outward until it covered his whole body, including the palms and soles. Two weeks prior to presentation, the patient experienced several days of sore throat, cough, and fever. He also complained of night sweats, headache, fifteen-pound weight loss, pharyngitis and visual disturbances during this time period. The patient had a past medical history of childhood sinus cancer that was treated with surgery. His last HIV test was 6 months prior to admission and was negative. He is sexually active with men and recently left a 6-year relationship after his partner admitted to infidelity. On admission, he was afebrile and normotensive. His physical exam was significant for tonsillar erythema and diffuse and painful lymphadenopathy. An erythematous maculopapular rash extended from the scalp to the feet, including the palms and soles. It was tender to palpation with indistinct borders and was not present on the mucous membranes. Labs were notable for white blood cell count of $11.1 \times 10^3/\text{mm}^3$, alkaline phosphatase 1165 U/L, ALT 110 U/L, AST 86 IU/L, and bilirubin 0.8 $\mu\text{mol}/\text{L}$. Lumbar puncture was performed which revealed 16 nucleated cells in tube 4 (56 % neutrophils) with a normal glucose and protein. RPR was positive with a titer of 1:64. Cerebrospinal fluid (CSF) VDRL was positive with a titer of 1:1. HIV antigen/ antibody screening test as well as Western Blot were positive: HIV viral load was 1.2 million copies/mL and CD4 count was 593. Other CSF studies, including herpes simplex virus and cryptococcal antigen, were negative. The patient was treated with continuous IV penicillin G infusion. He was counseled regarding his new diagnosis of HIV and was started on antiretroviral therapy during this admission. His rash resolved and his neurologic symptoms improved.

DISCUSSION: This case illustrates the challenge of differentiating recent HIV infection from secondary syphilis, as well as the synergistic relationship they have during co-infection. Fifty to ninety percent of patients with HIV have symptoms at presentation. These are usually influenza- or mononucleosis-like syndromes, with fever, rash, myalgias, sore throat, and lymphadenopathy. Less than 20 % of patients present with encephalitis or meningitis (1). Even among those with neurologic signs or symptoms, it is not common for these findings to reflect a concomitant opportunistic central nervous system infection. Syphilis is increasing in incidence, especially in men who have sex with men (MSM). In 2006, 64 % of cases of primary and secondary syphilis reported nationwide were among MSM (2). Active syphilis increases the risk of HIV infection 2- to 5- fold (2). The classic manifestation of neurosyphilis is syphilitic meningomyelitis, characterized by slowly progressive lower extremity weakness and paresthesias. The most common form of neurosyphilis, however, is asymptomatic neurosyphilis; patients who are without neurologic symptoms but have evidence of syphilis infection in their CSF. A third presentation of secondary syphilis, syphilitic meningitis, occurs in 5 % of patients, usually within the first 12 months of infection and is associated with a variety of neurologic manifestations (3). The similarities between secondary syphilis and recent HIV infection can pose diagnostic challenges for clinicians. As mentioned above, HIV can

cause many of the same symptoms as secondary syphilis such as rash, lymphadenopathy, and headache. Laboratory tests may also not be revealing, as both HIV and syphilis can cause changes in CSF studies and co-infection can lead to precipitous increases in viral load as well as rapid decreases in CD4 counts (3, 4). It is essential to understand the presentations of recent HIV infection and syphilis, whether isolated or during co-infection, to avoid missing either diagnosis. References 1. OPHTHALMOPLEGIA AND HYPOPITUITARISM AS THE INITIAL MANIFESTATION OF METASTATIC SMALL CELL CANCER Elliot Rhee; Rena Pollack. Montefiore Medical Center, Bronx, NY. (Tracking ID #1940180)

LEARNING OBJECTIVE 1: Recognize the clinical features of metastatic cancer to the pituitary

CASE: A 53 year-old man presented with 3 days of inability to open his right eye and diplopia. The patient denied any previous history of visual difficulties, but did mention a recent unintentional weight loss, back pain, and occasional headaches for the past few months. His only past medical history was a history of schizophrenia. Social history was significant for smoking one pack of cigarettes per day for the past 30 years. Vital signs were stable. Patient was found to be thin and cachectic with complete ptosis of the right eyelid. The right pupil was dilated, minimally reactive to light, and was fixed in the abducted position. The left eye was unaffected as well as all other cranial nerves remained intact. An admitting chest x-ray revealed collapse of the right middle lobe and hilar adenopathy. Initial CT of the head was unrevealing. Due to the continued persistence of ptosis and mydriasis on exam, an MRI was completed showing a 12 mm pituitary macroadenoma with deviation of the pituitary stalk to the right. Once this MRI result returned, a complete endocrine work-up was pursued due to concerns of endocrine axis dysfunction. Laboratory studies showed depressed levels of all hormones of the anterior pituitary as well as low levels of testosterone, cortisol, and free T4. A dedicated MRI with pituitary protocol showed a thickened infundibulum of 7 mm with heterogeneously enhancing soft tissue within the sella turcica. As a result of the findings on chest x-ray and MRI, a whole body CT scan was pursued as there was concern for diffuse metastatic disease. CT scan revealed a right lung mass with metastases to the liver, bilateral adrenals, ribs, thoracic and lumbar spines. Bronchoscopy was performed, and lung biopsy revealed small-cell neuroendocrine carcinoma.

DISCUSSION: Pituitary lesions are commonly encountered by general internists. It is estimated that about 20 % of the general population has a pituitary mass. Although pituitary adenomas are the most common type of sellar mass, and typically are benign, it is important to recognize that masses in this area can also be the result of diffuse metastatic disease as well as very rare instances of primary pituitary carcinoma. Approximately 5 % of patients with advanced malignancy are found to have pituitary metastases and are typically patients with lung or breast cancer. Furthermore, only 7 % of these patients with pituitary metastases become symptomatic during their lives. Once a pituitary adenoma is discovered, it should be fully evaluated for either hypersecretion or hyposecretion in addition to assessing for any symptoms. Patients may be asymptomatic or, if clinically significant, may have complaints of a non-specific headache, altered facial sensation, or vision changes such as diplopia or bitemporal hemianopsia. Panhypopituitarism and diabetes insipidus may also occur in patients with pituitary metastases due to destruction of the gland. It is critical to understand that pituitary lesions may be missed on routine CT scans, and that dedicated MRI of the pituitary is necessary when there is high clinical suspicion. Once a pituitary lesion is confirmed, it may not be easily distinguish on imaging alone. Some features, such as thickening of the infundibulum, invasion of the cavernous sinus, or invasion of the sella turcica, can be indicative of metastatic disease. Generally, treatment for pituitary metastases involves replacement of the deficient hormones as well as possible surgical resection. It is important for the clinician to recognize that pituitary masses have a wide array of clinical presentations and require full evaluation that may be sometimes missed with initial imaging. While pituitary metastases are rare and frequently asymptomatic, it is always important to consider metastatic disease in the differential diagnosis of a pituitary mass.

ORBITAL CELLULITIS WITH CAVERNOUS SINUS THROMBOSIS IN AN ELDERLY WOMAN: A CASE REPORT Kathryn A. Jobbins; Jessie Leyse; Reham Shaaban. Baystate Medical Center, Springfield, MA. (Tracking ID #1928949)

LEARNING OBJECTIVE 1: Recognition of posterior orbital cellulitis complicated by cavernous sinus thrombosis in the elderly.

LEARNING OBJECTIVE 2: Treatment of posterior orbital cellulitis complicated by cavernous sinus thrombosis.

CASE: An 84-year-old woman with a past medical history of chronic sinusitis presented with an acute history of acute right eye pain, erythema, and decreased ability to move the right eye secondary to severe swelling that had gotten progressively worse over 3 days. Of note, she had been evaluated as an outpatient for worsening hearing loss for 1 month, and was treated for sinusitis with oral antibiotics 2 weeks prior to this event. On examination, she had decreased visual acuity on the right, pain with movement of the eye, and surrounding erythema, swelling and cellulitis of the right eye, forehead and cheek. The sinuses were tender to palpation throughout. A CT scan was performed in the emergency department demonstrated pre- and post-septal cellulitis of the right orbit with soft tissue swelling of the right cheek. There was also bony erosion of the inferomedial orbital wall and opacification of the frontal and maxillary sinuses with no intracranial extension. The patient was seen by ENT, ophthalmology, and infectious disease consultants who recommended starting nasal saline rinses, dexamethasone, ceftriaxone and vancomycin. She initially responded well to this treatment regimen, however, after 2 days continued to have difficulty with movement of the right eye consistent with a partial third and partial sixth cranial nerve palsy with ptosis. The patient then underwent a CT head angiogram and venogram study which showed a 6 mm filling defect in the right cavernous sinus likely representing a thrombus. At this point neurology and neurosurgery were consulted who recommended starting the patient on anticoagulation given the morbidity and mortality associated with the diagnosis. Of note, the patient never underwent any surgical intervention while admitted to the hospital and no formal tissue biopsy was obtained to determine the causative agent of her infective source. The patient continued to improve and was discharged to a rehabilitation facility after 8 days to complete her 8 week course of IV antibiotics and anticoagulation. At her follow up visit 2 months later, she had near complete resolution of all her orbital cellulitis but with persistent sinusitis symptoms and subsequent outpatient deep wound culture was positive for *Serratia Marcescens*.

DISCUSSION: Posterior orbital cellulitis complicated by cavernous sinus thrombosis is rarely seen in the elderly population. Cavernous sinus thrombosis carries the potential for significant morbidity and treatment is often not straight forward. The presented rare case of an 84-year-old female highlights the clinical features in order to recognize posterior orbital cellulitis complicated by cavernous sinus thrombosis and the treatment options with long-term antibiotic coverage as well as anticoagulation until symptoms have resolved.

ORGANIZING EOSINOPHILIC PNEUMONIA : AN ORPHAN DISEASE

Navneet Kaur; Pahul Singh. SUNY Upstate Medical University, Syracuse, NY.
(Tracking ID #1938989)

LEARNING OBJECTIVE 1: Importance of early and prompt diagnosis of eosinophilic pneumonia which is a rare parenchymal lung disease to initiate therapy in a timely fashion.

CASE: A 53-year-old female presented to our institution with fever, cough and exertional dyspnea for one week duration after hiking and exploring caves during her recent visit to Las Vegas 1 month ago. She denied hemoptysis, weight loss or joint aches. Past medical history was unremarkable. Examination revealed temperature of 101 F and bibasilar crackles on lung exam. Laboratory values were unremarkable. Chest radiograph showed bilateral lower lobe infiltrates. CT thorax revealed multifocal airspace disease within posterior aspect of bilateral lower lobes. 2-D echocardiogram was unremarkable. Peripheral blood smear and serology for Histoplasmosis, Coccidioides, Aspergillus, Cryptococcus and Blastomycetes was unremarkable. Bronchoscopy was done and transbronchial biopsy showed organizing pneumonia with increased eosinophils with no evidence of malignancy on cytology, thus confirming the diagnosis of organizing eosinophilic pneumonia. Treatment was initiated with high dose of oral prednisone leading to marked improvement in the symptoms and the patient has been doing fine in last 2 months of follow-up.

DISCUSSION: Eosinophilic lung diseases are a group of diffuse parenchymal lung diseases characterized by infiltration of eosinophils of lung interstitium and alveolar spaces which may present as acute (<1 month) or chronic (>1 month) pneumonia. Exact etiology of eosinophilic pneumonia remains unknown. It has been suggested that it might be secondary to acute hypersensitivity reaction to an unidentified inhaled antigen. Clinical manifestations include febrile illness, non-productive cough, dyspnea and malaise. Laboratory values may reveal elevated erythrocyte sedimentation rate, increased ACE levels and peripheral eosinophilia. Chest radiograph and CT thorax reveals bilateral patchy ground glass or reticular opacities. Analysis of bronchoalveolar lavage fluid may reveal very high

percentage (more than 25 %) of eosinophils. Lung Biopsy may reveal organizing diffuse alveolar damage with prominent eosinophilia. Diagnosis of eosinophilic pneumonia can be established without lung biopsy in immunocompetent patients with pertinent history and eosinophilia on bronchoalveolar lavage fluid in absence of any infection. Systemic corticosteroids are the cornerstone therapy in eosinophilic pneumonia that help in prevention and reversal of respiratory failure. To summarize, although rare, our case reiterates the importance of early and prompt diagnosis of eosinophilic pneumonia to initiate therapy in a timely fashion.

OUCH, HOT SPOTS! PANNICULITIS ASSOCIATED WITH PANCREATITIS

Steven Lilly¹; Jake E. Turrentine². ¹Dallas VA Medical Center, Dallas, TX;
²University of Texas Southwestern, Dallas, TX. (Tracking ID #1938401)

LEARNING OBJECTIVE 1: Recognize that inflammatory skin lesions may rarely occur in the setting of pancreatitis which may mimic other systemic disorders.

LEARNING OBJECTIVE 2: Manage panniculitis in the setting of pancreatitis.

CASE: A 65 year-old male presented with diffuse abdominal pain, vomiting, jaundice, and “painful red spots” on both legs. These symptoms had been present for less than 1 week, but were worsening over the last 2 days, prompting his presentation. The rash was not pruritic, but was very painful when touched. Past medical history included diabetes mellitus type 2, hypertension, and psoriasis. His medications were metoprolol, insulin glargine, and etanercept. The patient denied smoking and alcohol use, and family history was noncontributory. On review of symptoms, he noted subjective fevers at home and loose stools, and stated that the current rash was unlike his previous psoriasis lesions. Physical exam demonstrated an obese man in mild distress, but vital signs were normal. Scleral icterus was present. His abdomen was severely tender to palpation, particularly in the midepigastrium and RUQ areas, but there was no Murphy’s sign or masses noted. Cutaneous examination revealed several exquisitely tender erythematous subcutaneous nodules on the bilateral shins, medial feet, and ankles without overlying ulceration, necrosis, or drainage. The largest lesion was approximately 3 cm in diameter. Laboratory studies showed an elevated serum lipase of 1210 U/L. Liver function tests were elevated in an obstructive pattern: total bilirubin 2.9 mg/dL, alkaline phosphatase 510 U/L, ALT 166 U/L, and AST 147 U/L. Abdominal ultrasound and CT scan with contrast showed peripancreatic fat stranding, a dilated common bile duct of 1.2 cm, and two hyperdense structures in the distal CBD consistent with choledocholithiasis. Once the diagnosis of gallstone pancreatitis was made, the gastroenterology service performed an ERCP to remove the retained stones and placed a stent for biliary drainage. Regarding the patient’s painful skin lesions, the initial differential diagnosis of the medical team included soft tissue infection, erythema nodosum (EN), and vasculitis. Given the myriad potential inflammatory and infectious causes underlying these conditions, other supportive workup included a CXR; HBV, HCV, HIV, and fungal serologies; PPD; ASO titer; and blood cultures, all of which were negative. Dermatology was consulted and two 5 mm punch biopsies of the skin were obtained: one for tissue culture and one for routine histology. Tissue cultures were negative and pathology revealed a lobular panniculitis with a mixed inflammatory infiltrate, surrounding necrotic fat leaving “ghost-like” outlines, and calcification consistent with pancreatic panniculitis.

DISCUSSION: This patient presented with painful nodules on the lower extremities suggestive of an underlying systemic condition in addition to pancreatitis. Erythema nodosum (EN) was initially considered given the appearance and tenderness of the skin lesions, and can be caused by a wide variety of disorders including infections, autoimmune disorders, malignancy, and medications. Vasculitis was ruled out based on the clinical exam, laboratory workup, and skin biopsy. Our patient was on etanercept for psoriasis, a TNF-alpha inhibitor. Etanercept has not been linked to EN and, in fact is sometimes used as a treatment of refractory cases. Since it is an immunosuppressing agent, it is also important to rule out an underlying infectious etiology of skin nodules with tissue culture and appropriate ancillary workup. Based on the histopathology described above, the diagnosis in this case was an unusual form of panniculitis, generally defined as inflammation of the subcutaneous fat. “Pancreatic panniculitis” is a rare variant of panniculitis characterized by fat necrosis and ghost adipocytes thought to be caused by pancreatic enzymes which are released into blood circulation in the setting of pancreatic disease. Lesions typically involve the lower extremities, and can occur in the setting of acute or chronic pancreatitis with an estimated incidence of 0.3–3 %. They can also be associated with pancreatic carcinoma, especially if the lesions are ulcerated or found on other areas of the body. Occasionally, the skin lesions can precede abdominal symptoms associated with pancreatic disease, which can manifest up to months later. The primary therapeutic measure for pancreatic panniculitis is to treat the underlying pancreatic disorder. Importantly, if the lesions are extensive, ulcerating, or progress despite the resolution of pancreatitis; further work-up should be done to exclude other pancreatic

pathology, particularly malignancy. In this case once the patient's pancreatitis was clinically resolved, the panniculitis lesions improved significantly in the following weeks.

PAGET - SCHROETTER SYNDROME: A CASE TO REMEMBER! Muhammad O. Azam; Rudin Gjeka; David Aggen; Zain I. Kulairi; Sarwan Kumar. Wayne State University, Rochester, MI. (*Tracking ID #1939542*)

LEARNING OBJECTIVE 1: Recognize the pathogenesis of effort thrombosis is not the same as other venous thromboembolic disorders.

LEARNING OBJECTIVE 2: Managing with anticoagulation alone is inadequate and can lead to residual disability and complications including pulmonary embolism, post-thrombotic syndrome and recurrent thrombosis. An aggressive multi faceted treatment strategy consisting of catheter-directed thrombolysis, with possible early thoracic outlet decompression, is essential for best outcomes.

CASE: 34 year old female with no co-morbid conditions presented to the ED with complains of left upper limb swelling and heaviness that gradually developed over 1 week. She had pain, swelling and mild numbness which was exaggerated on minimal exertion. There was no history of any trauma. No associated shortness of breath, chest pain or any weight loss. She was married with 7 children. Patient was not on any oral contraceptive pills. There was no family history of malignancy or hypercoagulable condition. On examination at presentation, patient was hemodynamically stable, with left non-pitting upper limb swelling up to the elbow joint that was tender on palpation with intact peripheral pulses. Initial lab workup including CBC, PT, and PTT were all normal. A complete coagulation workup was also ordered. Anti-thrombin, factor V Leiden, lupus anticoagulant, protein C & S levels were all normal. A left upper extremity venous evaluation was performed using duplex imaging with color and spectral Doppler. The internal jugular vein was completely compressible with no evidence of thrombosis. However, the subclavian, axillary, brachial and basilic vein proximally was noncompressible and dilated with acute-appearing thrombus. Patient was started with heparin infusion and cardiology was consulted. A venogram study of the left sub-clavian, axillary and the brachial veins was performed showing compression of the sub-clavian vein with congenital web deformity and a small thrombus was found that did not required a thrombectomy. Patient was started with Warfarin; therapeutic INR of 2–3 was achieved and discharged home on Warfarin.

DISCUSSION: Spontaneous thrombosis of upper extremity veins presenting as swelling and pain was first postulated by Sir James Paget in 1875. Von Schroetter was first to relate this syndrome to thrombotic occlusion of axillary and sub-clavian veins in 1884. Spontaneous thrombosis of upper extremity veins is termed as, Paget-Schroetter Syndrome (PSS) or Axillosubclavian vein thrombosis (ASVT) or Effort Thrombosis. PSS is a disease of young active individuals. Seventy-five percent of the cases occur on the dominant upper extremity after a vigorous exercise. Significant evidence now supports the role of anatomical abnormalities involving the thoracic outlet that includes cervical rib, congenital bands, hypertrophy of scalenus tendons and abnormal insertion of the costoclavicular ligament in the pathogenesis of effort thrombosis. Color doppler ultrasonography is currently the preferred initial test in the evaluation of suspected UEDVT due to cost efficiency and easy availability. Contrast venography is the gold standard for the diagnosis of UEDVT, but is not a preferred modality due to invasive nature, and high cost. Magnetic resonance (MR) and computed tomographic (CT) venography are superior to ultrasonography with MR venography having sensitivity 100 %. However, its applicability is limited due to high cost. Complications include pulmonary embolism, post-thrombotic syndrome and recurrent thrombosis. Although, pulmonary embolism from PSS is known, but is much less as compared to patients with lower extremity DVT or catheter related upper extremity DVT. Our patient was predominantly left-handed. She is a housewife with 7 children the youngest child was 1 year old. Patient said that lately, she has been overusing her arm for holding her children and the fact that her swelling got worsened on increased usage of the left arm. Coagulation profile was negative. However, venogram showed a web deformity of the subclavian vein with a small thrombus. Venography was done on our patient with intention of possible therapeutic thrombectomy. Effort thrombosis has been managed conservatively with limb elevation and anticoagulation alone. However, studies have showed a high incidence of residual symptoms, disability and recurrent thrombosis with conservative management. Therefore, it is important for clinicians to approach this aggressively. Various treatment modalities have been proposed for thrombus evacuation and achieving vascular patency. These may include local catheter-directed or systemic fibrinolytic therapy along with anticoagulation and/or surgery like percutaneous and surgical venoplasty, venous bypass and stents. In our patient, no surgical intervention was considered due to the small size of the thrombus. She was eventually managed conservatively with anticoagulation.

PAINFUL PROGRESSIVE PROXIMAL PARESIS Eloho Ufomata; Harish Jasti. University of Pittsburgh Medical Center, Pittsburgh, PA. (*Tracking ID #1937752*)

LEARNING OBJECTIVE 1: Evaluate a complaint of muscle weakness

LEARNING OBJECTIVE 2: Differentiate statin induced myopathy from HMG-CoA-antibody associated necrotizing myopathy

CASE: A 51 year old male with a history of hypertension, hypothyroidism and hyperlipidemia presented with weakness. Two months prior, he noticed persistent right shoulder pain, which was treated with an 8-day course of prednisone for a presumed shingles prodrome. He then developed weakness described as difficulty lifting both arms above his head, and lifting his legs while sitting, prompting presentation to the hospital. There, his labs were notable for a creatinine kinase of >4,000 and ANA of 1:80. His home medicine, red yeast rice, was discontinued due to possible causation, and he was discharged on prednisone 60 mg daily, with rheumatology follow up. During the next 4 weeks his condition worsened and he required assistance with ambulation and ADLs. He endorsed proximal muscle pain and dysphagia but denied fevers, chills, weight loss, rashes, chest pain, or SOB. He was re-admitted to the hospital for further work-up. Physical exam revealed a male in no acute distress, stable vital signs and unremarkable cardiovascular, respiratory, and integumentary exams. Neurological exam revealed normal cranial nerves, reflexes, cerebellar function, and sensation. Motor component was significant for 2/5 strength in the proximal muscles with intact strength in the distal muscles. Musculoskeletal exam revealed normal bulk and tender proximal muscles. Labs were notable for a normal CBC and BMP, with elevated transaminases, CK, LDH and aldolase. ANA and myositis panel (including anti-jo-1, anti-mi-2, and anti-SRP antibodies) were negative. EMG demonstrated a generalized myopathy with muscle inflammation/necrosis. Muscle biopsy revealed a necrotizing myopathy with membrane attack complex (MAC) deposition in the capillaries, and diffuse major histocompatibility complex (MHC) upregulation, suggestive of HMG-CoA-antibody associated necrotizing myopathy. He was treated with rituximab, methotrexate and physical therapy with improvement in his weakness and ability to perform ADLs.

DISCUSSION: The complaint of weakness is nonspecific and can describe muscle weakness, fatigue, exercise intolerance or pain. A thorough history and physical is the key to diagnosis. With true muscle weakness, the neurological and musculoskeletal exams localize the lesion to a CNS, PNS, or myopathic origin. For adult myopathy, the etiology could be metabolic, immunologic, toxic, or infectious. Initial testing includes CMP, CK, aldolase and LDH. If abnormal, TSH, ANA, HIV and myositis panel are helpful in further work-up. EMG characterizes and localizes the abnormal area, which can then be biopsied to elucidate the etiology. Certain populations with myopathy require further investigation. Patients with dermatomyositis or polymyositis warrant age-appropriate malignancy screening and evaluation for interstitial lung disease due to the high prevalence and implications on mortality. Suspected statin myopathy, which progresses despite statin withdrawal, should prompt consideration of HMG-CoA-antibody mediated necrotizing myositis. Though rare, it is strongly associated with high CK levels, and biopsy shows limited inflammation and presence of MAC. The anti-HMGCR test is diagnostic, and treatment involves aggressive immunosuppression. Weakness is a common complaint that can bode myopathic illness with significant consequences. A cost conscious evaluation can be performed by tailoring diagnostic tests to the illness script provided by the H&P, leading to a timely diagnosis and treatment.

PAINLESS AORTIC DISSECTION Jennifer Huang; Manuela Calvo. Montefiore Medical Center, Bronx, NY. (*Tracking ID #1934199*)

LEARNING OBJECTIVE 1: Identify atypical presentations of aortic dissection.

LEARNING OBJECTIVE 2: Recognize risk factors for aortic dissection.

CASE: A 70 year-old woman presented with 2 weeks of shortness of breath. She had a history of chronic obstructive pulmonary disease with a 110 pack-year smoking history. She also reported a productive cough, but denied chest pain or fevers. Her heart rate was 120 and her blood pressure was 110/70. She was afebrile and her oxygen saturation was 92 % on room air. She was able to speak in 5–6 word sentences only, and observed to have pursed lip breathing. She had a three out of six systolic murmur. Lungs were clear to auscultation without wheezes. There was no peripheral edema. Laboratory data was notable for a white blood count of 11 with 80 % neutrophilic predominance. Electrocardiogram was interpreted as sinus tachycardia without ST or T wave changes. Chest x-ray revealed hyperinflation without focal pulmonary consolidation. She was treated for a COPD exacerbation with inhaled bronchodilators, systemic steroids and antibiotics. Because she failed to respond to standard therapy for COPD, CT thorax with pulmonary embolism protocol was obtained to evaluate for PE versus other structural lung processes. The next morning, she was noted to be dyspneic and diaphoretic, but she again denied any

chest pain. She was hypertensive with a blood pressure of 169/104 and continued to be tachycardic with a heart rate of 118. Her oxygen saturation was 94 % on room air and she remained afebrile. Her lungs were still clear to auscultation. No focal neurologic deficits were noted. CT chest revealed a new Stanford type A aortic dissection in a 7-cm ascending aortic aneurysm which severely compressed the SVC. The patient was evaluated by cardiothoracic surgery and transferred emergently to the operating room. She underwent ascending aortic dissection repair and was discharged to a rehabilitation facility.

DISCUSSION: Early recognition of aortic dissection, a life-threatening process, is important to the internist. It classically presents as acute onset of chest, back or abdominal pain, and is usually diagnosed in patients with hypertension or atherosclerosis. However painless dissection has been reported, and accounts for less than 10 % of all cases, often in older patients with diabetes, aortic aneurysm, or previous cardiovascular surgery, though our patient was not known to have any of these co-morbidities. These patients may present with syncope, symptoms suggestive of heart failure, or neurological deficits, and are more likely to have type A dissections that involve the ascending aorta. Other unusual presentations include myocardial infarction, aortic regurgitation, vocal cord paralysis, Horner syndrome, renal failure and limb ischemia. The typical diagnosis can usually be made in over 90 % of patients with at least one of the following: 1) classic acute chest, back, or abdominal pain; 2) mediastinal widening on chest x-ray; or 3) pulse or blood pressure variation. ECG is often normal or shows nonspecific ST and T wave changes. However imaging studies are often still needed for definite diagnosis, which can be made with CT, MRI, or transesophageal echocardiography. While patients with dissections limited to the descending aorta can be managed conservatively, those with type A aortic dissections are considered surgical emergencies. Due to the significant mortality and morbidity associated with late diagnosis, physicians must keep aortic dissection as a differential for any patient presenting with shortness of breath, even in the absence of classic symptoms like chest pain.

PAINLESS ENLARGING BREAST MASS, WHAT COULD IT BE? Dima Dandachi; Mashooqe Dahar; Venu M. Ganipiseti. Presence Saint Francis Hospital, Evanston, IL. (*Tracking ID #1933763*)

LEARNING OBJECTIVE 1: Recognize the difference in presentation, prognosis and management between Primary breast lymphoma and Breast carcinoma.

LEARNING OBJECTIVE 2: Assess patients with Primary Breast Lymphoma for early Central Nervous system involvement.

CASE: A 59 years old Asian female patient, presented to the outpatient clinic after she noticed a right breast mass, rapidly increasing in size over the past 2 months. Patient denied any fever, chills, pain in her breast, weight loss. Past medical history is negative. Past surgical history is positive for tonsillectomy at the age of 12. She denied smoking, alcohol intake, or drug use. She does not taking any medications except multivitamins pill daily over the counter. She never had a colonoscopy, pap smear done last year was normal and mammogram done 2 years back was negative for any lesion. Vital signs were normal. Complete physical exam was benign except for a circumscribed, firm, non tender, not fixed to chest wall right breast mass with no lymphadenopathy and skin changes over the breast. A Mammogram was done showing a rounded dense mass in the central portion of the right breast measuring 4×3.5 cm that was not seen in the previous mammogram done 2 years back. US breast done showed right heterogeneous breast mass highly suspicious for malignancy and a small lymph node in the right axillary region measuring 5 mm. US guided core needle biopsy of the right breast mass was performed. Patient was thought to have breast carcinoma. Two weeks later, patient presented to the hospital with back pain, inability to defecate and bilateral leg weakness. MRI showed spinal cord mass at level of L3 extending into the neural foramina bilaterally suspicious for malignancy. Patient was diagnosed with cauda equina syndrome, started on intravenous dexamethasone, received emergency radiation to lumbar spine. Pathology of the breast biopsy came out showing diffuse high grade large B-cell lymphoma as evidenced by positive and strong staining for CD-20. LDH level 1344 IU/L (normal 91–180). Diagnosis was made of primary Breast cell Lymphoma with spinal metastasis. Patient improved and got discharged home to be started on R-CHOP chemotherapy as outpatient and to continue on radiotherapy.

DISCUSSION: Primary Breast lymphoma (PBL) is used to describe malignant lymphoma detected in the breast in the absence of previous history of lymphoma and absence of widespread disease at the time of diagnosis, with or without regional lymph nodes involvement. It is a rare disease. It is only seen in 0.4–0.5 % of malignant breast tumors. It is usually misdiagnosed as breast cancer

since it cannot be differentiated by clinical or radiographic findings. Breast lymphoma tends to be larger, grows rapidly, and is less likely to have skin erythema, peau d'orange and nipple involvement. Most of the lesions are oval shaped and circumscribed, no speculated margins or calcifications. To note that primary breast lymphoma was reported more among Chinese population similar to our patient. There are no clear guidelines regarding the best treatment modality. The use of combined chemotherapy and radiotherapy is considered to be more effective. Several studies showed that mastectomy did not affect the outcome in terms of survival or recurrence rates. Thus, it is not recommended. PBL has high incidence of central nervous system (CNS) involvement. Furthermore, CNS is the most common site of relapse. We are presenting a rare case of PBL misdiagnosed as breast carcinoma, complicated by early cauda equina syndrome.

PALPITATIONS AND METABOLIC DISTURBANCES IN A HEALTHY YOUNG MAN WITH CHRONIC HIGH-CAFFEINE ENERGY DRINK CONSUMPTION Ankeet Bhatt¹; Jonathan Salberg^{1,2}; Mamta Shah^{1,2}; Peruvamba Venkatesh^{2,1}. ¹University of Connecticut School of Medicine, Farmington, CT; ²Hartford Hospital, Hartford, CT. (*Tracking ID #1927353*)

LEARNING OBJECTIVE 1: Recognize energy drinks as a source of high concentration of caffeine and its potential adverse health risks including arrhythmia and metabolic disturbances.

LEARNING OBJECTIVE 2: Assess the impact of high caffeine energy drink consumption on serum and urine potassium contents.

CASE: HPI: 25-year-old male with a history of bipolar disorder, not on any medications, presents to the Emergency Department with 2 h history of acute onset of palpitations. Associated symptoms included 7/10, non-radiating, pressure like sub-sternal chest pain and three episodes of non-bloody, non-bilious vomiting. He denied fever, chills, headache, loss of consciousness, shortness of breath or an infective prodrome. Of note, patient mentioned high intake of "Five Hour Energy" drink, usually 3–4 1.93 fl. oz. bottles each day. Last intake was 3 bottles prior to onset of symptoms. He drank 2.5 bottles of the drink the night before presentation. Patient has been using Five-Hour Energy shots for the past 3–4 months, with increasing intake over the past 1.5 months. Patient has never had the aforementioned symptoms before. He worked as a delivery truck driver and had a poor dietary habit, which included fast food infrequently. PMH: Bipolar disorder, Type II; history of UTI Allergies: Contrast dye, Depakote, Lithium SH: Occasional marijuana and alcohol use. Patient reports 3–4 beers/week. Married with 2 children. Avid athlete. PE: Vitals: On admission: temperature 98.5, BP 125/76, non-orthostatic, HR 120–130, RR 18, O₂ sat 98 % on room air. General: He was awake, alert, oriented ×3. Physical exam within normal limits. Diagnostic Data: CBC/BMP on admission - WBC 11.4, hemoglobin 11.8, hematocrit 33.2, platelet count 226,000. Electrolytes (mEq/L): Sodium 140, potassium 2.4, chloride 101, bicarbonate 20., BUN 12, creatinine 0.7 Lactate 5.4. Glucose 149 mg/dL. Anion Gap 19. Urine electrolytes (mEq/L): Sodium 73, Potassium 57, Chloride 41 Calculated osmolality: 293 mOsm/kg. Delta-delta Ratio >2. EKG: Heart rate of 118 beats per minute, sinus tachycardia, possible atrial tachycardia. ST depressions in leads V4 through V6. QTc is prolonged at 540 milliseconds. Echocardiogram: hyperdynamic LV ejection fraction of 70 %.

DISCUSSION: Energy drinks which contain a significant amount of caffeine have grown in popularity over the past decade, now compromising over \$9 billion in sales with 6 billion drinks sold in the US in 2010. Five Hour Energy drinks contain a high dose (>1800 mg) "energy blend" contain taurine, glucuronic acid, caffeine, and other substances in small 1.93 fl. oz. container. These substances are mainly metabolized through the CYP 1A2 pathway and have the ability to cross the blood brain barrier. Toxicity with these substances can lead to seizures, agitation, psychosis, cardiac arrhythmia, and even death. Caffeine's has multiple systemic effects on the body, including a competitive phosphodiesterase inhibitor and adenosine receptor antagonist, inducing vasoconstriction and increased oxygen consumption. New studies in mice have shown that chronic caffeine consumptions can exacerbate renal failure, leading to the metabolic disturbances. This effect is particularly pronounced with concomitant metabolic syndrome. Research published in the NEJM showed 250 mg of caffeine increased plasma renin activity by 57 % 1 h after ingestion. While not previously described, such an increase in renin activity could account for renin-angiotensin-aldosterone axis activation and the phenomenon of hypokalemia with renal potassium wasting as seen in this patient. In addition, plasma norepinephrine and epinephrine concentrations increased 75 % and 207 % respectively with 250 mg caffeine dose, leading to significant sympathomimetic properties that could be responsible for a significant intracellular potassium

shift, leading to witnessed profound hypokalemia even despite the patient's elevated lactate level that likely suggests some cell lysis. Moreover, such physiology would account for the patient's elevated delta-delta ratio, with a high AG acidosis secondary to elevated lactate and a concurrent metabolic alkalosis secondary to aldosterone activation. In summary, the clinical effects of high caffeine energy drink ingestion can have serious consequences that providers should be aware of in order to adequately counsel their patients on the safe use of these substances. The consequences can be quite pronounced, eliciting a significant sympathomimetic response that can affect cardiac conduction and the renin-angiotensin-aldosterone axis, leading to arrhythmia and metabolic disturbances. Caffeine's intrinsic effect on cardiac conduction combined with profound hypokalemia associated with high caffeine consumption set the stage for dangerous arrhythmias. A ceiling of less than 500 mg of caffeine per day is generally considered a safe daily dose.

PANHYPOPITUITARISM, SARCOIDOSIS, AND AML: SIMULTANEOUS STORM OR COMPLEX CASCADE? Alice Williamson; Anne Weaver; Ramprasad Kandavar. Tulane University Health Sciences Center, New Orleans, LA. (Tracking ID #1926974)

LEARNING OBJECTIVE 1: Consider a broad, in-depth differential for fatigue.

LEARNING OBJECTIVE 2: Understand the wide range of symptoms associated with pituitary masses.

CASE: HPI A 66-year old man presented to the emergency department "feeling bad" for about 3 weeks. He endorsed fatigue, shortness of breath with exertion, feeling cold, anorexia, and intermittent fevers up to 101 ° F. His symptoms progressed until he could barely get out of bed. He also complained of worsened bilateral lower leg swelling over the past 3 months. His past medical history included hypertension and pancytopenia with bone marrow biopsy from 1 year prior to presentation consistent with iron-deficiency. His vital signs at presentation included temperature of 99.2 F, heart rate of 89, blood pressure of 108/54, with respirations 18. He was in no acute distress, spoke slowly, and was fully oriented though his personality seemed blunted. Conjunctiva were pale and skin was flakey; spleen was moderately enlarged; and he had 2+ pitting pedal edema. His exam was otherwise normal. He was pancytopenic with WBC 3.2, Hgb 8.7, MCV 85, PLT 121. His sodium was 128, ESR 82, total protein 8.2, and albumin 2.8. Chest x-ray revealed some interstitial fluid. Thyroid studies reveal central hypothyroidism (TSH 1.35, Free T4 0.41), and ACTH stimulation test resulted with baseline cortisol 1.06, 30-minute cortisol 4.53, and 60-minute cortisol 7.09. Pituitary pathology was suspected, and MRI brain revealed mild enlargement of the pituitary gland. Bone marrow biopsy revealed myelodysplastic syndrome with 1–2 % blasts. Follow Up Our patient was treated with hydrocortisone, levothyroxine, and testosterone, and was discharged home. Within 2 months, he developed a rash, which was biopsied and consistent with granulomatous dermatitis, possibly sarcoidosis. Still being worked up for the underlying cause of pituitary enlargement and due to concern for malignancy-associated pituitary disease, MRI was repeated as an outpatient in preparation for pituitary biopsy: enlargement had completely resolved 3 months after initial MRI. CT chest revealed mediastinal and hilar lymphadenopathy, and repeat bone marrow biopsy (performed 4 months after presentation) was consistent with acute myeloid leukemia with 40–50 % blasts.

DISCUSSION: Our patient initially presented with symptoms of pituitary insufficiency. Symptoms improved within the first few doses of hormone replacement. Sarcoidosis can infiltrate the pituitary, leading to symptoms of panhypopituitarism, the treatment of which is hydrocortisone. Our patient's pituitary enlargement resolved with hydrocortisone and, in the meantime, he developed granulomatous dermatitis and was found to have hilar lymphadenopathy, both of which are consistent with sarcoidosis. While sarcoidosis is known to exist with malignancies, sarcoidosis is not commonly associated with AML; when the two do coincide, the question remains: is the sarcoidosis actually a response to tumor antigen of AML, or does the impaired T-cell response of sarcoidosis predispose patients to AML? Further research and cotemporaneous cases need to be explored to help determine the pathways and interactions of this medical conundrum.

PARADOXICAL BREATHING: AN IMPORTANT PHYSICAL EXAM FINDING IN A PATIENT WITH METASTATIC MELANOMA Riddhi Shah¹; Ekta Kapoor²; Melissa Glenna¹; Svetomir Markovic³. ¹Mayo Clinic, Rochester, MN; ²Mayo Clinic, Rochester, MN; ³Mayo Clinic, Rochester, MN. (Tracking ID #1939293)

LEARNING OBJECTIVE 1: Recognize bilateral diaphragmatic paralysis due to drug-induced phrenic nerve palsy as an etiology of subacute dyspnea

LEARNING OBJECTIVE 2: Recognize the unique immunologic side effects of checkpoint inhibitors, a novel class of antineoplastic agents

CASE: A 66-year-old male presented to his primary care physician with complaints of shortness of breath and fatigue for 1 week. He complained of significant dyspnea in the recumbent position, which markedly improved in upright position. He denied cough, fever, chest pain or similar prior complaints. His past medical history was significant for metastatic choroidal melanoma for which he was treated with 4 cycles of ipilimumab, an FDA approved cytotoxic T-lymphocyte associated antigen-4 (CTLA-4) inhibitor. A chest X-ray and echocardiogram of the heart were normal, and he was empirically initiated on oral antibiotics. He presented to our institution 2 days later with worsening symptoms. On examination, he appeared comfortable, and his vital signs were within the normal range. Pertinent findings included decreased breath sounds at the bases bilaterally and paradoxical breathing. A CT chest ruled out pulmonary embolism and acute pneumonitis. A sniff test to assess for diaphragmatic paralysis was normal. However, given that it may be normal in patients with bilateral diaphragmatic paralysis and our high index of suspicion based on physical examination, an electromyogram (EMG) was performed. This was suggestive of bilateral severe phrenic neuropathy. An ultrasound confirmed bilateral diaphragmatic paralysis. Examination of the vocal cords by direct laryngoscopy showed normal vocal cord function (thereby ruling out vagal nerve involvement). To assess for a mechanical cause for the bilateral phrenic nerve paralysis, an MRI of the cervical spine and brachial plexus was done. Both these studies were unremarkable. A serum paraneoplastic panel was normal. Given the lack of evidence for a direct infiltration of the phrenic nerves by melanoma, the absence of a serum antibody (based on a negative paraneoplastic panel), and the fact that ipilimumab has been associated with immunologic toxicities, a diagnosis of inflammatory amyotrophy secondary to ipilimumab was made (variant of Parsonage Turner syndrome). Since the patient's respiratory condition deteriorated over the next 7 days, requiring non-invasive ventilation, he was started on high-dose corticosteroids. He had a dramatic improvement in his symptoms, and he was successfully weaned off the steroids over the next month. At his most recent follow-up 12 months later, he has unfortunately developed progressive melanoma requiring a change in his therapy. His respiratory status has remained stable with no shortness of breath.

DISCUSSION: Ipilimumab is the first immunomodulatory drug that received FDA approval for the treatment of metastatic melanoma by the FDA in 2011. It acts primarily by inhibiting CTLA-4, which in turn releases the inhibition of cytotoxic T-lymphocytes, and allows them to destroy the melanoma cells in vivo. Unfortunately, this reactivation of T-lymphocytes can have significant immunologic side effects. Indeed, in the original registration phase 3 trial that led to its approval, ipilimumab was associated with an immunologic side-effect in up to 60 % patients. The most common manifestations include skin rash, diarrhea, panhypopituitarism, and adrenal insufficiency. Other rare autoimmune conditions such as acquired hemophilia A, pure red cell aplasia, sarcoidosis and myasthenia gravis have also been reported. To the best of our knowledge, bilateral phrenic nerve paralysis has not been previously reported with ipilimumab. The vast majority of patients who experience severe toxicity as a result of ipilimumab are managed with high-dose corticosteroids for a short duration, followed by a rapid taper. This therapy is associated with high response rates. Interestingly, several reports suggest that patients who experience an immunologic event are more likely to have an anti-neoplastic effect, thereby suggesting that some degree of immune-mediated effects are desirable. Immune checkpoint inhibitors and other immunomodulatory drugs are making tremendous advances in the treatment of many cancers, and ipilimumab alone has been tested in 12 different malignancies. As internists, we need to be cognizant of its protean side effects. It is important to promptly recognize the manifestations of toxicities, including the rare ones such as bilateral diaphragmatic paralysis, for timely initiation of appropriate therapy. And finally, this case report underscores the importance of a thorough physical examination, since no investigations could have replaced the astute clinical observation of paradoxical breathing that clinched the diagnosis in our patient.

PARASITE CAUSING ACUTE ABDOMINAL PAIN Jessica C. Li; Sara L. Swenson. California Pacific Medical Center, San Francisco, CA. (Tracking ID #1939508)

LEARNING OBJECTIVE 1: Classical gastric anisakiasis manifests as acute abdominal pain 1–12 h after ingestion of raw fish and can also cause an allergic reaction. Treatment is removal of the parasite during endoscopy or symptomatic as the worm cannot survive within the human host for more than a few days.

LEARNING OBJECTIVE 2: A thorough history, including recent foods consumed, combined with prompt endoscopy is the key to suspecting a diagnosis of anisakiasis!

CASE: A 47 yo man with no significant past medical history presented to the emergency room with sudden-onset epigastric pain for the last 36 h. The pain was intermittent and 8/10 in severity at its worst, was dull and pressure-like with radiation

to the lower abdomen and back, and was associated with decreased appetite. The pain was not associated with nausea, vomiting, diarrhea, constipation, hematochezia, hematemesis, or NSAID use. Notably, the patient reported eating mackerel at home the night before his symptoms developed. On physical examination, the patient was afebrile. Abdominal examination revealed normal bowel sounds and a non-distended, non-tender abdomen without hepatosplenomegaly. Labs were unremarkable. CT of the abdomen and pelvis revealed wall thickening of the mid and lower gastric body and antrum with mesenteric and retroperitoneal adenopathy most concerning for infiltrative gastric carcinoma with possible metastatic adenopathy. Subsequent upper endoscopy showed two non-bleeding gastric ulcers and a 2 cm anisakis worm exiting one of the ulcers. The worm was removed during the endoscopy as definitive treatment. The patient continued to experience some mild pain but was discharged in an improved condition.

DISCUSSION: This case illustrates a classic presentation of gastric anisakiasis. Anisakiasis includes all infections caused by members of the genus *Anisakis*. Most human infections are due to *Anisakis simplex*, a nematode most commonly found in salmon, herring, cod, and mackerel. Given its prevalence and increasing raw and undercooked fish consumption in the US, the incidence of anisakiasis should increase. If a third stage anisakis larva is ingested, it will attach to the stomach wall. The worm directly invades the stomach wall, causing pain, nausea and vomiting that occurs within 1–12 h after a meal. The burrowing worm can perforate the stomach wall or, as in our patient, cause an inflammatory reaction of the gastric wall. The worm can also cause an allergic reaction resulting in pruritis, rash, tingling of the oropharynx and anaphylactic shock. It can also reach the intestines causing diffuse abdominal pain, distention, ascites or even intestinal obstruction or perforation. Ileal involvement can mimic acute appendicitis. Laboratory testing can show an eosinophilia, which this patient did not have, especially in those with an allergic reaction. In the stomach, definitive treatment is removal of the worm. If the larvae makes it into the intestine, it usually passes through in a few days and treatment is symptomatic. However, a complication such as obstruction may require surgery. Albendazole has been used, but its effectiveness has not been studied in randomized trials. When taking a history for acute abdominal pain it is important to find out what the patient has eaten recently so as not to overlook the possibility of an intestinal nematode!

PARNAGE-TURNER SYNDROME: AN UNUSUAL PRESENTATION
Charu Ramchandani; Waleed Quwatli; Khalid Abdel-Gadir. Unity Health System, Rochester, NY. (*Tracking ID #1939501*)

LEARNING OBJECTIVE 1: Identifying unusual presentation of Parsonage-turner syndrome involving phrenic nerve, leading to hemi-diaphragmatic paralysis.
CASE: 72 year old female came to the clinic few weeks after undergoing right total knee replacement with complains of shortness of breath on exertion, burning left neck and left upper arm pain interfering with her sleep. She denied any complaints of weight gain, palpitations, edema, chest pain, orthopnea or paroxysmal nocturnal dyspnea. Her past medical history was significant for rate controlled atrial fibrillation, hypertension and osteoarthritis. Her home medication consisted of Rivaroxaban for her atrial fibrillation and, Atenolol and Irbesartan for her high blood pressure. On examination her oxygen saturation at rest and exercise was normal, but on chest percussion there was dullness, decreased vocal fremitus and decreased breath sounds at the left lung base. On imaging, her Chest x-ray revealed atelectasis and elevated left hemidiaphragm which on Sniff test concluded left hemidiaphragm paralysis; computed tomography (CT) scan of the chest showed new moderate elevation of left hemidiaphragm with atelectasis in the left lower lobe and the magnetic resonance imaging (MRI) of the cervical spine ruled out any nerve root compression. In 2009, patient had a similar history of pain, paresthesia and weakness of her left arm few weeks following her left knee replacement, for which she had an extensive work-up to find the cause. During that time, MRI was negative for any compressing or infiltrating lesion, but the nerve conduction study and electromyography concluded moderate left lower trunk brachial plexopathy strongly suggestive of acute brachial neuritis. Over years, her neuropathic pain was controlled with Gabapentin and left arm weakness improved with physical therapy.

DISCUSSION: Parsonage-turner syndrome also known as acute brachial neuritis or neuralgic amyotrophy is an idiopathic immune mediated neuritis with asymmetric involvement of brachial plexus. It is a rare condition most commonly reported as an idiopathic form triggered by surgery, viral infection, vaccination, trauma and strenuous exercise. A hereditary form of neuralgic amyotrophy has also been described in case reports which presents in a similar fashion with recurrent attacks preceding an inciting event. A typical case of Parsonage-turner syndrome presents with a dull aching/burning shoulder/arm pain within a few days to weeks after the inciting event and is followed by shoulder girdle and/or arm weakness. But very few cases have been reported in literature

that involves a phrenic nerve, causing hemi-diaphragmatic paralysis leading to dyspnea. Important differential diagnosis to keep in mind is cervical radiculopathy which unlike brachial neuritis involves only one nerve root. Electromyogram and nerve conduction study are crucial to confirm the diagnosis but its findings should always be correlated with patient's history and physical examination. Treatment is supportive with analgesic and physical therapy. But some studies have reported corticosteroid to be helpful during the acute phase, to expedite the recovery and reduce the pain. Intravenous immunoglobulin and plasma exchange are other therapies that have been reported with unknown results. In patients with persistent disabling diaphragmatic paralysis, laparoscopic plication of diaphragm is an option but data on its effectiveness is lacking. Patient's recovery may take upto 3 years but in some cases, persistent residual deficits have been reported. In this case report brachial plexopathy and phrenic neuropathy following surgery and without any known etiology is strongly suggestive of Parsonage-Turner syndrome. We believe such presentation can be helpful to for internist/physician in recognizing this disorder in a timely fashion and thus avoid any unnecessary/expensive diagnostic and therapeutic interventions.

PECTUS EXCAVATUM: A RARE BUT POTENTIALLY REVERSIBLE CAUSE OF ATRIAL FIBRILLATION Mai Kaga; Leonard Amoruso; Peter Rattner. Beth Israel Medical Center, New York, NY. (*Tracking ID #1895510*)

LEARNING OBJECTIVE 1: Recognize important physical exam findings, such as pectus excavatum (PE), as a cause of atrial fibrillation (AF).

CASE: A 24 year old female, with no past medical history, presented to the emergency department (ED) complaining of palpitations, associated with dizziness, for 1 day. The patient was found to be in atrial fibrillation (AF) with rapid ventricular response at 158 beats per minute (bpm). The patient was medically cardioverted and sent home. The patient returned to the ED the next day because she "did not feel right." Her electrocardiogram (ECG) showed normal sinus rhythm with a heart rate of 74 bpm, enlarged p waves, and anterior t-wave inversions. The patient was admitted to the cardiac care unit. Physical exam revealed a young, tall, thin woman with long limbs and deep voice. Pectus excavatum (PE) was noted on visual exam. Extremities were significant for long bones, and hyperlaxity, with positive Steinberg test and positive wrist sign. Cardiac exam revealed a loud p2, and a grade IV holosystolic murmur, heard best at the left heart border, with right ventricle heave. Transthoracic echocardiogram (TTE) revealed extrinsic compression of the right ventricular free wall. Cardiac MRI showed PE compressing the right ventricular free wall with narrowing of the right ventricular outflow tract. The patient was transferred to another institution to undergo a nuss procedure for surgical expansion of the chest wall.

DISCUSSION: The etiology of AF in this patient is most likely PE, causing mechanical impingement of the right ventricle, leading to dysfunction and right atrial enlargement. The clinical significance of PE depends on the severity, cardiopulmonary function, and cosmetic impact on the patient. The most common complaints among patients with PE are chest pain, poor endurance, and shortness of breath. Evaluation of PE is done with ECG, TTE, CT scan, and MRI. TTE evaluation can be difficult in patients with severe deformities. However, it is important to evaluate the degree of right ventricular compression in these patients to assess cardiopulmonary function. Surgical correction improves cosmetic appearance in most patients and cardiopulmonary functions in some patients. Generally accepted indications for surgery are severe deformity, cardiac compression and displacement, conduction abnormalities, restrictive abnormalities on pulmonary function testing and failed prior PE surgical correction. This case illustrates the importance of physical exam findings, such as PE, as a potentially reversible etiology of AF.

PELVIC ACTINOMYCOSIS MASQUERADE AS PYELONEPHRITIS AND NEPHROLITHIASIS Robert P. McClung¹; Sarah A. Holzman¹; Jai Eun Lee¹; Benjamin D. DeMoss²; Kimberly D. Manning¹. ¹Emory University School of Medicine, Atlanta, GA; ²Emory University School of Medicine, Atlanta, GA. (*Tracking ID #1937946*)

LEARNING OBJECTIVE 1: Recognize an uncommon pelvic infection associated with long-term use of an intrauterine device

LEARNING OBJECTIVE 2: Diagnose invasive actinomycosis using minimally invasive testing

CASE: A 59-year-old woman presented to the emergency department with subjective fevers, chills, flank pain, dysfunctional voiding symptoms and urine discoloration. Her past medical history was notable for asthma, an appendectomy and placement of an intact Lippe's loop intrauterine device (IUD) 25 years ago. On physical exam, the patient was febrile to 38.8 °C with a heart rate of 124. She exhibited exquisite right-sided costovertebral angle tenderness and diffuse abdominal tenderness. Laboratory

studies revealed leukocytosis (WBC 22.4 k with 90 % neutrophils), thrombocytosis of 495,000, and normocytic anemia (hemoglobin of 8.5 g/dL). Urinalysis was notable for 3+ leukocyte esterase, 3+ hemoglobin, numerous WBCs, and negative nitrites. CT scan of the abdomen and pelvis revealed right-sided hydronephrosis without renal calculi and a 14.6 cm complex retroperitoneal mass extending from the proximal right ureter to the right adnexa. Broad-spectrum antibiotics were initiated, a nephrostomy tube was placed to relieve hydronephrosis, and the patient was admitted for management of presumed pyelonephritis and workup of her retroperitoneal mass. Differential diagnosis for her complex mass focused on neoplastic etiologies (ovarian malignancy or sarcoma) and infectious etiologies such as tubo-ovarian abscess. Her ovarian malignancy markers were unremarkable. Gonorhea and chlamydia testing and blood and urine cultures were all negative. A Papanicolaou smear and a bedside endometrial biopsy revealed innumerable infiltrating Actinomycetes. Ertapenem was selected to treat both *Actinomycetes* species and a likely polymicrobial superinfection of the mass, both of which were later confirmed by endometrial culture. The patient improved markedly with appropriate antibiotic therapy, but open surgical management was eventually chosen based on the size of the mass and continued urinary obstruction.

DISCUSSION: *Actinomycosis* is a chronic granulomatous disease caused by anaerobic, gram-positive bacteria commensal to the oropharynx, gastrointestinal and genitourinary tract. In rare cases, this unusual organism produces invasive infection of the head and neck, thorax, or abdomen and pelvis. One common predisposing factor for abdominopelvic actinomycosis is appendicitis, especially with perforation and foreign body placement in the gastrointestinal or genitourinary tract. Pelvic actinomycosis is commonly associated with continuous IUD use of over 5 years. Approximately 7 % of IUD users have *actinomycetes* species on cervical cytology, but only 2–4 % of these colonized IUD patients are estimated to develop invasive actinomycotic infections. Pelvic actinomycosis resembles a neoplasm on radiographic imaging and is commonly treated as such, frequently leading to surgical intervention. It is not until final surgical pathology results return that the true identity is uncovered. Early diagnosis requires a high index of clinical suspicion. Infections often resolve with antibiotics alone, though surgical debridement may still be required to manage abdominopelvic complications. This case demonstrates effective preoperative diagnosis of pelvic actinomycosis via endometrial biopsy in advance of exploratory surgery. This case also illustrates the importance of obtaining a complete sexual history. The patient's longstanding IUD, which could have been overlooked, was the crucial link to her diagnosis and appropriate workup.

PERCUTANEOUS VACUUM THROMBECTOMY OF RIGHT HEART THROMBUS Ahmed Al-Badri; Sean Wilson; Chad Klinger; Carlos E. Ruiz. Lenox Hill Hospital, New York, NY. (*Tracking ID #1940316*)

LEARNING OBJECTIVE 1: – Diagnose patients with large right heart thrombus when hemodynamically stable.

LEARNING OBJECTIVE 2: – Management of large right heart thrombus in surgically high risk patients using a novel technique.

CASE: The patient is a 71 year-old man with a past medical history of hypertension, anemia, chronic kidney disease and recent diagnosis of lung cancer with an 80 lb weight loss who presented to the emergency department complaining of dizziness associated with dyspnea on exertion and weakness for 36 h prior to presentation. Electrocardiogram showed sinus tachycardia and a new right bundle branch block. Computed tomography angiography (CTA) was performed revealing a large pulmonary embolus in the right main pulmonary artery extending into the right lower lobe arteries and the presence of an intracardiac filling defect. A transesophageal echocardiogram (TEE) revealed a large mobile mass, likely clot, in the right atrium (RA) extending from the superior vena cava with prolapse into the right ventricle (RV) during diastole. Given the patient's medical comorbidities including the newly diagnosed lung cancer and poor nutritional status, the patient was deemed too high risk for surgical embolectomy. Thrombolytic therapy was considered to be high risk as well because of the potential for thrombus fragmentation and distal embolization. Therefore, percutaneous retrieval of the clot via vacuum thrombectomy with the AngioVac® suction cannula (Vortex Medical, Norwell, MA) was attempted and complete en bloc removal of the right atrial thrombus was achieved without complication.

DISCUSSION: Right sided heart thrombi can develop directly within the right heart chambers or from embolization of peripheral venous clots that accidentally lodge in right heart structures on their way to lungs. Type A thrombi with a worm-like shape are extremely mobile, frequently move back and forth through the tricuspid orifice, and may cause cardiovascular collapse when entrapment occurs. They are relatively rare and can be seen in 4–18 % of patients presenting with acute pulmonary embolism. Patients with type A thrombi have a very poor prognosis with high early mortality rates of 44 % with severe and often fatal

pulmonary embolisms. Whereas Type B thrombi attach to the atrial or ventricular wall indicating that they are probably of local origin. Mobile right heart thrombi causing acute pulmonary embolism require urgent aggressive therapy, but current management strategy remains controversial. Thrombolytic therapy can be successfully used for some patients but carries a 22 % risk of major hemorrhage. In addition, thrombolytic therapy should be used with caution with large mobile thrombi, as the risk of fragmentation and embolism is high. Surgical removal of the clot is another option, but multiple medical comorbidities may prohibit the operative management. Vacuum thrombectomy using the AngioVac® suction cannula (Vortex Medical, Norwell, MA) is an attractive modality allowing complete en bloc removal of the right atrial thrombus potentially avoiding a complex, high risk surgical procedure.

PERSISTENT HYPOGLYCEMIA: THE PANCREAS REVEALS ITSELF Rekha Thammana. Emory University, Atlanta, GA. (*Tracking ID #1937841*)

LEARNING OBJECTIVE 1: Recognize chronic pancreatitis as a cause of both hyperglycemia and hypoglycemia.

LEARNING OBJECTIVE 2: Choose diabetic regimens that minimize hypoglycemia in patients with chronic pancreatitis.

CASE: A 58 year old African-American man presents to an urban safety-net hospital after he was found obtunded at the entrance of a local church. He is a known diabetic whose last medication of record was metformin. On admission, his blood glucose was 10 mg/dL. On computed tomography of the abdomen, multiple calcifications were seen at the pancreatic head. He was admitted to the intensive care unit and placed on an intravenous dextrose solution. His mental status improved after 48 h of intravenous dextrose. At the time of his initial presentation, his insulin level was 8.05 mcu/mL. His C-peptide level was less than 0.10 ng/mL, and his oral hypoglycemic screen was negative. He later revealed a history of alcohol abuse and chronic pancreatitis. He was actually taking premixed insulin 70/30 for management of his diabetes. His persistent hypoglycemia was due to excess exogenous insulin administration in the setting of a blunted hypoglycemic response due to chronic pancreatitis.

DISCUSSION: Chronic pancreatitis is an under-recognized etiology of diabetes. Alcohol abuse accounts for 70–90 % of cases of chronic pancreatitis, with most remaining cases due to genetic causes like cystic fibrosis. Alcoholic chronic pancreatitis has a median age of onset of 44, and it is associated with reduced pancreatic endocrine and exocrine function. Up to 80 % of patients with alcoholic chronic pancreatitis will develop diabetes within 10 years of chronic pancreatitis diagnosis. Endocrine dysfunction will involve deficiencies in both insulin and glucagon production. Normal pancreatic function dictates a decrease in insulin excretion at a serum glucose of 80–85 mg/dL. In our patient's case, insulin levels remained relatively high because of exogenous administration. His intrinsic insulin production was non-existent, as evidenced by his low C-peptide level. Glucagon is normally triggered at a glucose of 60–75 mg/dL. While glucagon levels were not investigated, we suspect that our patient's glucagon response to hypoglycemia was blunted or absent due to his history of chronic pancreatitis. While he should have had a preserved stress response to hypoglycemia with the release of epinephrine, it was not enough to counteract hypoglycemia without intravenous dextrose. Chronic undernourishment from homelessness and alcohol abuse may have played a role in decreasing glycogen stores, thus also preventing a robust response to hypoglycemia. Given the likelihood of an underreported substance abuse history, clinicians should explore the possibility chronic pancreatitis when first diagnosing patients with diabetes. Their management strategy should differ in patients with chronic pancreatitis given the significant risk of hypoglycemia. Clinicians should manage this population in a similar way to type I diabetics, mostly avoiding oral hypoglycemics. Ideally, these patients can be managed with basal-bolus insulin, as this is the most physiologic regimen. Premixed insulin, which our patient was taking, carries a higher risk of hypoglycemia and should also be avoided. Most importantly, more liberal glycemic control is acceptable in a population with secondary diabetes as the risks of hypoglycemia are so high. While hypoglycemic events are not uncommon in diabetic patients, not all hypoglycemia is created equal. It is important to view patients in the context of their full medical, social and family history. This case highlights the importance of understanding the complexity of a patient's disease process and customizing their care appropriately.

PHEO-FI-FO-FUM ! Lawrence Purpura; Seema Qayum. Tulane University Health Sciences Center, New Orleans, LA. (*Tracking ID #1927104*)

LEARNING OBJECTIVE 1: Recognize the clinical presentation of a pheochromocytoma/extrarenal paraganglioma

LEARNING OBJECTIVE 2: Learn the most sensitive/specific biochemical testing for diagnosing a pheochromocytoma/extrarenal paraganglioma

CASE: A 36 year-old woman presented in hypertensive emergency with a blood pressure of 244/143, accompanied with bitemporal, 9/10 throbbing headache. She reported having similar headaches periodically for the past 4 months, associated with increased anxiety and elevations in her baseline systolic blood pressure, despite taking her home anti-hypertensives. She had mild right upper quadrant tenderness to deep palpation, but neurological, pulmonary, and cardiac exams were normal. Labs were within normal limits. The patient had a history of a right $4 \times 2 \times 5$ cm retrocaval mass on computed tomography and had initially presented to the hospital that day for endoscopic ultrasound guided biopsy. A secondary hypertension work-up revealed normetanephrines of 2165 pg/mL (normal: 0–145) and metanephrines of 21 (normal: 0–62). An outpatient 123-I-metiodobenzylguanidine scan revealed abnormal uptake in the area of the retrocaval mass with no other sites of uptake. She was pretreated with doxazosin for 2 weeks then underwent open laparotomy for the removal of the mass. Pathology confirmed diagnosis of extra-adrenal paraganglioma, and repeat plasma-free and fractionated metanephrines and blood pressure 2 months later were normal.

DISCUSSION: Pheochromocytomas are neuroendocrine tumors comprised of chromaffin cells and found mainly in the adrenal medulla, however 10–20% are extra-adrenal and known as "extra-adrenal paragangliomas." Both have the ability to secrete catecholamines and produce symptoms, most commonly hypertension, tachycardia, pallor, headache, panic or anxiety attacks; The triad of headache, palpitations and diaphoresis carries a high sensitivity for pheochromocytoma. Classical symptoms, uncontrolled hypertension, an adrenal incidentaloma, or a family history of pheochromocytoma warrant catecholamine biochemical testing, with plasma-free metanephrines being the most specific and sensitive test. If biochemical tests are unequivocal, imaging can be performed with T2-weighted magnetic resonance imaging being the choice modality. If high risk of malignancy, a 123-I-metiodobenzylguanidine scan is performed to look for metastases. Surgical removal is the standard of care for most pheochromocytomas, and to prevent catecholamine-induced complications during surgery, the patient is pretreated with alpha-adrenoreceptor blockade for 10 to 14 days. Phenoxybenzamine is the drug of choice due to its noncompetitive alpha-blockade, however prazosin and doxazosin may also be used. A beta-adrenoreceptor blocker is added to competitive alpha-blocker after several days; care must be taken to avoid the loss of beta-adrenergic induced vasodilation before alpha-blockade, as unopposed alpha-vasoconstriction can lead to hypertensive emergency. The patient requires at least 1 day of intensive care observation post-resection to monitor for hypotension and hypoglycemia. Non-hereditary, unilateral cases carry good prognosis, but persistent hypertension is common.

PHOSPHATE NEPHROPATHY DUE TO COLONIC IRRIGATION THERAPY

Vijan Joshi; Naoka Murakami; Wan L. Lam. Beth Israel Medical Center, New York, New York, NY. (*Tracking ID #1937123*)

LEARNING OBJECTIVE 1: Distinguish phosphate nephropathy from other forms of acute kidney injury.

LEARNING OBJECTIVE 2: Recognize that colonic irrigation treatments used in alternative medicine pose a potential risk for phosphate nephropathy.

CASE: A 52-year-old male with a past medical history of HIV on HAART (CD4 470, viral load undetectable), presented with nausea and vomiting for 3 days, and anuria for 1 day. Vital signs on admission were all within normal limits. Physical exam was significant for oral thrush and mild tenderness to palpation in the lower quadrants of the abdomen. Labs were significant for acutely elevated BUN (75 mg/dL), creatinine (11.91 mg/dL, baseline 1.14 mg/dL 3 months prior to presentation), K 5.5 mEq/L, Ca 7.9 mg/dL, Phos 11.1 mg/dL and an anion gap metabolic acidosis (pH 7.24, CO₂ 33 mmHg, HCO₃ 17 mg/dL). Urinalysis was positive for blood and protein, but negative for WBCs and casts. Hemodialysis was initiated for symptomatic uremia on the third day of hospitalization. Additional history revealed that the patient had begun receiving colonic irrigation treatments 3 months prior to admission, and had thus far received three enema treatments. It was suspected that his acute renal failure could be due to high phosphate containing enemas. A kidney biopsy was performed, which demonstrated marked diffuse deposition of calcium phosphate in the tubules consistent with phosphate nephropathy, with concomitant tubular atrophy and interstitial fibrosis. The patient's symptoms improved after initiation of hemodialysis, and he was instructed to discontinue his colonic treatments upon discharge.

DISCUSSION: This case illustrates a potential complication of colonic irrigation therapy. Phosphate nephropathy is used to describe acute renal failure with characteristic histologic findings on renal biopsy of widespread calcium phosphate deposition in the renal tubules. Typically, this nephrocalcinosis is associated with hypercalcemia, but in acute phosphate nephropathy, the precipitant is a large phosphate load delivered to the distal nephron. While the mechanism by which this causes acute renal failure is unknown, it is hypothesized that an increased intratubular phosphate concentration results in the precipitation of calcium phosphate salts, causing luminal obstruction and inflammation. Our patient's laboratory results were consistent with hyperphosphatemia and normocalcemia, and there was no other clear precipitant of these abnormalities based on his history and medications. While the adverse effects of

phosphate-containing enemas including renal failure are well documented, our case is unique in that it highlights a disturbing consequence of a form of alternative medical therapy that has been receiving increasingly more popular media attention. The FDA currently does not regulate the use of colon-cleansing regimens, and alternative medicine practitioners are not required to verify the contents of their enema products. In 2006, the FDA issued a warning regarding the potential for kidney injury in patients taking oral sodium phosphate bowel cleanses, and the FDA required that a boxed warning be added to two oral sodium phosphate containing medications in 2008. While most of the literature surrounding phosphate nephropathy involves phosphate-containing bowel purgatives used for the purposes of colonoscopy preparation or constipation relief, there is little literature published on the adverse effects of colonic irrigation when used as a form of alternative medicine. Physicians should be aware of the side effects that colonic irrigation therapy can carry for their patients, and should consider the possible risks associated with any alternative medical therapy.

PHYTOBEZOAR IN THE SETTING OF DIABETIC GASTROPARESIS

Jenny Koo; Laura Y. Sue; Pearl Yu. UC San Diego, San Diego, CA. (*Tracking ID #1922249*)

LEARNING OBJECTIVE 1: Recognize the signs and symptoms of small bowel obstruction, and know the risk factors for developing a phytobezoar.

LEARNING OBJECTIVE 2: Understand the long term management after diagnosis of a phytobezoar

CASE: A 76 year old female with history of diabetes mellitus type 2 and no prior abdominal surgery presents to the emergency department with 2 days of left upper quadrant pain, nausea, and vomiting. She was diagnosed with diabetic gastroparesis and discharged home with metoclopramide. The patient returned the next day with worsening abdominal pain with vomiting and inability to tolerate oral intake. Computer tomography (CT) scan of the abdomen revealed small bowel obstruction. A nasogastric tube was placed, and patient was admitted. She was found to have a focal cut off point in the distal ileum and would require surgery to correct this. Exploratory laparotomy with enterotomy was performed. The jejunum was significantly dilated and hyperemic, a rock-hard intraluminal mass was found at the mid to distal jejunum a transition point. The mass was mobile and not consistent with a bowel wall tumor. The mass was described intraoperatively as "greenish, irregularly shaped bezoar consistent with a phytobezoar." Post-operatively, the patient resumed normal bowel function within 10 days, tolerated oral intake of a regular diet and fluids. Patient was advised to minimize insoluble fiber intake and increase fluid intake.

DISCUSSION: Phytobezoars are formed from high indigestible fiber. Some common predisposing factors to formation of phytobezoars include excessive fiber intake, decreased gastric motility (ie. diabetic gastroparesis, hypothyroidism), adhesions secondary to abdominal surgery, and inadequate mastication. Phytobezoars account for as much as 2–5 % of mechanical small bowel obstructions; however, clinical presentation of a phytobezoar with a surgical abdomen is rare (only 1.1%). Patients may present with nausea, vomiting, and abdominal pain. The most common locations for phytobezoar obstruction are in the stomach (due to inability to pass the pyloric sphincter) or at the terminal ileum. Diagnosis is made with computer tomography (CT) scanning, which would show mottled gas pattern and a dilated small bowel proximal to block. A well-defined mass with mottled appearance associated with an encapsulating wall is suggestive of a phytobezoar. Treatment may include gastric lavage, endoscopic removal, or in this case, surgical removal. Long term management includes reducing intake of insoluble fibers, and reducing risk factors for gastroparesis. This case illustrates an uncommon cause of mechanical small bowel obstruction. The patient's history of diabetes mellitus predisposes her to gastroparesis, which in turn increases her risk of forming a phytobezoar obstruction.

PITFALL OF OMEPRAZOLE: COMMONLY PRESCRIBED IN THE WORLD

Syo Tano¹; Koichiro Kimura¹; Masato Yoshihara¹; Munehisa Atsumi¹; Shinichi Mizuno²; Mitsunori Iwase¹. ¹TOYOTA memorial hospital, Toyota, Aichi, Japan; ²TOYOTA memorial hospital, Toyota, Aichi, Japan. (*Tracking ID #1929571*)

LEARNING OBJECTIVE 1: Recognize that the treatment approach to syndrome inappropriate secretion of ADH (SIADH).

LEARNING OBJECTIVE 2: Describe the signs and symptoms of hyponatremia associated with Omeprazole.

CASE: A 61 year-old man with no remarkable past medical history complained palpitation and hand tremor. The patient had abdominal pain and loss of appetite 1 week before and proton pump inhibitor (PPI), Omeprazole was prescribed the day before admission. Four hours after he took the medicine, palpitation, trembling,

nausea and continuous dizziness occurred gradually. Since the symptoms were not improved even on the next day, he came to our hospital. Vital signs and physical examinations were normal except for tremor of his right hand. He was restless, but his consciousness was alert. There were no remarkable neurological findings. Laboratory studies showed serum sodium decreased at 114 mEq/L, high CK and low serum osmolality. Urine osmolality was high and urine sodium was also high. Other studies including complete blood cell count, serum chemistry, and endocrine tests: thyroid pituitary, adrenal functions were normal, but secretion of ADH was elevated at 6.5 pg/mL. There were no abnormal findings on the chest X-ray and the head, chest and abdominal CT images. Thus, he was diagnosed as SIADH of unknown etiology. Initial treatment was fluid restriction, 3 % saline and discontinuation of Omeprazole. Since the sodium level elevation was faster than expected with 3 % saline, it was necessary to use sodium free infusion. At the same time, his urine osmolality was decreased from 493 mOsm/kg H₂O to 62 mOsm/kg H₂O. After 2 days of fluid treatment, the serum sodium level returned to normal range and he was discharged free of any symptoms.

DISCUSSION: SIADH is thought to be caused by variable etiologies such as CNS disorder, tumor, surgery, infection and medicine. The treatment includes combination of water restriction and intravenous saline, while the treatment of underlying diseases or problems are needed. It is important to avoid overly rapid correction of serum sodium level because it is known as the risk of central pontine myelinolysis (CPM). In the presented case, the cause of SIADH was thought to be Omeprazole because of his medical history and clinical course after the admission. Although many papers which suggest the usefulness of PPI such as Omeprazole, there are not many papers reporting about its side effects. A few reports described the appearance of hyponatremia and rhabdomyolysis associated with Omeprazole. Although the mechanism is uncertain, it is suggested that Omeprazole make sodium excrete in urine or increasing secretion of ADH. Shiba, et al. presented a case of hyponatremia caused by Omeprazole. In his case, the serum sodium level was not corrected despite extensive supplementation of sodium before discontinuation of Omeprazole. In our case, since the sodium level elevation was faster than expected, it was needed to use sodium free infusion to avoid CPM. The reason of the rapid improvement of the SIADH was thought to be discontinuation of Omeprazole. In summary, although the frequency is relatively low, PPI like Omeprazole, which is commonly prescribed all over the world, has critical side effects such as hyponatremia and rhabdomyolysis. Therefore it is necessary to recognize the importance of medical history and consider SIADH as a differential diagnosis in patient with nonspecific symptoms prescribed with Omeprazole.

PLEURAL EFFUSION AND DYSPNEA FROM AN UNLIKELY SOURCE

Laura Nichols; Kurt J. Pfeifer; Apoorv Broor. Medical College of Wisconsin, Wauwatosa, WI. (*Tracking ID #1928599*)

LEARNING OBJECTIVE 1: Describe a case of intrahepatic cholangiocarcinoma with an unusual presentation of dyspnea and pleural effusion

LEARNING OBJECTIVE 2: Diagnose cholangiocarcinoma using histologic stains to differentiate from metastatic malignancies such as colon or lung

CASE: A 57-year-old man with a history of diabetes mellitus and cirrhosis secondary to alcohol abuse presented with 10 days of pleuritic chest pain and dyspnea. Admission examination revealed tachycardia, oxygen saturation of 91 % on room air and dullness to percussion with decreased breath sounds over the left lung. White blood cell count was elevated to 63,800/mm³ with 80 % neutrophils. Liver enzyme testing revealed elevated alkaline phosphatase of 340 U/L. Chest CT revealed a very large, loculated left pleural effusion with periaortic and retrocardiac adenopathy. Pleural fluid analysis was consistent with an exudative process (LDH 1493 U/L and total protein 4.2 g/dL). Multiple samples were negative for malignant cells. CT scan of the abdomen was performed to investigate the patient's lymphadenopathy and demonstrated a 4.5×4.0 cm hepatic lesion with periaortic, retrocrural, and aortocaval lymphadenopathy. Extreme leukocytosis with peak WBC count of 106,000/mm³ was thought to be reactive, and peripheral smear and flow cytometry confirmed only 15 % monoclonal CD20-positive B cells compatible with a B cell lymphocytosis. Biopsy of the liver mass was performed and interpreted as adenocarcinoma with features favoring biliary origin (cholangiocarcinoma). Negative results for napsin A and TTF-1 made metastatic lung adenocarcinoma unlikely. Positive high-molecular-weight cytokeratin, in addition to positive results for CK 17 and HBME favored a biliary origin. Given the extent of his disease, the patient elected not to undergo treatment and was discharged to hospice.

DISCUSSION: Cholangiocarcinoma is an uncommon malignancy, accounting for only 3 % of gastrointestinal neoplasia. Of these, only 10 % involve the intrahepatic biliary system. Intrahepatic cholangiocarcinoma generally presents with dull right upper quadrant pain, weight loss, and elevated alkaline phosphatase levels or is

incidentally discovered on imaging. Though our patient had multiple risk factors for cholangiocarcinoma (cirrhosis secondary to alcohol abuse and diabetes), his was an atypical presentation with pulmonary metastasis and pleural effusion. Though 10–20 % of patients have peritoneal involvement at presentation, distant metastasis is uncommon and spread generally occurs through direct extension. Furthermore, our patient had significant leukocytosis consistent with leukemoid reaction. Though this has been described in previous case reports of GM-CSF-producing cholangiocarcinoma, it is an exceedingly rare entity. Cholangiocarcinoma can be difficult to differentiate from other adenocarcinomas such as those originating from the colon or lung. However, as in this case, special stains can be performed to more definitively diagnose this malignancy.

PNEUMONITIS, EOSINOPHILIA AND INFERTILITY Eunicee Chuang; Leila Ganjehe. Mount Auburn Hospital, Cambridge, MA. (*Tracking ID #1939989*)

LEARNING OBJECTIVE 1: To recognize In Vitro Fertilization as a possible cause of eosinophilic pneumonia.

CASE: 39 year old Filipino women presented to the ED with shortness of breath, dry cough and lightheadedness for 4 days. She is usually very active and noted mild orthopnea and dyspnea while running. Denied chest pain, edema, and fever. Patient is undergoing fourth cycle of in vitro fertilization. She had used Lupron, esterase and vaginal progesterone. This cycle was different in that the progesterone has been administered in a sesame oil vehicle, injected intramuscularly. This started about 3 weeks prior. She has no other significant past medical history or medication. Denied tobacco or alcohol. In the ED, afibrile, BP 108/66, HR 111, RR 30, sO₂ 86 % RA. In mild respiratory respiratory distress, lungs with few soft crackles and decreased breath sounds in the basis, cardiovascular exam unremarkable except minimal elevated jugular venous pressure of 6–7 cm of water with no hepatomegaly. Carotids are 2+ and equal without bruit. Extremity with no edema. WBC 14.52 k/CMM with 14 % Eosinophil, Eos Count 290/cmm, hemoglobin 14.1 g/dL, hematocrit 39.8 %, platelet count 321 K/cmm, first troponin 0.15 ng/mL. Chest Xray showed diffuse interstitial infiltrates as well as small bilateral pleural effusion. Patient was admitted with diagnosis of eosinophilic pneumonitis. She was started on methylprednisolone 1 g daily for 2 days and changed to prednisone as she was improving. Echocardiogram showed EF 45–50 % with global hypokinesis with no valvular disease. A drug-induced eosinophilic pneumonia was suspected. The OB/GYN recommended stop the i.m. form of progesterone also because of failure of the IVF (decrease in Hcg). Patient was discharged on prednisone. On 2 weeks follow up, patient was asymptomatic, repeat CXR was improved. She was tapered off the steroids over 30 days with no recurrence of the symptoms.

DISCUSSION: Eosinophilic pneumonia is a syndrome characterized by nonspecific pulmonary symptoms varying from mild to severe, life-threatening, respiratory failure. The diagnosis is usually suggested by peripheral alveolar opacities at the chest X-ray, with alveolar and usually peripheral blood eosinophilia. Acute eosinophilic pneumonia may be idiopathic or be related to various causes such as parasitic infections and drug-induced, such as amiodarone, methotrexate, NSAIDs. The addition of GnRH agonists to the IVF treatments has been used for the Luteal phase supplementation and it has mainly consisted of progesterone or hCG. Progesterone can be administered orally, i.m., or vaginally. We report a case of acute eosinophilic pneumonia induced by i.m. administration of progesterone used as luteal phase support after IVF. Symptoms improved as the i.m. form was discontinued and corticosteroids started. Sesame oil (used as excipient) and benzyl alcohol (used as preservative) could both be incriminated in the development of the type IV delayed hypersensitivity reaction. Although such reactions are exceedingly rare, specialists providing care to patients using these products should beware of potential adverse reactions and their subsequent management.

POLYCYSTIC OVARY SYNDROME IN ASIAN-AMERICAN ADOLESCENT WOMEN Victoria T. Liu; Karen Y. Cheng; Pearl Yu. University of California, San Diego, La Jolla, CA. (*Tracking ID #1939487*)

LEARNING OBJECTIVE 1: Recognize clinical features of polycystic ovary syndrome in Asian-American, adolescent women.

LEARNING OBJECTIVE 2: Evaluate polycystic ovary syndrome in adolescent women.

CASE: An 18 year old Chinese-American girl with unremarkable medical history presented for oligomenorrhea since menarche at age 12. Previously, menses had been 3–4 times yearly, but recently decreased to once yearly. Patient complained of weight gain, and slight hair growth between breasts and legs. She denied fatigue, cold intolerance, and acne. Family history was remarkable for breast cancer in mother.

Physical exam revealed deepening of voice; no thyromegaly, acanthosis nigricans, acne or hirsutism. Initial testing revealed borderline free testosterone (16 ng/dL, female reference 1.2–9.9 ng/dL), total testosterone (71 ng/dL, female reference 9–55 ng/dL), dehydroepiandrosterone (DHEA) (7.78 ng/mL, female reference 1.33–7.78 ng/mL), and luteinizing hormone: follicle stimulating hormone ratio of 2. Also notable were decreased sex hormone binding globulin (18), mildly elevated hemoglobin A1C (HgbA1C) of 6.2 %. Thyroid stimulating hormone, and anti-thyroperoxidase antibody were within normal limits. Pelvic transabdominal ultrasound showed no cystic ovaries. Patient was diagnosed with probable polycystic ovary syndrome (PCOS). Due to family history of breast cancer, we recommended progestin-only therapy to regulate menstrual cycles, induce withdrawal bleeding, and reduce the risk of endometrial hyperplasia. We also encouraged lifestyle modification for elevated HgbA1C suggesting insulin resistance, and referred patient to endocrinology for further evaluation.

DISCUSSION: Currently, 3 major sets of diagnostic criteria exist for PCOS. The National Institutes of Health (NIH) criteria require 1) oligomenorrhea or amenorrhea, and 2) either clinical or biochemical hyperandrogenism. The Rotterdam criteria require 2 of the 3 following: the 2 NIH criteria, and polycystic ovaries by ultrasound. The Androgen Excess and PCOS Society criteria are similar, but require hyperandrogenism to be present. Diagnosis of PCOS remains difficult because there is no full consensus on diagnostic criteria. The most common clinical features of PCOS in adolescent women are hirsutism, menstrual irregularities, obesity, acanthosis nigricans and persistent acne. PCOS hirsutism typically grows in a male pattern. However, Asian-American women are less likely to show overt hirsutism, so index of suspicion must be high. Approximately two-thirds of PCOS patients have anovulatory symptoms, ranging from amenorrhea to dysfunctional uterine bleeding. However, diagnosis in adolescents is complicated by the fact that even in the general adolescent population, approximately half of menstrual cycles are anovulatory in the first 2 years after menarche. Polycystic ovaries are less frequently found on ultrasound in adolescent compared to adult PCOS patients (69 vs. 87 %), and polycystic ovaries can be a transient finding in adolescents. Approximately 50 % of PCOS patients are obese. Lastly, 50–75 % of PCOS patients have insulin resistance. In evaluating probable PCOS, androgen excess should first be confirmed by laboratory testing. Notably, the standard testosterone assay may not be accurate in women, so confirmation by mass spectrometry is recommended. Subsequently, other causes of hyperandrogenism should be excluded by endocrine testing (eg. congenital adrenal hyperplasia, Cushing syndrome) and ultrasound (eg. ovarian tumor, adrenal tumor).

POORLY CONTROLLED CHRONIC MYELOGENOUS LEUKEMIA AND AN UNEXPECTED LEGAL GUARDIAN Charles J. Lenz; Roger Yu. Mayo Clinic, Rochester, MN. (Tracking ID #1939575)

LEARNING OBJECTIVE 1: Recognize the importance of identifying patients with court appointed legal guardians in the health care setting.

LEARNING OBJECTIVE 2: Recognize the role of a court appointed legal guardian in the decision making process for a legally incompetent patient who appears to possess capacity to make medical decisions.

CASE: A 34-year-old gentleman with a past medical history significant for substance abuse, chronic pain, and chronic myelogenous leukemia (CML) in the chronic phase was admitted to the hospital for worsening pain in the bilateral hips, knees, and clavicles. On admission, the patient was started on IV hydromorphone which controlled the pain quite well. The patient had a reported history of medication non-compliance and admitted to being on a self-reduced dose of ponatinib. Physical exam was unremarkable. There were no apparent abnormalities in mental status. CBC revealed blood counts consistent with well-controlled CML. Out of concern for medication non-compliance and undertreated CML a peripheral smear and peripheral blood PCR for BCR-ABL were performed. The peripheral smear and manual differential were negative for blasts. The PCR for BCR/ABL p210 mRNA transcripts revealed 81.8 % bcrabl (p210):abl on the international scale. On this scale, 0.1 % is considered a major molecular response and indicates good control. This patient's results were indicative of very poorly controlled CML and likely medication non-compliance. This was very concerning to the medical team, and the patient was educated about the importance of taking his medications as prescribed. At this point, the patient was transitioned from IV hydromorphone to oxycodone with continued control of his pain. Social work was involved to discuss outpatient options which could potentially increase medication compliance. It was through the assistance of social work that at this point it came to the medical team's attention that the patient had a court appointed legal guardian and conservator. The document appointing this patient's guardian had been on file within the hospital system at the time of admission and supplied the guardian with the power to make all medical decisions for the

patient. The medical guardian had the sole power to provide consent for treatment. The patient had been appointed a guardian due to lacking sufficient understanding or capacity to make or communicate responsible decisions concerning needs for medical care, nutrition, clothing, shelter, and safety in the setting of ongoing substance abuse. The medical team reached out to the patient's guardian who expressed concern that the patient was not taking his necessary medications at home and continuing to abuse substances. The guardian also requested that the patient be transitioned to a less potent narcotic pain reliever given his history of substance abuse. The patient was informed of this discussion and the plan to transition from oxycodone to tramadol. The patient became irate and wished to leave the hospital against medical advice (AMA). The medical team felt this would not be in his best interest unless all outpatient options to increase medication compliance were exhausted. The patient's guardian agreed that the patient should remain in the hospital. The patient did not meet criteria to be placed on a 72-hour-hold. However, given his guardian's wishes, security was notified that the patient would need to be held in the hospital if he attempted to leave. After a long discussion, the patient agreed to stay without the need to physically detain him. Eventually he was discharged to a location agreed upon by both the patient and his guardian with tramadol for pain control.

DISCUSSION: This case illustrates a couple of important legal and ethical points. First, it illustrates the importance of a systematic approach to clearly identify patients with legally appointed decision makers in the healthcare setting. This ensures that the appropriate person be consulted for important decisions regarding both treatment and consent. Secondly, this case illustrates the ethical responsibility of the medical team to hold an incompetent person in the hospital if the medical decision maker agrees that the patient should stay. This responsibility persists even when legally incompetent patients exhibit apparent capacity to make a decision, and when the patient does not meet criteria to be placed on a 72-hour-hold.

POSITIVE SPUTUM AFB STAINING: IS IT ALWAYS TUBERCULOSIS? Dipenkumar Modi; Hirva Mamdani; Theresa Vettese. Wayne State University, Detroit, MI. (Tracking ID #1939101)

LEARNING OBJECTIVE 1: To recognize nontuberculous mycobacteria as an important cause of AFB positive sputum

LEARNING OBJECTIVE 2: To recognize the importance of PCR in final identification of mycobacterial species in AFB stain positive sputum

CASE: A 64 year old Caucasian man presented with left sided pressure like chest pain after using cocaine. He had similar self-limited episodes of chest pain in the past. On review of systems, he reported having fever, night sweats, and unintentional loss of about 10 lbs over 6 weeks along with cough productive of yellowish sputum for 1 week. Chest X-ray showed left upper lobe nodular opacities with ill-defined/speculated borders. Review of past history revealed that he had been having chronic left upper lobe cavitation for 4–5 years which had never been worked up in the past. He also had a positive PPD while in prison about 15 years ago with suboptimal treatment for latent tuberculosis for 3 months. CT Thorax showed 3.6×2.2×2.7 cm size cavities in left upper lobe with hyper-densities within the lumen. Based upon above presentation, tuberculosis was the most likely possibility. Patient was kept under isolation and three sputum samples were sent for AFB stain and culture, out of which two samples came back positive for AFB. Subsequent mycobacterial PCR testing revealed it to be nontuberculous mycobacteria. Because of presence of hyper-densities within the cavity, aspergillus infection was also one of the possibilities, which was ruled out with low serum aspergillus antigen level. Finally diagnosis of *Mycobacterium Kansassii* lung infection was made based upon sputum PCR testing.

DISCUSSION: AFB smear-positive sputum, especially in the presence of a cavitary lung lesion is generally considered to be *Mycobacterium tuberculosis* unless proven otherwise. However, this test is not specific for tuberculous mycobacteria. Non-tuberculous mycobacteria (NTM) related lung disease can also have similar presentation with AFB positive sputum which poses a significant diagnostic challenge. *Mycobacterium kansasii* has traditionally been considered the most virulent of the NTM. It is the second most common NTM after *Mycobacterium avium* complex. It does not require contact tracing as it is not transmitted by person-to-person contact. *M. kansasii* infection most commonly manifests as a chronic pulmonary disease mimicking classic tuberculosis. Less commonly, the organism causes extra-pulmonary disease, such as scrofula-like lymphadenitis, sporotrichosis-like cutaneous infection, osteomyelitis, and tenosynovitis. Risk factors for *M. kansasii* lung infection include smoking, alcoholism, prior tuberculosis, and HIV infection. Its clinical and radiographic presentation is indistinguishable from MTB, including low grade fever, productive cough, and weight loss with radiologic evidence of cavitary lesion mostly involving upper lobes. Because of this, it is very important to consider the possibility of NTM in such patients and mycobacterial PCR is helpful in making the diagnosis. Treatment mainly includes daily isoniazid (300 mg/day), rifampin

(600 mg/day), and ethambutol (15 mg/kg/day) until culture negative on therapy for 1 year.

POST-PRISON BLUES: UTILIZING A PRIMARY CARE STUDENT-FACULTY COLLABORATIVE CLINIC TO CONCURRENTLY TREAT HEROIN ADDICTION, PTSD AND HEPATITIS C Kimberly Sue¹; Harper Hubbeling¹; Christine Kuo¹; Katy Brubaker¹; Luyi Xu¹; Carina Fernandez-Golarz¹; Marya J. Cohen¹; Alex Keuroghlian². ¹Harvard Medical School/MGH-Chelsea, Chelsea, MA; ²Massachusetts General Hospital, Boston, MA. (*Tracking ID #1930384*)

LEARNING OBJECTIVE 1: (1) Recognize that patients leaving prison are at high-risk for chronic and infectious diseases, psychiatric illness, substance use disorders and violent victimization

LEARNING OBJECTIVE 2: (2) Recognize, manage and coordinate care for some common multidisciplinary clinical problems for patients leaving prison and identify common psychosocial stressors for patients recently released from prison within our co-located primary care and psychiatric clinic

CASE: HPI: Mr. M is a 54-year-old man with a history of mood disorders, heroin addiction, Hepatitis C and over 25 total years in prison presenting to establish primary care, psychiatric care and suboxone maintenance treatment. Our clinic is uniquely oriented towards serving post-incarcerated patients with co-located medical and psychiatric services provided by medical students working with staff faculty supervision. PMH: Significant for cocaine and heroin dependence. He relapsed on heroin 6 months after release from prison in the context of depression and posttraumatic stress disorder (PTSD). Experiences nightmares and flashbacks. Two suicide attempts in prison and four lifetime overdoses. Hepatitis C diagnosed while incarcerated in 2003, treatment naive. Social History: Grew up in single-parent Italian household, survived childhood sexual abuse. He has spent a total of 27 years in prison mostly related to crimes to support drug use. He is currently unemployed. Sexually active with girlfriend. Twenty pack-year smoking history. Physical Exam: General: Tall man, overweight, many tattoos, well-groomed, track marks on R hand, anxious affect Abd: Soft, nontender, no masses, no hepatosplenomegaly. No evidence of stigmata of chronic liver disease Diagnostic Studies: Urine Tox: Positive for opiates, cocaine, buprenorphine LFTS: AST 92, ALT 112 Hep Serologies: HBVsAb Positive, HBVsAg Negative, HCVAb Positive, Genotype 1A, VL 7,910,000, HIV Negative

DISCUSSION: Mr. M is a 54-year-old man seeking to establish primary care and treatment for heroin addiction, depression and PTSD. His case is further complicated by hepatitis C infection and history of lengthy incarceration. In our co-located clinic, we provided Mr. M with weekly CBT for PTSD, prazosin for nightmares, doxepin for depressed mood and insomnia, and 12 mg daily suboxone for heroin addiction. We also manage his Hepatitis C and future treatment given elevated risks for depression or suicidality. Our student-faculty clinic provides streamlined treatment for this patient's medical and psychiatric illnesses as well as addressing social factors such as unemployment. The patient benefits from active communication and collaboration between teams about his treatment as well as the clinic's efforts to create a positive environment and a consistent relationship with the patient. Such patients often are unable to keep their appointments for many reasons including experiencing medical mistreatment in prison, a general mistrust of healthcare systems, feeling stigmatized or judged, lack of transportation or even lacking basics like clothing or a cellphone. Individuals emerging from the prison system are both sicker and at greater risk of death than the general population; for the first 2 weeks post-release patients face an alarmingly acute mortality risk: 3–8 fold above the general population (Binswanger et al. 2007). Perhaps the most confounding aspect of taking care of these patients is the complex interrelationship between chronic conditions and treatments: for example, PEG-IFN/RBV treatment for Hepatitis C potentially exacerbating mental illness (Maru et al. 2010). Inmates use street drugs to self-medicate for untreated psychiatric illness and psychiatric issues characterized as "post-incarceration syndrome" limit help-seeking behavior and willingness to trust service providers (Rich et al. 2001). Consistent with these findings, Mr. M faces increased risks of morbidity and mortality upon release from prison. Such patients have pressing social situations such as homelessness and ongoing drug use that must be addressed simultaneously or even prior to addressing medical and psychiatric needs. In our clinic, we assisted the patient with Social Security disability and transportation needs. The structure of our student-faculty clinic, with special attention to patients with histories of incarceration, is an exemplar model for addressing health disparities and providing excellent clinical care for this vulnerable population. POST-TRANSFUSION PURPURA: A DIFFICULT DIAGNOSIS Gaurav Goyal; Peter Silberstein. Creighton university medical center, Omaha, NE. (*Tracking ID #1927374*)

LEARNING OBJECTIVE 1: Recognize the entity of post transfusion purpura in the appropriate clinical setting.

LEARNING OBJECTIVE 2: Distinguish between PTP and other causes of thrombocytopenia like ITP and drug induced Thrombocytopenia.

CASE: HPI: 78 y/o Caucasian female presented to the ER after she developed sudden onset bleeding from the oral mucosa and bloody stools. She was recently discharged from the hospital 9 days ago when she was admitted due to trauma causing subdural hematoma and received 1 unit of platelet transfusion at that time. Her platelet level on discharge was 190,000/microL. She had an uneventful course after that until she developed spontaneous bleeding. Past medical history was significant only for anemia of chronic kidney disease and gout. Initial Laboratory studies: Platelet count on admission was found to be 4000. Other laboratory studies showed LDH 343, INR 1.0, PTT 23, Absolute reticulocyte count 129.8, Hgb 7.3, Fibrin Degradation products 10–40, Haptoglobin 58, Total bilirubin 0.7, creatinine 2.3, AST 22, ALT 13. Peripheral smear showed no evidence of schistocytes. Hospital course: The patient was already started on Dexamethasone 40 mg daily on the suspicion of immune thrombocytopenia. The platelet count dropped further to 2000 the next day. PTP was then suspected and the patient was started on high dose IVIG at 1 g/kg/day for 2 days along with the continuation of the Dexamethasone for a total of 4 days. Platelet count went up to 14,000 and 35,000 on days 2 and 3 respectively and the bleeding stopped spontaneously with that, thus pointing towards PTP. Patient was tested for antibodies to platelet antigen PIA1, now known as Human platelet antigen 1a (HPA-1a) and she tested positive for the same, thus confirming our suspicion of PTP. Patient was later seen as an outpatient follow up and her platelet count was 148,000 after 2 weeks and she did not have any further episodes of bleeding. For further confirmation, we performed platelet genotyping which showed that the patient was homozygous for the rare allele b/b (most common one being a/a which is present in 98 % of the population).

DISCUSSION: Post-Transfusion purpura is a rare transfusion reaction that can occur after transfusion of any platelet-containing product (red cells, platelets, or granulocyte concentrates). Female to male ratio in the total of about 250 reported cases is 26:1. Ninety-eight to ninety-nine percent of Caucasian women are PIA1/HPA-1a positive, as are their spouses. PTP might be thought of as a delayed transfusion reaction involving platelets. Patients with PTP can present with severe thrombocytopenia that develops 5 to 10 days following transfusion. PTP can be confused with drug-induced or immune thrombocytopenia, since the blood and bone marrow smears are consistent with immune platelet destruction in all these disorders. Since drug induced thrombocytopenia and de novo ITP appearing in someone who has recently been transfused is relatively rare, the appropriate hiatus time until the appearance of thrombocytopenia, and its severity, must alert the physician to the correct diagnosis. Nonetheless, the diagnosis of PTP is confirmed by identification of alloantibodies to HPA-1a/PIA1 and the absence of the platelet antigen HPA-1a, both of which conditions were satisfied in the above case. The management of PTP includes high dose IVIG (400 to 500 mg/kg per day, usually for 5 days or 1 g/kg per day for 2 days) and it usually takes about 4 days for the platelet count to increase up to the level of 100,000/microL. The clinical course of PTP may be severe with a mortality rate of 10–20 %. It emphasizes the importance of being alert to the possibility of PTP in appropriate clinical setting, along with being aware of the possible pitfalls in the diagnosis of this under-diagnosed condition. POTENTIALLY DELAYED DIAGNOSIS IN AN OBESE ASTHMATIC PATIENT Jenny Koo¹; Laura Y. Sue¹; Pearl Yu². ¹UC San Diego School of Medicine, San Diego, CA; ²UC San Diego Medical Center, La Jolla, CA. (*Tracking ID #1924018*)

LEARNING OBJECTIVE 1: Evaluate acute or worsening dyspnea in a patient with asthma

LEARNING OBJECTIVE 2: Describe the differential diagnosis for a mass in the anterior mediastinum

CASE: A 52 year old woman with asthma, morbid obesity, gastroesophageal reflux disease [GERD], and untreated obstructive sleep apnea [OSA] presented with 2 weeks of non-bloody productive cough, worsening dyspnea, and “rattling” in the chest. In the preceding 6 months, the patient had had three upper respiratory infections [URIs]. The infections had caused worsening of asthma symptoms, including increased chest tightness and recently, orthopnea. Symptoms did not respond to oral corticosteroids, including a prolonged gradual taper. The patient also reported 3 months of intermittent dysphagia with solid foods and recent onset of night sweats. There was no dysphagia with liquids, fever, chills, or weight loss. The lungs were clear to auscultation bilaterally and peak flow was approximately 80–90 % of predicted. The patient was thought to be having another asthma exacerbation. She was advised to use her short-acting beta-agonist inhaler as needed and to monitor peak flow values. Because of the chronicity of symptoms, a chest x-ray was ordered. It showed marked widening of the mediastinum. Follow-up CT chest revealed a large infiltrative anterior mediastinal mass that compressed the left mainstem bronchus, left brachiocephalic vein, and possibly the aorta and main pulmonary artery. Core needle biopsy of the mediastinal mass revealed aggressive B cell lymphoma. Subsequent imaging and biopsies did not show involvement beyond the mediastinum. The patient was started on a multi-cycle regimen of methotrexate and R-EPOCH chemotherapy for her Stage I-EB lymphoma.

DISCUSSION: The anterior mediastinum includes the thymus, extra-pericardial aorta and its branches, great veins, and lymphatic tissue. Therefore, the differential for an anterior mediastinal mass includes thymoma, germ cell tumor, mediastinal cyst, or lymphoma. It can also rarely include extension of thyroid or parathyroid tissue. The patient with an anterior mediastinal mass can be asymptomatic or can present with chest pain, cough, or compressive symptoms of dyspnea and dysphagia, as this patient did. Given the history of moderate persistent asthma, the patient's symptoms were initially attributed to an asthma exacerbation in the context of repeated URIs and increased workplace stress. She was appropriately advised to continue corticosteroid/long-acting beta-agonist therapy for her asthma and to manage co-morbidities, including GERD and OSA. It is possible that the patient's morbid obesity and perimenopausal state also contributed to a delayed diagnosis, as she had night sweats but no other constitutional symptoms such as weight loss. Furthermore, the patient's morbid obesity may have been a risk factor for lymphoma development. Possible mechanisms for the elevated risk include increased levels of circulating adipocytokines in obesity and the development of insulin resistance with insulin-like growth factor-I production, which promotes cell proliferation. This case illustrates the importance of chest imaging in cases of prolonged, unresponsive acute exacerbations of chronic asthma, especially in patients with previously well-controlled asthma.

PRE-ECLAMPSIA AND HELLP SYNDROME AS AN INITIAL PRESENTATION OF PRIMARY ANTI-PHOSPHOLIPID SYNDROME Amy Loden, Washington University, Saint Louis, MO. (Tracking ID #1936036)

LEARNING OBJECTIVE 1: Recognize the internists role in the treatment of medical complications arising during pregnancy

LEARNING OBJECTIVE 2: Diagnose and confidently treat ante-partum complications and manage post-partum health of women based on obstetric diagnoses

CASE: A 28 year old G1P0101 was referred by her obstetrician to an internist for persistent hypertension following preterm delivery at 29 and 6/7 weeks secondary to pre-eclampsia and HELLP Syndrome (hemolysis, elevated liver transaminases and low platelets). She had no prior medical or surgical history, and no known allergies. She was taking amlodipine 5 mg daily and hydrochlorothiazide 25 mg daily which were started by her obstetrician when hypertension failed to resolve immediately post-partum. She had no toxic habits. Her father has hypertension. She had normal vital signs with a blood pressure of 125/75 and fundoscopic, cardiovascular, neurologic, musculoskeletal and dermatologic examinations were unremarkable. She was advised to stop anti-hypertensive therapy and subsequent ambulatory blood pressure monitoring was normal. Initial studies were notable for positive ANA with a titer of 1:80. Subsequent evaluation showed no anti-dsDNA antibodies, normal ENA panel and 24 h urine, but was notable for positive anti-β2 glycoprotein IgG antibody at 17.8 units/mL (normal level is <10 units/mL). Repeat testing 12 weeks later again revealed IgG antibodies against the β2 glycoprotein at 22.4 units/mL. Anti-cardiolipin and anti-lupus anticoagulant antibodies were never positive. She was diagnosed with primary antiphospholipid syndrome. Treatment was initiated with daily aspirin. She was advised of her increased future risk for hypertension and both cardiovascular and

cerebrovascular disease given her history of pre-eclampsia and will follow-up annually with her internist. The patient's obstetrician and internist agreed with the pre-conception treatment plan and to initiate heparin upon discovery of pregnancy.

DISCUSSION: Patients with a history of pre-eclampsia should be followed post-partum for monitoring and preventative care for cardiovascular and cerebrovascular disease.[1,5] Internists should be aware that women meeting certain obstetric criteria (more than three miscarriages prior to 10 weeks gestation, fetal death after 10 weeks gestation, or preterm delivery from eclampsia or pre-eclampsia) need immunologic evaluation for APS.[2,3] If anti-cardiolipin, anti-β2 Glycoprotein, or anti-lupus anticoagulant antibodies are detected, a repeat assessment should be performed no sooner than 12 weeks. [2,3] Patients with APS should take daily low dose aspirin and should not use contraceptives or hormone replacement therapy containing estrogen. [2,4] Upon discovery of pregnancy, internists should be comfortable maintaining a low dose aspirin regimen and initiating heparin for patients with APS.[2,4] Because these patients have a high risk of early miscarriage, failure to follow these guidelines, even to wait until the patient's first obstetric visit (commonly between 8 and 10 weeks), significantly increases the chance of pregnancy loss.[2,4] Multi-specialty collaboration is essential for early diagnosis for women at risk for ante- and post-partum medical complications. Internists do not frequently consider obstetric complications as they may relate to a patient's current or future medical problems and obstetricians may not adequately stress to patients the future risks indicated by ante-partum medical complications. As illustrated by this case, the referral by the patient's obstetrician for persistent post-partum hypertension was appropriate for multiple reasons. First, ensuring that the obstetric diagnoses of preterm delivery secondary to pre-eclampsia and HELLP Syndrome are communicated to the patient's internist inform aggressive monitoring and preventative care for cardiovascular and cerebrovascular disease in the post-partum setting and allow for new diagnoses to be discovered. Second, the treatment protocol for APS to be instituted upon discovery of pregnancy will reduce the risk of early pregnancy loss regardless of whether the patient's obstetrician or internist discover the pregnancy. Finally, the communication between the patient's obstetrician and internist revealed the patient's need for preconception counseling for future pregnancies based on a new diagnosis. 1. PREMATURE CLOSURE AND DELAYED DIAGNOSIS: A CASE OF ABOMINAL PAIN Jason Dukes², Lee S. Shearer¹. ¹Weill Cornell Medical College, New York, NY; ²Weill Cornell - New York Presbyterian Hospital, New York, NY. (Tracking ID #1937942)

LEARNING OBJECTIVE 1: To recognize clinical features of abdominal pain that should prompt further evaluation.

LEARNING OBJECTIVE 2: To recognize the risk of cognitive biases such as premature closure of inquiry.

CASE: Initial Presentation and Diagnosis: -A 70 year-old woman with PMH HTN presented to the ED with RUQ/epigastric pain radiating to the back. -She had poor appetite, but normal bowel movements, no nausea, vomiting, diarrhea, fever, chills, CP, SOB. Pain was not associated with food. -On exam, the patient was afebrile with normal vital signs, and RUQ/epigastric ttp without rebound or guarding. -Labs, including CBC, BMP, LFTs, amylase, lipase, were within normal limits. -Patient was treated with nexium, famotidine, Maalox, and viscous lidocaine with little relief. -A RUQ U/S and AXR were obtained which demonstrated multicystic structure posterior to the pancreas. -CT A/P (Figure 1) demonstrated a multiloculated cystic mass of the body/tail pancreas measuring 9.0×10.6 cm. -EUS/FNA was performed. The pancreatic cystic fluid demonstrated acellular proteinaceous material negative for malignant cells. She was diagnosed with a benign pancreatic cyst as the cause of her pain. -Given the patient's persistent abdominal pain, there was a plan for surgical intervention, but patient declined. Instead, she was managed medically as an outpatient with vicodin and tramadol. Interval History: -Over the course of a year, the patient was noted to have a significant decline in function with increasing pain not relieved in any position, decreased PO intake, and constipation. -Repeat CT A/P (Figure 2) showed an interval increase in size of a multiseptated pancreatic tail cystic lesion with internal areas of calcification, again probably representing a benign neoplasm. Additionally, new lytic changes involving the T11, T12 and L1 vertebral bodies

with associated peripherally enhancing right paravertebral fluid collection involving the right psoas muscle and right erector spinae muscle with possible epidural extension. -An MRI (Figure 3) identified lesions involving the vertebral bodies and posterior elements of T11, T12 and L1 with pathologic compression fractures of T11 and T12. There was also epidural extension and retroploration of the pathologic fracture of the T11 vertebral body resulting in marked canal stenosis with cord compression and intramedullary edema and a discrete lytic lesion in the T9 lamina/spinous process. -The patient was emergently taken to neurosurgery for decompression with T9-L2 fusion. Revisiting the Diagnosis: -The patient's presentation and radiographic findings were puzzling and it was difficult to pinpoint a unifying diagnosis to reconcile all of her symptoms. The differential diagnosis revolved around infectious and malignant etiologies. -Arguments for tuberculosis were location (lower thoracic and lumbar vertebrae), involvement of disc space and paravertebral fluid collection in the psoas muscle. However, there was no significant anterior subligamentous spread or anterior vertebral body destruction which is more typical of tuberculosis. -A malignant etiology such as multiple myeloma or lymphoma was also considered. However, when comparing prior imaging studies, there appeared to be contraction of the T9 spinous process lesion, suggesting a more indolent process that healed in one area but progressed in another, which is not consistent with malignancy. -Ultimately, pathology identified diffuse large B cell lymphoma and the patient is currently undergoing RCHOP treatment.

DISCUSSION: 1) The patient's abdominal pain was persistent, poorly controlled, and associated with a progressive decline in function. Her age (>50), gender, duration of pain >1 month, and pain that was not relieved by lying down were additional concerning clinical features that prompted further evaluation. 2) In clinical decision making, it is important to acknowledge cognitive biases such as premature closure that may impact patient care. Premature closure of inquiry, or search satisfaction, occurs when development and evaluation of a broad differential diagnosis is terminated once one diagnosis seems to explain the symptoms. Alternative diagnoses are not further pursued. In this case, premature closure may have occurred when the patient's abdominal and back pain were attributed to the enlarging pancreatic cyst. Avoiding such cognitive pitfalls may have identified this lymphoma at an earlier stage.

PRIMARY COLORECTAL LYMPHOMA PRESENTING WITH PRESYNCOPE: SOMETIMES HOOBEATS DO COME FROM ZEBRAS

Lauren E. Radziejewski; Nina M. Schwenk; Christopher M. Wittich. Mayo Clinic, Rochester, MN. (*Tracking ID #1934858*)

LEARNING OBJECTIVE 1: Recognize unusual and serious causes of presyncope.

LEARNING OBJECTIVE 2: Diagnose primary colorectal lymphoma presenting as a presyncopeal event.

CASE: A 70-year-old retired nurse presented to the outpatient clinic after a presyncopeal event. It occurred upon rising from a chair after consuming one alcoholic beverage. During the week following the event, she continued to experience transient lightheadedness and bilateral pulsatile tinnitus. Her past medical history was significant for hypothyroidism, osteopenia, melanoma in situ status post wide local resection, hiatal hernia, and diverticulosis. Her age-appropriate cancer screening was up-to-date. Her last colonoscopy, 7 years prior, was technically difficult due to sigmoid stricture. At presentation, her blood pressure was 143/61 mmHg, pulse 82 beats per minute, and oxygen saturation 96 %. She appeared well, was alert, and neurologically intact. Skin turgor was normal and mucous membranes were pink. Examination of the heart, lungs and abdomen were normal. She recently noticed occasional red blood spotting on toilet paper after wiping, which she attributed to bleeding hemorrhoids. Laboratory studies revealed normocytic anemia, with a hemoglobin 8.3 g/dL and MCV 87.5 fL. An upper endoscopy demonstrated a single, non-bleeding Cameron erosion and non-obstructing Schatzki ring. An initial colonoscopy was aborted due to difficulty advancing beyond the known stricture. A fecal hemoglobin study was obtained and was found to be positive despite absence of active bleeding in the esophagus. Repeat colonoscopy, under anesthesia, was therefore performed. This revealed an ulcerated, non-obstructing mass in the proximal ascending colon measuring 5 cm in length. Histologic examination demonstrated diffuse large B-cell lymphoma. Subsequent PET confirmed the avid circumferential mass in the ascending colon with adjacent conglomerate FDG avid lymphadenopathy. Bone marrow biopsy revealed no atypia. She was initiated on R-CHOP therapy, and has received 3 cycles to date with excellent initial response to therapy.

DISCUSSION: Dizziness accounts for more than 2 million emergency department visits in the United States annually. Potentially morbid causes of syncope include myocardial infarction, cardiac dysrhythmia, pulmonary embolism, stroke, and hemorrhage. Less serious causes include anxiety, vestibular dysfunction, POTS and venous insufficiency. Primary colorectal lymphoma is a very rare occurrence, responsible for only 0.1–0.5 % of all colorectal malignancy. Of these, most tumors

occur within the cecum, perhaps due to a high percentage of lymphatic tissue. Diffuse large B-cell lymphomas represent the most common histological subtype. Typical presenting symptoms include abdominal pain, unintended weight loss, and changes in bowel habits. Risk factors include male gender, history of inflammatory bowel disease, and immunodeficiency. Treatment modalities include surgical resection, radiation, and chemotherapy. Prognosis varies with treatment. CHOP therapy has been the mainstay with long term survival averaging 40–55 %, while the addition of Rituximab appears to improve prognosis by 10–15 %. We describe a case of presyncope in a previously healthy 70-year-old woman. Evaluation ultimately revealed a rare colonic malignancy for which the patient demonstrated atypical symptoms and possessed no risk factors. This case highlights the importance of avoiding premature case closure during the initial evaluation of dizziness and near syncope, particularly in a previous healthy individual.

PRIMARY DUODENAL PLASMACYTOMA AS AN UNCOMMON CAUSE OF GASTROINTESTINAL BLEEDING Devalkumar Rajyaguru. University of Pittsburgh Medical Center-Mercy, Pittsburgh, PA. (*Tracking ID #1928737*)

LEARNING OBJECTIVE 1: Recognize this rare entity as a cause of gastrointestinal tumors

LEARNING OBJECTIVE 2: Manage primary gastrointestinal plasmacytoma

CASE: A 70-year-old Caucasian male presented with 4 week history of exertional shortness of breath and fatigue. His past medical history was notable for coronary artery disease, atrial fibrillation, hypertension and type 2 diabetes mellitus. Patient was taking Coumadin for his atrial fibrillation. Physical examination showed conjunctival pallor, but was otherwise unremarkable. He was also noted to have positive hem occult stools. Abnormal laboratory values on admission included a hemoglobin level of 6.8 g/dL and an international normalized ratio (INR) of 3.3. Patient was transfused 2 units of packed red blood cells and upper gastrointestinal endoscopy was performed, which showed a large malignant looking fungating, infiltrative, ulcerated mass with bleeding areas in the second part of duodenum. Biopsies were taken with a cold forceps for histology. In addition, biopsy with jumbo forceps was also performed and more than 15 pieces were sent to pathology for further evaluation. The histology demonstrated multiple portions of duodenal mucosa with masses of apparent plasma cells, which stained positive for lambda light chains. Neoplastic cells were reactive for plasma cell marker CD138, finding consistent with plasma cell neoplasia. The negativity for the B-cell marker CD20 excluded the possibility of marginal zone B-cell lymphoma of mucosa. Serum electrophoresis and immunofixation did not show any monoclonal immunoglobulins. Urine immunofixation identified a monoclonal protein as a free monoclonal lambda type, a finding identified in approximately 25 % of plasmacytoma cases. The serum light chain assay yielded kappa of 18.3 mg/L and lambda as 783 mg/L, with a Kappa/Lambda ratio of 0.02. Skeletal survey did not show any evidence of a lytic or blastic osseous lesion. Positron emission tomography (PET)/CT scan was performed which showed $6.4 \times 5.6 \times 10$ cm mass at the region of second portion of duodenum with mild fluorodeoxyglucose (FDG) uptake with standardized uptake value (SUV) of 2.4. Subsequent bone marrow biopsy showed mildly hypercellular bone marrow with normal trilineage hematopoiesis with less than 5 % plasma cells. Together, these findings confirmed a final diagnosis of a primary extramedullary plasmacytoma of the duodenum.

DISCUSSION: Plasmacytomas are localized collections of neoplastic monoclonal plasma cells that form masses in bone or other organs. It accounts for approximately 3 % of plasma cell malignancy. Plasmacytomas can be either primary, without signs of bone marrow involvement such as solitary plasmacytoma of bone or solitary extramedullary plasmacytoma, or may occur in association with multiple myeloma representing extraskeletal spread of the disease. Primary extramedullary plasmacytoma is a rare form of the disease with 7 % only manifesting in the gastrointestinal tract. The presenting symptoms of gastrointestinal plasmacytomas may present with anorexia, weight loss, nausea, abdominal pain, vomiting, occult blood loss and rarely with overt gastrointestinal bleeding. Endoscopically, plasmacytoma may appear as discrete ulcers, ulcerated mass, thickened gastric folds, multiple polyps, small plaques or diffuse infiltrative lesions. Thus, as the endoscopic appearance of plasmacytomas varies significantly and may be similar to other more common conditions such as poorly differentiated or metastatic neoplasms, lymphoma and gastrointestinal amyloidosis. Thus, pathological and immunohistochemical examination of endoscopic biopsies is crucial for making an accurate diagnosis. In a patient with solitary plasmacytoma, multiple myeloma has to be ruled out because this requires systemic treatment. No general consensus guidelines for treatment currently exist. However, based on the well-known radiation sensitivity of plasma cell tumors, radiotherapy is accepted as a standard therapy. Surgery for extramedullary plasmacytomas can also offer cure and may be the preferred treatment for some

patients. If complete resection is not feasible, then combined radiation or chemotherapy is recommended, especially for large or poorly differentiated tumors. To date, there are no long term follow-up studies of gastrointestinal plasmacytomas. The course of extramedullary plasmacytoma is generally favorable with a 70 % disease-free survival at 10 years. The rate of progression of extramedullary plasmacytoma to multiple myeloma ranges from 11 to 30 %, at 10 year. After any successful initial treatment, progression of solitary plasmacytomas to multiple myeloma is possible and long term follow up is necessary. This case illustrates the importance of awareness of this rare entity when considering evaluation of gastrointestinal tumors. A diagnosis of primary gastrointestinal plasmacytoma entails detailed work-up for multiple myeloma and a strict oncologic surveillance.

PRIMARY HYPERPARATHYROIDISM IN PREGNANCY PRESENTING AS ACUTE PANCREATITIS IN SECOND TRIMESTER Nick Youssefi; Christopher Russo. University of California, San Francisco Fresno, Fresno, CA. (*Tracking ID #1934186*)

LEARNING OBJECTIVE 1: The purpose of this clinical vignette is to aid physicians recognize how to diagnose and manage concurrent hyperparathyroidism and acute pancreatitis, especially in the pregnant population.

CASE: A 28 year old, gravida 1 para 0 female presents to the emergency room with 1 day history of abdominal pain, epigastric, radiating to her back. Associated nausea, vomiting, decreased appetite. Patient never had these symptoms before. No history of alcohol consumption and patient was only taking prenatal vitamins. Patient had received in vitro fertilization prior to this pregnancy and her gestational age was 17 weeks. Physical examination reveals patient is alert and abdominal exam reveals epigastric tenderness with minimal rebound tenderness and guarding. Laboratory studies reveals elevated serum Lipase 3356 U/L (12–53), serum Amylase 2967 U/L (20–130), serum WBC 24,000 k/UL (4–11), serum Calcium 13.5 mg/dL (8.5–10.5), serum Parathyroid hormone 177 pg/mL (14–72), and low serum Phosphorus 1.5 mg/dL (2.7–4.5). Ultrasound abdomen reveals enlarged pancreas measuring 5.5 cm in thickness. Ultrasound of the neck reveals a 2.1 cm lesion in the inferior segment of the right lobe posterior to the thyroid gland. A diagnosis of hyperparathyroidism-induced acute pancreatitis is made based on clinical, laboratory, and radiological evidence. Endocrinology is consulted and started Calcitonin 200 units twice daily, fluid resuscitation, and Lasix 20 mg every 8 h. Surgery is consulted and parathyroidectomy is performed and histopathology is consistent with parathyroid adenoma. Patient tolerates procedure well and is discharged home with calcium supplementation. The patients serum calcium and PTH levels normalize 2 days post-operative with serum WBC and lipase levels gradually normalizing 1 month later. Patient is currently 30 weeks gestation with no symptoms and is expecting twins.

DISCUSSION: Acute pancreatitis and hyperparathyroidism in pregnancy is very rare. After a thorough review of the literature, there were only 2 published papers describing 14 total patients who were diagnosed with hyperparathyroidism induced acute pancreatitis in pregnancy. The incidence of acute pancreatitis in patients with hyperparathyroidism is reported to be only 1.5 %. During pregnancy, active ionized calcium decreases, which causes a resulting increase in secretion of the parathyroid hormone. Furthermore, the existence of parathyroid hormone increases the risk of pancreatitis. Acute pancreatitis should be in the differential diagnosis of unexplained nausea, vomiting, abdominal pain during pregnancy and hypercalcemia should prompt evaluation for concurrent hyperparathyroidism.

PRIMITIVE NEUROECTODERMAL TUMOR OF THE SPINE 25 YEARS AFTER PINEOCYTOMA RESECTION Avan Armaghani¹; Benji Zusman¹; Danny Estupinan²; Jesse Kresak³; Meredith Wicklund²; Peter W. Stacpoole¹. ¹University of Florida, Gainesville, FL; ²University of Florida, Gainesville, FL; ³University of Florida, Gainesville, FL. (*Tracking ID #1936947*)

LEARNING OBJECTIVE 1: Recognize that although pineocytoma is a benign tumor of the pineal gland, it is part of a spectrum of diseases and can undergo malignant transformation to pineoblastoma or primitive neuroectodermal tumor.

LEARNING OBJECTIVE 2: Recognize that patients with a history of pineocytoma who have signs, symptoms and imaging that are suggestive of normal pressure hydrocephalus (NPH), should have a contrasted MRI of the spinal cord to rule out possible primitive neuroectodermal tumor of the spine.

CASE: A 72 year-old male with past medical history significant for resection of a pineocytoma 25 years ago, type II diabetes mellitus, hypertension, hyperlipidemia and obstructive sleep apnea, presented with a four-month history of progressive worsening gait disturbance, frequent falls, urinary and fecal incontinence and

cognitive decline. Approximately 1 year ago, the patient began experiencing progressively worsening back pain, which was refractory to physical therapy, NSAIDs and cortisone injections. An MRI of the spine was performed at that time and suggested arthritic changes with worsening spinal stenosis. The patient subsequently underwent an L3-L4 spinal fusion, but his symptoms did not improve post-operatively. Over a four-month period following the surgery, the patient became increasingly weak, developed gait impairment, experienced frequent falls, urinary and fecal incontinence and short-term memory deficits. Given the patients progressive cognitive decline, he was hospitalized for further workup. A head CT showed ventriculomegaly without apparent obstruction or pineal tumor recurrence. A diagnosis of NPH was initially proposed, but two high volume lumbar punctures provided no relief of his symptoms. CSF studies showed markedly elevated protein (242 mg/dl) with pleocytosis out of proportion to the red blood cells (RBC: 30,000 mm³; WBC 60 mm³, poly 58 % lymph 42 %). Gram stain and bacterial culture were negative. A CSF flow study showed communicating flow without compressive lesions. White blood cell count was 17 thou/mm³, and urine culture grew >100,000 col/ml enterococcus faecalis. The patient was discharged home with antibiotics with plan to follow-up in 1 month. The patient's clinical status continued to worsen and he was re-admitted approximately 1 week later. Physical exam was notable for severe bradyparesis and bradykinesia, frontal release signs, Parinaud's syndrome, and diffuse hyper-reflexia. A repeat lumbar puncture was performed and CSF studies revealed xanthochromia, elevated protein 284 mg/dl, RBC 10,150 mm³. Cytology returned no malignant cells. Bacterial, fungal, AFB culture, cryptococcal antigen, CMV PCR, and VDRL were all negative. Contrast MRI of the cervical, thoracic and lumbar spine showed innumerable enhancing nodules along the surface of the spinal cord in all regions. Notably in the lumbar region, the largest nodule measured 8×10 mm and displaced the cauda equina nerve roots to the right. CT chest, abdomen and pelvis did not identify a primary source of malignancy. An L2 laminectomy with intradural tumor resection was performed. Pathology results showed malignant small blue cell tumor, with neuroendocrine features consistent with primitive neuroectodermal tumor (PNET). The patient's clinical status continued to decline. He was discharged to hospice before passing away 1 week later.

DISCUSSION: PNETs are a group of rare, highly aggressive tumors composed of undifferentiated "small round blue cells" that resemble the embryonic neural tube. These tumors can be present both peripherally and centrally. Within the CNS, they are most common in the cerebellum but can also present in the spinal cord. Only about 1 % of all PNETs are found in the spinal cord and can be seen intramedullary, intradural-extramedullary and extradurally. Spinal PNETs often present with neurologic signs and symptoms referable to a spinal or root level. Our patient presented with progressive neurological dysfunction initially concerning for NPH. However, CSF pleocytosis and elevated protein in the absence of identifiable cerebral origin was concerning for a spinal CSF blockage. Contrasted imaging studies of the spinal cord revealed enhancing nodules, with biopsy confirming PNET. Given the patients history of resected pineocytoma, this presentation may represent late recurrence with transformation to a PNET, or a primary spinal PNET. Although pineocytoma is a benign disease, it is part of a spectrum of diseases and has been shown to undergo malignant transformation to a pineoblastoma or PNET. Therefore, it is important to recognize that patients with history of pineocytoma who present with signs, symptoms and imaging that are suggestive of NPH may have recurrence of the tumor. Prognosis for PNET remains poor with 5-year survival less than 10 % in adults over the age of 45. Treatments including radical resection, and radiation/chemotherapy have not been proven to be effective in prolonging survival in patients with this devastating disease.

PROBABLE LABETALOL-INDUCED ANGIOEDEMA: A CASE REPORT Akihiro Kobayashi^{1,2}; Samuel Acquah². ¹Beth Israel Medical Center, New York, NY; ²Beth Israel Medical Center, New York, NY. (*Tracking ID #1927532*)

LEARNING OBJECTIVE 1: Consider labetalol as a potential cause of angioedema

CASE: 79 year-old-woman presented to the hospital for hypertensive urgency. She had a history of chronic hypertension for which she was on Amlodipine 10 mg daily and Chlorthalidone 50 mg daily. No personal or family history of angioedema. Initial blood pressure was 234/117 mmHg and she received oral Amlodipine 5 mg, Losartan 50 mg and Metoprolol 50 mg on admission for better blood pressure control. After admission the patient remained hypertensive and intravenous Labetalol 20 mg was given. Three hours after administration of Labetalol, patient developed angioedema manifested by lip and tongue swelling requiring endotracheal intubation. Laboratory studies showed normal C4 and C1 inhibitor function. Losartan and Metoprolol were discontinued and Labetalol and Amlodipine were continued to treat blood pressure. Her symptoms resolved in 3 days with intubation and supportive treatment after

which she tolerated extubation. Four days after resolution of swelling she developed a second episode of angioedema requiring a second intubation. Amlodipine was discontinued. Labetalol was however continued and titrated up to 800 mg every 8 h for blood pressure control. This second reaction resolved after 5 days of intubation and supportive treatment and patient was again extubated. However, the patient developed third episode of angioedema 4 days later which was more severe compared with the previous 2 episodes. This third episode required a longer intubation (8 days). Labetalol was the only medication which had been used consistently all three times and the severe reaction was thought to be due to increased doses of Labetalol. Application of the Naranjo adverse drug reaction probability scale determined a probable link between Labetalol and Angioedema.

DISCUSSION: Labetalol is a beta-blocker with alpha-blocking activity. It is widely used for the treatment of essential hypertension, hypertensive urgency/emergency. Its beta-blocking activity decrease heart rate and cardiac output and alpha-blocking activity produce vasodilation, which is thought to be a mechanism of peripheral pitting edema. Although the exact mechanism of angioedema due to BBs is not well understood, a previous case report has proposed a theory by which BBs increase histamine release by decreasing intracellular cyclic adenosine monophosphate leading to angioedema. We carefully reviewed all medications that the patient received during the 3 episodes of angioedema. Labetalol was the only medication which had been used consistently all three times. The application of the Naranjo adverse drug reaction probability scale determined a probable link between labetalol and angioedema. We also found that each subsequent episode of angioedema was worse than the previous, which can be correlated with the increased doses of labetalol. Although ACEs-induced angioedema is not thought to be associated with dose, our clinical observation found a link between her symptoms and the dosage of labetalol, which may suggest non-allergic etiology of labetalol-induced angioedema. We believe this is the first case report to link Labetalol to angioedema. Since Labetalol is widely used to treat various cardiovascular conditions, clinicians should aware of the possibility of Labetalol as a cause of angioedema.

PROFOUND PANCYTOPENIA AND HEPATITIS: HEMOPHAGOCYTIC LYMPHOHISTIOCYTOSIS (HLH) OR HEPATITIS-ASSOCIATED APLASTIC ANEMIA? Amy Clouse; Nancy Feldman. Olive View - UCLA Medical Center, Sylmar, CA. (*Tracking ID #1937072*)

LEARNING OBJECTIVE 1: Distinguish HLH from hepatitis-associated aplastic anemia using diagnostic criteria.

LEARNING OBJECTIVE 2: Differentiate findings on bone marrow biopsies in HLH versus aplastic anemia.

CASE: Mrs. R is a 36 year old woman with no significant past medical history, who presented with 2 weeks of fatigue, dizziness, abdominal pain, joint pain and epistaxis. On admission, she was profoundly pancytopenic with an ANC<100, platelet count 12 k, hemoglobin 7.9, transaminitis (AST/ALT 400/500's), alkaline phosphatase of 130–150's, and elevated total bilirubin (5, increased to 19). She denied any prior drug or toxin exposure, and autoimmune workup was negative. She did endorse URI symptoms several weeks prior to admission. A broad infectious workup for hepatitis was unrevealing other than mild EBV and CMV viremia, with PCR's of 5000 and 400, respectively. She had evidence of prior infection with parvovirus. The acute hepatitis panel was negative. On imaging, she had hepatomegaly, but no splenomegaly. Liver biopsy showed possible "feathery necrosis", but did not show hemophagocytosis. She had three bone marrow biopsies, which showed hypocellularity with <5 % cellularity without evidence of hemophagocytosis, consistent with aplastic anemia. HLH characteristically has a normocellular bone marrow and splenomegaly. Despite these studies, she met 5 of the 8 proposed criteria for HLH: 1) elevated soluble IL-2; 2) elevated triglycerides (400's); 3) pancytopenia; 4) hepatitis with significant jaundice and; 5) daily fevers >38.5. She also had a progressively elevating ferritin (1770 at admission to >8000). As she met criteria for both HLH and hepatitis-associated aplastic anemia, she was treated for both. Following treatment for EBV with IVIG and valacyclovir, she was given solumedrol, cyclosporine, and ATG, all without improvement. Ultimately, the patient expired from complications of prolonged pancytopenia after more than 2 months of hospitalization.

DISCUSSION: Hemophagocytic lymphohistiocytosis (HLH) and aplastic anemia are two separate diseases processes. In this case where the patient fits the diagnostic criteria for both, a therapeutic challenge arises in the absence of a clear diagnosis. This prompts a review of how to distinguish aplastic anemia from HLH. Both are characterized by immune dysregulation, and can be associated with hepatitis and jaundice. Both can be precipitated by viral infections and autoimmune syndromes. Bone marrow biopsies may be helpful in distinguishing the two diseases, but the absence of hemophagocytosis in the bone marrow does not preclude HLH. The

critical juncture in this case was the cellularity of the bone marrow. In almost all cases of HLH, the bone marrow cellularity in HLH is normal to slightly decreased, while by definition it is profoundly hypocellular in aplastic anemia. There are case reports of untreated HLH evolving to aplastic anemia, which may explain why Mrs. R fit criteria for both. Her prognosis was poor with either diagnosis. The treatment of both disorders involves immunosuppression, to which unfortunately this patient did not respond.

PSEUDORENAL FAILURE CAUSED BY SPONTANEOUS RUPTURE OF THE URINARY BLADDER Naokatsu Ando¹; Naoya Taki¹; Ayako Kumabe¹; Yoshioki Nishimura¹; Michiko Kudo¹; Tsuneaki Kenzaka¹; Gurpreet Dhaliwal²; Masami Matsumura¹. ¹Jichi Medical University, Shimotsuke, Japan; ²University of California, San Francisco, and San Francisco VA Medical Center, San Francisco, CA. (*Tracking ID #1935039*)

LEARNING OBJECTIVE 1: Diagnose azotemia associated with massive ascites.

LEARNING OBJECTIVE 2: Recognize rupture of the urinary bladder as a rare cause of azotemia.

CASE: A 63-year-old man presented with a 2 month history of abdominal distension. Two months before admission, the patient noticed dysuria which improved spontaneously within several days. Shortly thereafter abdominal distension developed and progressed over the next 2 months. At an outpatient visit 4 days before admission, he had gained 2.4 kg of body weight and the serum creatinine was 0.8 mg/dL. Three days before admission, dysuria recurred. He had had a 30 year history of diabetes mellitus, 1 year history of dyslipidemia, and 7 year history of transitional cell carcinoma of the bladder treated by nine episodes of transurethral resection of bladder tumor (TUR-BT). The latest TUR-BT was performed 6 months before this admission. He was receiving 200 mg per day of bezafibrate and 26 units per day of short acting insulin. There was no history of trauma, fever, abdominal pain, myalgias, hematuria, dyspnea, or edema. On examination, his abdomen was profoundly distended but non-tender. There were no signs of end stage liver disease. Laboratory findings included a serum albumin 5.0 g/dL, urea nitrogen 87 mg/dL, creatinine 6.1 mg/dL, and potassium 5.5 mmol/L. Urinalysis revealed 3+ proteinuria and 1+ occult blood with white cells 30–49 per high-power field and no red cell casts. Urine biochemistry showed urea 612 mg/dL, creatinine 110 mg/dL, potassium 25 mmol/L, and protein 1.5 g per gram of creatinine. Fractional excretion of sodium was 3.2 %. Urine culture was not obtained. Computed tomography (CT) scan showed massive ascites without hydronephrosis, cirrhosis, or masses. Clear yellow-colored peritoneal fluid obtained by abdominal paracentesis revealed albumin 0.3 g/dL, urea 134 mg/dL, creatinine 21.4 mg/dL, and potassium 7.6 mmol/L. Serum-ascites albumin gradient was 4.7 g/dL. The peritoneal fluid white blood cell count was 170/ μ L with 92 % macrophages, 4.5 % neutrophils, and 3.5 % methothelial cells. Cytology showed no atypical cells. Within 17 h of urinary catheter placement, 4,800 mL of urine was excreted and abdominal distension improved dramatically. Urine cytology showed mesothelial cells which were consistent with those in peritoneal fluid. On hospital day 3, serum creatinine normalized to 0.8 mg/dL. Retrospective evaluation of the CT scan from admission showed partial wall thinning in the apex of the urinary bladder which was consistent with the lesion of the latest TUR-BT. We diagnosed pseudorenal failure caused by spontaneous rupture of the bladder. On hospital day 8, cystography revealed no perforation of the bladder. The patient was discharged from the hospital with an indwelling transurethral catheter.

DISCUSSION: This patient had a pseudorenal failure serum biochemical profile caused by leakage of urine into the peritoneal cavity, where urea, creatinine, and electrolytes equilibrated across the peritoneum with the blood. Spontaneous rupture of the bladder due to wall fragility induced by multiple TUR-BT procedures was suspected. Pseudorenal failure occurs when azotemia results from reabsorption of urine solutes through peritoneum after intraperitoneal bladder rupture rather than through a reduction in the glomerular filtration rate. Physicians should consider urinary ascites when ascites without a known cause of portal hypertension is accompanied by blood tests that suggest acute kidney injury.

PULMONARY ARTERIAL HYPERTENSION AND HUMAN IMMUNODEFICIENCY VIRUS INFECTION Avyan Armaghani¹; Ashkan Karimi¹; Talha Nazir³; Hassan Alnuaimat²; Richard Conti³. ¹University of Florida, Gainesville, FL; ²University of Florida, Gainesville, FL; ³University of Florida, Gainesville, FL. (*Tracking ID #1934516*)

LEARNING OBJECTIVE 1: Recognize that pulmonary arterial hypertension (PAH) is a rare complication of HIV infection, and testing for HIV should be included in the work-up of patients with newly diagnosed PAH.

CASE: A 49-year-old male presented from an outside hospital with several months history of progressive shortness of breath. A right heart catheterization performed at the outside hospital recorded right atrial pressure of 32 mmHg, right ventricular pressure of 93/32, pulmonary artery pressure of 103/55, and pulmonary capillary wedge pressure of 19 mmHg. The patient was transferred to our hospital for further workup and management of PAH. A trans-thoracic echocardiogram revealed normal left ventricular function but a severely dilated right ventricle, severe right ventricular systolic dysfunction, and severely elevated right ventricular systolic pressure of 106 ± 5 mmHg. CT scan of the chest showed normal lung parenchyma. V/Q scan did not show evidence of pulmonary embolization and ruled out chronic thromboembolic cause of PAH. The patient did not have any clinical manifestations to suggest connective tissue disorders and serologic work-ups including ANA, rheumatoid factor, c-ANCA, p-ANCA, anti-SCL-70, anti-Sm, anti-Sm-RNP, anti-SSA, and anti-SSB antibodies were negative. The antigen/antibody combo test for HIV returned positive and was confirmed by western blot. HIV virus titer was measured in blood by PCR at 76,000 copies/ml and CD4 count was 131 cells/mm³. The patient reported high-risk heterosexual behavior several years ago, and he received blood transfusion after colorectal surgery for diverticulitis in 2009 both posing as possible risk factors for acquiring HIV infection. However, the patient denied any sign/symptoms to suggest neglected HIV diagnosis prior to the current presentation. The patient was ultimately diagnosed with group 1 pulmonary hypertension (WHO classification) secondary to HIV infection. He was started on furosemide, tadalafil, and ambrisentan for treatment of PAH and was referred to the local health department to initiate HAART therapy for HIV infection.

DISCUSSION: This case report will familiarize internists with the work-up for pulmonary arterial hypertension (PAH), which includes testing for HIV. PAH is a rare complication of HIV infection, the first case was reported in 1987. HIV has been shown to cause plexogenic pulmonary arteriopathy, medial hypertrophy, intimal fibrosis, pulmonary veno-occlusive disease, and in situ thrombosis, which all lead to PAH. Typically, PAH in the context of HIV infection occurs late in the disease process in patients who already have other stigmata of HIV or AIDS. However, in this case HIV infection was discovered as part of the initial work-up for PAH in an otherwise healthy patient.

PULMONARY EMBOLISM: AN UNUSUAL CONSEQUENCE OF AMEBIC LIVER ABSCESSSES Mitchell Luu; Ryan Laponis. University of California, San Francisco, San Francisco, CA. (*Tracking ID #1937130*)

LEARNING OBJECTIVE 1: Develop a differential diagnosis and initial work-up for liver abscesses

LEARNING OBJECTIVE 2: Diagnose and treat extra-intestinal amebic infections

CASE: A 53 year-old homeless man presented with 6 months of progressive right upper quadrant discomfort, malaise and intermittent fevers. Significant exam findings included a palpable liver edge 10 cm below the costal margin, and a grade 3/6 systolic murmur best heard at the left lower sternal border. Transthoracic echocardiography showed a 3 cm irregular mobile mass extending from the right atrium into the right ventricle, consistently with thrombus. CT abdomen revealed a 17 cm complicated cystic lesion in the liver. The patient later developed hypoxia and severe respiratory distress, and a CT angiography of the chest demonstrated a large subsegmental pulmonary embolus. The patient underwent interventional radiology-guided drainage of the hepatic lesion, with removal of 2 liters of "anchovy-paste" purulence. Repeat CT abdomen revealed persistent hepatic abscesses, with thrombus extending from the right hepatic vein into the inferior cava and right atrium. Lab tests revealed leukocytosis without eosinophilia and an elevated ESR. Liver function tests, including synthetic function were normal. Blood bacterial, fungal and mycobacterial cultures were negative. Stool culture and ova-parasite studies were negative. Bacterial and fungal cultures of the liver abscess were negative. Liver cytology was negative for malignancy and amoeba. HIV and viral hepatitis serologies were negative. Amebiasis IgG levels returned back elevated. The patient was diagnosed with an amebic liver abscess complicated by an intracardiac thrombus and subsequent pulmonary embolus. He was treated with anticoagulation and 10 days of metronidazole.

DISCUSSION: Liver abscesses are very rare and are generally classified by three etiologies: 1) pyogenic, 2) amebic, and 3) fungal. Bacterial infections are the most common (80 %) and are often due to multiple organisms, predominantly *E. Coli* and *K. Pneumoniae*. Amebic liver abscesses occur in 10 % of cases and are most often due to *E. Histolytica*. Fungal abscesses are primarily from *C. Albicans*. Initial evaluation includes complete blood count, liver function tests, blood cultures, serology for *E. Histolytica* and imaging with ultrasound, CT or MRI. After initial evaluation, percutaneous needle aspiration should be performed for microbiologic and pathologic evaluation. *Entamoeba histolytica* is a single-cell parasite with high prevalence in developing countries. In the United States, amebiasis is

commonly seen in travelers to endemic regions, immigrants from countries with poor sanitation, institutionalized persons, and men who have sex with men. Most infected individuals are asymptomatic, but common symptoms include diarrhea, weight loss and fevers. Amebic liver abscesses are the most common extra-intestinal amebic infection. Diagnosis of amebic liver abscesses requires: 1) space-occupying liver lesion and 2) positive serology. Ultrasound and CT are sensitive for identifying the space-occupying lesion. Serology is highly sensitive (>94 %) and specific (>95 %) for infection, but may be falsely negative in the first 7 days of infection. Complications include abscess rupture, peritonitis and hepatic vein/IVC thrombosis (as was seen in this patient). Treatment involves a 7–10 day course of oral metronidazole and has a cure rate >90 %. Although not required for treatment, aspiration or surgery should be considered for cysts with imminent rupture, clinical deterioration, or lack of response to therapy.

PULMONARY HYPERTENSION AS A PRESENTING FEATURE OF METASTATIC GASTRIC CANCER Daniel Ling¹; Rajan Sagger². ¹UCLA, Los Angeles, CA; ²UCLA, Los Angeles, CA. (*Tracking ID #1925543*)

LEARNING OBJECTIVE 1: Recognize pulmonary tumor thrombotic microangiopathy as a rare cause of pulmonary hypertension complicating metastatic adenocarcinoma

LEARNING OBJECTIVE 2: Evaluate a new diagnosis of pulmonary hypertension

CASE: A 58 year old Korean female with remote history of pulmonary tuberculosis presented to her primary care physician with 1 month of progressive dyspnea on exertion, palpitations, and dysphagia. Physical examination was remarkable for decreased breath sounds at the right base but no rales, peripheral edema, or jugular venous distention. Chest x-ray demonstrated a right-sided pleural effusion. Pleural fluid studies from thoracentesis revealed an exudative effusion, but microbiology and cytology were negative. Upper endoscopy was performed to evaluate the patient's dysphagia and was unremarkable; she was started on omeprazole for presumed gastroesophageal reflux. CT angiogram of the chest was negative for pulmonary embolism, but did reveal bronchiectasis, dilated pulmonary arteries, and spiculated lung nodule. Echocardiogram showed preserved left ventricle systolic function; however, the estimated pulmonary artery pressure was elevated (50 mmHg). The patient's pleural effusion continued to reaccumulate requiring recurrent thoracentesis, and she was subsequently admitted to the hospital for worsening dyspnea and hypoxia. Repeat echocardiogram showed worsening of estimated pulmonary artery pressure (88 mmHg). Right heart catheterization confirmed the severity of her pulmonary hypertension and also demonstrated normal pulmonary capillary wedge pressure and cardiac output. The patient had no history of relevant exposures or family history of pulmonary hypertension (PH). Further evaluation included HIV testing, V/Q scan, liver function tests, and ANA, Scl-70, SSA/SSB, RF, and RNP/SM antibodies, which all returned negative. Pulmonary function tests showed mixed severe obstructive and restrictive disease, which in combination with her prior CT results raised the question of PH due to lung disease. However, these findings were not thought to adequately explain the degree of PH, suggesting that an idiopathic component was also present. A pleural drainage catheter was placed and she was started on sildenafil with improvement in symptoms prior to discharge. One month later she was readmitted with worsening dyspnea on exertion and fatigue as well as back pain. Labs were notable for hemoglobin of 5.3. CT angiogram of the chest was again negative for pulmonary embolism but did show new sclerotic and lytic lesions of the spine. Upper endoscopy revealed a 6 cm irregularly shaped gastric ulcer; biopsy returned with signet ring gastric adenocarcinoma. The unusual aspects of her presentation now appeared consistent with a diagnosis of pulmonary tumor thrombotic microangiopathy secondary to metastatic gastric cancer. Despite numerous attempts at hemostasis including repeat endoscopy and gastric artery embolization, she continued to have severe bleeding episodes and eventually transitioned to comfort care.

DISCUSSION: This patient presented initially with dyspnea on exertion which appeared to be multifactorial due to recurrent pleural effusion, pulmonary hypertension without right heart failure, and mixed obstructive and restrictive lung disease, but a unifying cause of these findings remained unclear. Assessment included a right heart catheterization to confirm the diagnosis of precapillary PH and exclude left heart failure as the underlying etiology. An appropriate workup for PH was performed including evaluation for connective tissue, pulmonary, liver, and chronic thromboembolic diseases. While PH related to lung disease and idiopathic PH were considerations for this patient, several factors supported an alternative explanation. Severe PH with mean pulmonary artery pressure greater than 35 mmHg is reported in only 1–5 % of patients with obstructive lung disease. Furthermore, pleural effusions are typically only seen in PH with concurrent right heart failure. Generally, a diagnosis of idiopathic PH should remain open to reconsideration as new developments arise in the clinical course. This patient's aggressive metastatic gastric adenocarcinoma eventually declared itself, providing a unifying explanation of her overall presentation. Pulmonary tumor thrombotic microangiopathy is a rare entity

that is typically associated with mucin-secreting adenocarcinomas, and most commonly gastric cancer. Tumor emboli to the lungs cause occlusion of small arteries with intimal proliferation and activation of the coagulation cascade, leading to pulmonary hypertension and eventually cor pulmonale. Clinically, patients can have a subacute to fulminant progression of dyspnea and hypoxia. CT angiogram and V/Q scan are insensitive tests but may show small subsegmental filling defects. Definitive diagnosis requires pathological examination. Therapy primarily involves treatment of the underlying malignancy, although case reports have also described the use of anticoagulation or steroids.

PYOGENIC HEPATIC ABSCESS SECONDARY TO STREPTOCOCCUS ANGINOSUS: A RARE COMPLICATION OF SIGMOID DIVERTICULITIS

Adrienne L. Clark¹; Francis E. Dailey²; Jeffrey R. Lewis³. ¹University of California, Los Angeles, Los Angeles, CA; ²Saint Louis University, Saint Louis, MO; ³University of California, Los Angeles, Los Angeles, CA. (*Tracking ID #1918791*)

LEARNING OBJECTIVE 1: Recognize that sigmoid diverticulitis may lead to hepatic abscess

CASE: A 59-year-old female presented with 1 week of progressive nausea, abdominal pain, and tactile fevers. She had a history of diverticulosis on colonoscopy 2 years prior, and 2 episodes of presumed diverticulitis 6 months and 1 month prior which had self-resolved after 2–3 days. She was tachycardic with involuntary guarding on palpation of the epigastrium and left lower quadrants. Laboratory studies revealed WBC 19.5/mm³, 86 % neutrophils, and newly elevated liver enzymes (AST/ALT 117/237, alkaline phosphatase 154, GGT 103 U/L). CT abdomen/pelvis with contrast revealed diverticulosis with diverticulitis in the proximal third of the sigmoid colon without evidence of abscess and a multiseptated rim-enhancing lesion in hepatic segments 7 and 8 measuring 8.7×10.4×8.8 cm, consistent with abscess contiguous with the middle hepatic vein. She was started on piperacillin/tazobactam. She underwent percutaneous CT-guided abscess drainage with placement of an indwelling pigtail catheter on hospital day 2. Abscess fluid grew pan-sensitive Streptococcus anginosus. She was transitioned to ertapenem, although blood cultures from time of admission and anaerobic cultures were ultimately negative. Drain output slowed, her leukocytosis persisted, and repeat imaging on HD#6 showed a stable abscess. She underwent drain replacement on HD#7 and subsequent operative hepatotomy on HD#11, with two JP drains left in place post-operatively. While repeat imaging showed persistent abscess, she clinically improved, and was discharged home ambulatory and on an oral pain regimen to complete 6 weeks of IV ertapenem. After a relatively symptom free interval, she developed several months of intermittent diarrhea and left lower quadrant pain. Given her history of likely recurrent sigmoid diverticulitis, she underwent semi-elective sigmoid colectomy 15 months later.

DISCUSSION: Sigmoid diverticulitis may rarely lead to cases of hepatic abscess with or without coexistent pylephlebitis. Liver abscess is most frequently associated with biliary tract disorders such as stones, obstructive malignancy, strictures, and congenital conditions. It may also be caused by hematogenous dissemination of organisms in association with systemic bacteremia or transient local portal circulation bacteremia, leading to liver abscess directly or via localized septic thrombophlebitis. Patients with liver abscess typically present with nonspecific constitutional symptoms and diffuse abdominal pain/tenderness. Early and accurate diagnosis relies on prompt identification and localization with ultrasound or CT imaging. Treatment focuses on both timely administration of broad-spectrum antibiotics and percutaneous or surgical drainage. The *S. anginosus* which grew from this patient's cultures is a member of the "Streptococcus milleri Group" (SMG) of bacteria now actually classified into three distinct species, *S. intermedius*, *S. constellatus*, and *S. anginosus*. The first case of SMG hepatic abscess was reported in 1975. Since then these have been identified as one of the important pathogens of liver abscess, although a sigmoid diverticular source is rarely reported. SMG are considered part of the normal flora of the gastrointestinal tract but with known potential to cause abscesses and systemic infections. If isolated from culture with no clinically apparent abscess, this should prompt further radiographic evaluation.

PYOGENIC LIVER ABSCESS Saranya Sasidharan; Jessica Hurst. Boston Medical Center, Boston, MA. (*Tracking ID #1939048*)

LEARNING OBJECTIVE 1: While pyogenic liver abscesses are most often the result of biliary tract disease and comparatively less frequent, failure to consider an intrahepatic infection early when confronted with a mixed hepatocellular/cholestatic pattern can delay treatment and worsen prognosis.

LEARNING OBJECTIVE 2: There may be a role for colonoscopy in the workup of liver abscess of unknown origin.

CASE: A 62 year old man presented with 1 week of fatigue, anorexia, myalgias, and chills. He reported dark urine and yellowing of his eyes and skin. He admitted to taking naproxen, as well as cold medicine with acetaminophen several days prior. He denied fevers and abdominal pain. He reported consuming up to 12 beers per day. Past medical history included arthritis, and PTSD. He was afebrile, normotensive, but tachycardic to 110. He had scleral icterus and jaundice without spider angiomas or palmar erythema. His abdomen was obese, nontender without hepatomegaly. He was oriented without asterixis. Labs were notable for creatinine 2.4, WBC 14, AST 569, ALT 430, alkaline phosphatase 486, total bilirubin 12.5, direct bilirubin 10.0, INR 1.3 (previously <1), acetaminophen level 6. Ultrasound showed diffuse steatosis and gallbladder sludge, but no ductal dilatation or portal vein thrombus. A 4.1 cm ill-defined area of fatty sparing in the right lobe and 2.8 cm area in the left were also noted. The initial diagnosis was presumed alcoholic hepatitis, with a component of acetaminophen related injury, without evidence of acute liver failure. His renal function improved with fluids. However, his leukocytosis worsened to 21, INR elevation persisted, and although most of his LFTs improved his bilirubin lagged. He developed low grade fevers; ceftriaxone and metronidazole were started. CT showed two liver lesions (up to 5.4×5.6 cm) concerning for abscesses, with gallbladder distention and pericholecystic fat stranding concerning for perforation. Serial CT-guided drainage of the liver abscesses revealed methicillin-susceptible *staph aureus*. Transthoracic echocardiogram, chest xray, and blood cultures were normal. Antibiotics were switched to nafcillin and the patient improved.

DISCUSSION: There has been a rise in the incidence of pyogenic liver abscess (PLA), now reported to be 3.6 per 100,000. The mortality rate of PLA has remained stable at 5.6 %; poor prognostic indicators include acute respiratory failure, gas forming liver abscess, or anaerobic infections. Mechanisms of hepatic seeding are often the result of biliary disorders (producing polymicrobial infections) and less often due to bacteremia or systemic infection (producing monomicrobial infections, often due to *staph* or *strept*). In 7.4 % of patients initially diagnosed with cryptogenic abscess, colonoscopy reveals mucosal abnormalities ranging from high grade dysplasia to adenocarcinoma. This case was unusual for several reasons. First, diagnosis was delayed due to the presence of alcohol and acetaminophen use. The patient's lack of abdominal pain and initially fever obscured the true diagnosis, although the mixed pattern of LFT abnormalities, worsening leukocytosis, and development of fevers were clues that this case was not classic for alcoholic hepatitis. Second, a single microorganism, *staph aureus*, was identified, but there was no evidence of hematogenous spread and a primary source of infection was never identified.

QUADRIPLEGIA IN A PATIENT WITH WEST NILE ENCEPHALITIS

Rathan Reddy¹; Kenneth C. Raney¹; Gregg Shalan². ¹Methodist Dallas Medical Center, Dallas, TX; ²Methodist Dallas Medical Center, Dallas, TX. (*Tracking ID #1939045*)

LEARNING OBJECTIVE 1: Diagnose a viral illness in its acute stage

LEARNING OBJECTIVE 2: Recognize an atypical presentation of West Nile encephalitis

CASE: West Nile virus can cause neurologic disease in the form of meningitis and encephalitis. It is important to consider in patients who present with acute febrile illness in the presence of altered mental status, especially during mosquito season in summer and early fall. A common manifestation of neuroinvasive West Nile disease is a poliomyelitis-like asymmetric flaccid paralysis. It is quite rare for the disease to result in quadriplegia. A 65 year old Caucasian male with a past medical history of diabetes, hypertension, osteoarthritis and hyperlipidemia presented to our hospital with acute onset fever, emesis and altered mental status. The patient's wife reported he was sent home from work earlier that day due to nausea and vomiting. Given the patient's acute decline in mental status, a lumbar puncture was performed immediately upon admission. CSF analysis was unremarkable, demonstrating a WBC count of 1/mm³, elevated glucose of 108 mg/dl and a normal protein of 51 mg/dl. The patient's CSF studies were negative for VDRL, cryptococcal neoformans, and HSV. Originally, the patient's West Nile antibodies were negative, however, CSF analysis with West Nile PCR tested positive. Over the course of the next week, the patient's initial symptoms began to resolve, including a return to baseline mental status. The day after clinical improvement, the patient once again spiked a fever and the following morning, he became somnolent and was unable to answer questions or follow commands. Again, because of his rapid clinical decline, lumbar puncture was repeated. Cytology of the CSF showed a WBC count of 185/mm³ and repeat titers for West Nile IgG and IgM returned elevated. The patient continued deteriorating rapidly, soon requiring intubation and mechanical ventilation. He became flaccid in all four extremities. A neuromuscular study performed by the neurocritical care specialist showed absent reflexes and complete paralysis of all four extremities. A short trial of

IVIG was attempted, however, provided no benefit. He remained intubated for 14 days before the family decided to withdraw care in honor of the patient's wishes.

DISCUSSION: Due to the severity of our patient's disease and unique and rapid onset of quadriplegia, little could be done to prevent mortality. This case illustrates how awareness of atypical presentations of common diseases is important for timely diagnosis and implementation of appropriate therapy.

RAPIDLY PROGRESSIVE AND CATASTROPHIC OUTCOME OF ATHEROSCLEROTIC DISEASE Michelle M. El-Hosni; Dipenkumar Modi; Diane L. Levine. Wayne State University School of Medicine, Detroit, MI. (*Tracking ID #1939394*)

LEARNING OBJECTIVE 1: Diagnose peripheral artery disease and recognize features of critical limb ischemia

LEARNING OBJECTIVE 2: Recognize racial disparity in the diagnosis and progression of peripheral artery disease

CASE: A 75-year-old African American woman with a past medical history of untreated hypertension and depression was admitted for progressive worsening dry gangrene of the left foot over 3 months duration. She noticed 40–50 lb weight loss over the last 6 months and reduced exercise capacity. The patient was found to be afebrile, hypertensive, and tachycardic. Physical examination revealed bilateral prominent carotid bruits, undetectable bilateral femoral and lower extremity pulses, and left pedal edema with necrotic skin lesions over the first three digits. Laboratory results revealed elevated troponins (0.772) without ST-T wave changes, LDL (154) and HbA1C (7.6) Arterial Duplex was obtained which showed monophasic blood flow in common femoral arteries but absent blood flow in femoral veins, popliteal, posterior tibial, anterior tibial and peroneal veins bilaterally consistent with critical limb ischemia. CT Angiogram of the abdomen showed severe atherosclerotic disease involving the abdominal aorta with eventual complete occlusion of the distal abdominal aorta beyond the origins of the renal arteries, and opacification through the bilateral iliac arteries, superficial femoral and popliteal arteries. TTE showed small left ventricular cavity with near cavity obliteration, moderate LVH and hyperdynamic left ventricular systolic function with impaired relaxation pattern. Patient was managed for NSTEMI with IV heparin. Surgical intervention was deferred because of recent ACS. The patient was readmitted 1 week later with worsening dry gangrene of the left foot. On hospital day 2, she developed new-onset atrial fibrillation with rapid ventricular response. On EKG, STEMI was noticed with rapid up-trending troponins up to 13.6. Repeat TTE revealed new appearance of severe hypokinesia of basal to mid inferior and infero-lateral segments. Cardiac catheterization revealed 95 % stenosis of the proximal LAD and total occlusion of both the proximal LCX and distal RCA. Two bare metal stents were placed in the proximal and mid LAD. Head CT without contrast was obtained because of declining mental status, which revealed left maxillary sinusitis, possible subacute infarction involving inferior right precentral gyrus, chronic microvascular disease, and intracranial calcific atherosclerosis. Her clinical condition progressively worsened with continuous rise in troponins leading to cardiac arrest. Despite aggressive effort, the patient expired.

DISCUSSION: Peripheral artery disease (PAD) is a common circulatory problem in which narrowed arteries reduce blood flow to limbs. According to the ACC/AHA practice guidelines, risk factors for atherosclerosis, such as cigarette smoking, diabetes, dyslipidemia, and hypertension increase the likelihood of developing lower extremity PAD. Lower extremity critical limb ischemia (CLI) occurs in 1–2 % of patients above 50 years of age with PAD. CLI outcomes at 1 year are: 50 % alive with both limbs, 25 % amputation, and 25 % cardiovascular mortality. In all patients with PAD, antiplatelet therapy is recommended to reduce cardiovascular risk. Primary amputation is more frequently performed on patients with PAD who are nonwhite, low-income, and uninsured. Specifically, African American patients undergo amputation at 2–4 times the rate of white patients. The advanced ischemia observed in this population suggests a delayed diagnosis of PAD, likely due to a lack of primary care. Better education of the symptoms and consequences of PAD to the general population and providers may reduce the rate of amputation, especially among the economically disadvantaged. This patient's chronic, untreated HTN likely predisposed her to the development of atherosclerosis and aortoiliac occlusive disease (PAD), confirmed by Arterial Duplex and CT Angiography. Early blood pressure control could have stunted this fatal progression. If untreated, PAD results in critical limb ischemia, as evidenced by worsening lower extremity pain, non-healing wound/ulcer, and skin discoloration/gangrene. Per guidelines, antiplatelet therapy was initiated to reduce the risk of MI, stroke, and vascular death. Anti-hypertensives, statins, and blood glucose control were used for risk factor reduction. IV antibiotics were indicated until cellulitis and risk of infection could be ruled out. Patient was ineligible for surgical revascularization due to co-morbid cardiac abnormalities.

Amputation of gangrenous tissue was deferred as it would lead to chronic non healing ulcer due to significantly diminished circulation and risk of infection. The patient's rapid demise may have been prevented by early, aggressive treatment and risk reduction.

RAPIDLY PROGRESSIVE INTRACRANIAL GIANT CELL ARTERITIS; A RARE AND CATASTROPHIC PHENOMENON Devin B. Malik; Sourabh Aggarwal. Western Michigan University School of Medicine, Kalamazoo, MI. (*Tracking ID #1939169*)

LEARNING OBJECTIVE 1: Recognize that Giant Cell Arteritis (GCA) may present with stroke like symptoms, and could represent intracranial GCA which is exceedingly rare, as stroke in GCA is usually due to extracranial stenosis of carotid and/or vertebral arteries.

CASE: A 79 year old lady presented to us complaining of frontal headaches and odynophagia. Physical examination was unremarkable. Labs revealed an elevated erythrocyte sedimentation rate (ESR) of 82 mm/h. Computer tomography angiogram (CTA) done to evaluate headaches was unremarkable. The patient was referred to a rheumatologist for further evaluation with labs revealing ESR of 115 mm/h. ANA and ANCA tests were negative but a temporal artery biopsy was diagnostic for GCA. Prednisone 60 mg daily was started with gradual improvement of symptoms. Prednisone was slowly tapered over 3 months to 30 mg daily when patient developed right-sided weakness, dysarthria and word finding deficits. CTA of head showed infarcts in left frontal deep matter and cerebral white matter. New multifocal stenosis including stenosis of bilateral cavernous and paraclinoid internal carotids arteries, proximal portions of left anterior cerebral, middle cerebral and left posterior communicating artery and distal cervical left vertebral artery were found compared to previous CTA. These were consistent with intracranial vasculitis. Aspirin 81 mg was started. Lumbar puncture and echocardiogram were unremarkable for any other etiology. She was started on high dose steroids and cyclophosphamide, however the patient opted for hospice.

DISCUSSION: Intracranial vasculitis leading to CVA in a patient with biopsy proven GCA has been reported extremely rarely. GCA almost exclusively affects the extracranial vessels sparing the intracranial vessels. It is postulated that the pathologic inflammation of GCA targets the arterial elastic tissue of extracranial vessels and the intracranial vessels are spared as they have little or no elastic tissue in their media and adventitia layers. Our patient developed intracranial vasculitis while on steroids which to the best of our knowledge has never been reported previously. This case of intracranial vasculitis highlights an extremely rare cause of CVA and to our knowledge is the first report of GCA associated intracranial vasculitis developing while on corticosteroid therapy.

RARE CAUSE OF A "BROKEN HEART" IN RHEUMATOID ARTHRITIS Jennifer Zora; Aluoch Aloice; Robin Klein. Emory, Atlanta, GA. (*Tracking ID #1940118*)

LEARNING OBJECTIVE 1: Recognize the pathophysiology of hyperviscosity syndrome.

LEARNING OBJECTIVE 2: Review the clinical manifestation of hyperviscosity syndrome.

CASE: A 45 year old female presents with progressive shortness of breath and lightheadedness. Past medical history was notable for Rheumatoid Arthritis treated with weekly abatacept. Physical exam demonstrated jugular venous distension but not synovitis, joint effusion, or rash. Laboratories revealed a positive anti-citrullinated protein antibody and rheumatoid factor, negative double-stranded Deoxyribonucleic acid (DNA), platelet count of 128,000 per microliter, an international normalized ratio of 1.5, total protein of greater than 12 g per deciliter (gm/dL) and albumin of 2.4 g/dL. She underwent right heart catheterization which revealed a cardiac index of 1.39 L/min, pulmonary artery pressure of 45/27 mm Hg (mm Hg) and severe RV dysfunction with a mixed venous oxygen (MVO₂) saturation of 22 % and pulmonary capillary wedge pressure of 7 mm of Hg. She was started on dobutamine and epoprostenol sodium therapies with for decompensated right heart failure. Ventilation perfusion scan was obtained and demonstrated multiple mismatched defects in the right lung characteristic for acute pulmonary embolism. Heparin therapy was started and was complicated by persistent, severe epistaxis. Repeated clotting of her blood specimen tubes for lab draws was also noted. Her simultaneous increased bleeding and clotting was perplexing. Her viscosity was found to be very high at 8.4 (normal range 1.4–1.8 units), and serum protein electrophoresis revealed polyclonal gammopathy. Notably, Von Willebrand factor function and quantity and factor VIII levels were within normal range. She was diagnosed with hyperviscosity syndrome.

She underwent plasmapheresis twice, and her viscosity normalized. Following this, CT chest did not demonstrate evidence of true pulmonary embolism, and heparin was stopped. She was ultimately discharged on a decreased dose of epoprostenol sodium with normalization of her MVO2.

DISCUSSION: Hyperviscosity syndrome is a rare, potentially reversible complication of rheumatoid arthritis caused by polyclonal gammopathy. Monoclonal gammopathies such as multiple Waldenström macroglobulinemia causes 85 % of cases of hyperviscosity in contrast to polyclonal gammopathy. The primary mechanisms postulated for hyperviscosity in rheumatologic disease include binding of rheumatoid factor immunoglobulin M (IgM) and or immunoglobulin G (IgG). Hyperviscosity syndrome leads to both abnormal clotting and bleeding tendencies. The exact mechanism for the bleeding caused by this process is not understood but could involve platelet dysfunction and/or clotting factor destruction. Likely, slow movement of the viscous blood of blood in the pulmonary vascular system led to this patient's (incorrectly) suspected pulmonary embolism and her severe pulmonary hypertension. Initial therapy with plasmapheresis was largely effective therapy for our patient. Long-term immunosuppression will be attempted with in an effort to potentially reverse her pulmonary hypertension/right heart failure and free her from her reliance on chronic epoprostenol sodium therapy. Thus, this case demonstrates that it remains important to maintain a broad differential for cardiopulmonary complaints in our patients with rheumatologic disease. In this case, right heart failure was caused by a rare complication of rheumatoid arthritis, hyperviscosity syndrome. History, physical and careful analysis of abnormal laboratory values remain paramount in these complex patients.

RARE CAUSE OF THROMBOCYTOPENIA Sparsha Kukunoor, University of Connecticut, Hartford, CT. (*Tracking ID #1940274*)

LEARNING OBJECTIVE 1: Identify the relationship between thrombocytopenia and transfusion

LEARNING OBJECTIVE 2: Recognize the differential diagnosis of acute thrombocytopenia in a critical care setting

CASE: 26 year old man with end stage renal disease, hypertension, anemia due to chronic kidney disease, diabetes who was admitted to the ICU for hypoxic encephalopathy was diagnosed to have worsening anemia after 3 weeks of ICU stay, he then received one unit of packed red blood cell transfusion. Five days later he was found to have acute drop in platelet count from 389,000/UL to less than 5,000/UL the next day. Only symptom being epistaxis. Peripheral smear did not show platelet clumping or schistocytes. There was evidence of toxic granulation, decreased lymphocytes and no platelets were visible. Bone marrow suppression was unlikely due to the acute drop. ADAMTS 13, Direct Coombs test, triglyceride, ferritin, HPF4, vitamin B12 and folate and tick borne antibody screen was negative. A immune related event was suspected at this point due to the acuteness. Platelets were transfused with no improvement in post transfusion platelet counts. Post transfusion purpura was considered and human platelet antigen genotyping and antibody testing was sent out. Methylprednisolone 40 mg IV every 6 h was started along with IVIG treatment. There was no improvement in his thrombocytopenia. After 2 days plasmapheresis was started on a daily basis, this showed a gradual improvement in his platelet counts to 70,000/UL in 3 days time. His tests confirmed anti-HPA-1a antibody. He was later transferred on to hospice care due to his encephalopathy and other comorbidities and finally died.

DISCUSSION: Post Transfusion purpura is a form of severe thrombocytopenia occurring after transfusion of blood products. It is usually seen in individuals with HPA negative platelets, most often seen in multiparous women who have been immunized with HPA positive pregnancy. It can also be seen in men 5–10 days after transfusion with a sudden decrease in platelet count. It is seen in the form of an anamnestic response with the formation of HPA antibodies which react with the individuals own platelets which are HPA negative. The mechanism of this still remains unclear, a number of subtypes of HPA have been reported in the past. Our patient had no history of transfusion in the past or any history of thrombocytopenia. Diagnosis is based on the identification of the antibody in the serum of a patient who lacks the corresponding antigen, anti-HPA-1a being the most common, these tests may take days to weeks. Therapy should not be delayed. Platelet transfusion is generally not helpful in the management of this condition as the platelet count drops further even with platelet transfusions. The treatment of Post Transfusion Purpura is steroids, IVIG, exchange transfusion and sometimes plasma pheresis. Our patient was refractory to steroids and IVIG, and responded well to the plasmapheresis.

RARE PRESENTATION OF GASTROINTESTINAL TUBERCULOSIS Fadi Niyazi, Henry Ford Hospital, Detroit, MI. (*Tracking ID #1927265*)

LEARNING OBJECTIVE 1: In the United States, tuberculosis is relatively rare, and primarily manifests as pulmonary disease. This case describes a rare presentation of extra-pulmonary tuberculosis.

CASE: A 42 year old previously healthy male, who moved to United States from India in 2001, presented 6 weeks after an open repair of incarcerated right inguinal hernia with a 3 week history of difficulty passing urine and abdominal fullness associated with decreased appetite. He was initially evaluated by a urologist for urinary symptoms and started on Tamsulosin, and he tried over the counter medications for his gastrointestinal symptoms with no relief. With continued symptoms and increased abdominal discomfort he presented to the emergency department. The patient admitted to having a positive PPD test when he first moved from India, but did not complete a full course of medical treatment. He denied hematemesis, weight loss, night sweats, chills, nausea, vomiting, melena or hematochezia. Exam revealed a soft but mildly tender abdomen, positive fluid wave, no hepatosplenomegaly, normal bowel sounds, and no palpable pelvic lymph nodes. CT abdomen and pelvis revealed multiple intra-abdominal hypodense lesions that may represent low attenuation lymph nodes, with ascites. Differential diagnosis included broadly infectious etiologies versus neoplasia. Labs showed PSA of 1.01 ng/mL, and colonoscopy was entirely normal. Diagnostic laparoscopy with lymph node and peritoneal biopsy was performed, with intra-operative findings including multiple milliary peritoneal implants, inflamed peritoneum, and clear greenish ascites, with 3 l subsequently drained. Peritoneal fluid analysis showed cell count of 1385 WBC/uL with predominant lymphocytes and monocytes, glucose of 89 mg/dL, protein of 5.7 g/dL, albumin of 3.4 g/dL, and was negative for malignant cells by flow cytometry. Intra-operative frozen sections examined under microscope revealed organizing necrotizing and non-necrotizing granulomatous inflammation, consistent with gastrointestinal tuberculosis, with no evidence of neoplasm. Patient was started on isoniazid, pyridoxine, rifampin, pyrazinamide and ethambutol with clinical improvement noticed in an outpatient visit few weeks later.

DISCUSSION: Gastrointestinal tuberculosis is defined as infection of the peritoneum, hollow or solid abdominal organs, or abdominal lymphatics with Mycobacterium tuberculosis. Gastrointestinal tuberculosis is rare in the United States, but represents the sixth most common extra-pulmonary location worldwide. Patients usually present with non-specific gastrointestinal symptoms, and the diagnosis is often delayed and is made through a combination of radiologic, endoscopic, microbiologic, histologic, and molecular techniques. Surgery is occasionally required for diagnosis. Antimicrobial treatment is the same as for pulmonary tuberculosis.

RECOGNIZE THE IMPORTANCE OF PRE-EMBOLECTOMY CT PULMONARY ANGIOGRAPHY IN SUSPECTED MASSIVE PULMONARY EMBOLISM Akihiro Kobayashi^{1,2}; Pierre Kory². ¹Beth Israel Medical Center, New York, NY; ²Beth Israel Medical Center, New York, NY. (*Tracking ID #1938452*)

LEARNING OBJECTIVE 1: Recognize the importance of pre-embolectomy CT pulmonary angiography in suspected massive pulmonary embolism.

CASE: A 68 year-old man was admitted for evaluation and treatment of obstructive uropathy due to benign prostatic hyperplasia. On his second day of hospitalization, he suddenly developed shortness of breath. Vital signs revealed blood pressure 80/60 mmHg, heart rate 110/min, respiratory rate 30/min, and 90 % saturation while receiving supplemental oxygen via face mask at 10 L/min. His chest was clear to auscultation and a chest radiograph was unremarkable. Pulmonary embolism (PE) was suspected, however, CT pulmonary angiography (CT-PA) could not be performed due to the development of severe hypotension requiring norepinephrine followed by respiratory failure requiring tracheal intubation. Immediate transfer to the medical intensive care unit (MICU) was performed. In the MICU, a bedside transthoracic echocardiogram (TTE) revealed a severely dilated right ventricle (RV) with reduced function. Bedside compression venous ultrasonography revealed a thrombus in the left common femoral vein. Despite initiation of intravenous heparin for presumed massive PE, the patient remained hypotensive requiring escalating doses of norepinephrine. Due to hemodynamic instability, transport for confirmatory CT-PA was deferred and empiric intravenous tissue-plasminogen activator (t-PA) was initiated based on the high clinical pretest probability of massive PE. Despite t-PA, his hypotension persisted and surgical consultation for thrombectomy was sought. Due to worsening hemodynamics the patient was rushed to the operating room for surgical thrombectomy. A pre-operative transesophageal echocardiogram did not reveal central pulmonary emboli. Main and right pulmonary artery dissection with catheter exploration was performed but no thrombotic material was obtained. An inferior vena cava filter was

placed. Heparin was continued, and his hypotension and respiratory failure resolved over days. A CT-PA on post-operative day 2 revealed bilateral segmental and subsegmental pulmonary emboli.

DISCUSSION: Emergent surgical embolectomy in massive PE is indicated when thrombolytic therapy is contraindicated or has failed and should be considered when hemodynamic instability is likely to cause death before thrombolysis can take effect. Current guidelines have stated that thrombolysis and thrombectomy are justified without a definitive diagnosis of PE in patients with suspected massive PE and RV dysfunction on TTE. Although thrombectomy may be justified without a CT-PA, existing literature suggests that extraction of emboli is limited to the level of segmental pulmonary arteries. This patient required escalating doses of vasopressor despite treatment with both intravenous heparin and t-PA. An emergent surgical embolectomy was performed without a pre-operative CT-PA to establish both the presence and location of thrombi and, as a result, no embolic material could be obtained. The presumed failure of surgical embolectomy was due to the majority of emboli residing in the subsegmental pulmonary arteries at the time of operation. This outcome suggests that, although patients with suspected massive PE are at high risk of death, the importance of avoiding unnecessary and highly invasive procedures such as thrombectomy may outweigh the risks of delay and transport incurred by CT-PA. Thus, CT-PA should be more strongly considered before surgical embolectomy in suspected massive PE.

RECURRENT ACUTE CORONARY SYNDROME DURING EXACERBATIONS OF IMMUNE THROMBOCYTOPENIC PURPURA: THE ROLE OF PLATELET MICROPARTICLES David E. Kim¹; Kenneth A. Schwartz².

¹Michigan State University, East Lansing, MI; ²Michigan State University Breslin Cancer Center, Lansing, MI. (Tracking ID #1938718)

LEARNING OBJECTIVE 1: Recognize that ITP can present as a pro thrombotic state possibly via the generation of platelet microparticles

LEARNING OBJECTIVE 2: Manage acute thrombosis in setting of ITP

CASE: 67 year old male with history of chronic episodic ITP with normal platelet counts between episodes of acute thrombocytopenia, was admitted to the hospital for lower extremity petechiae and blood filled blisters of the oral mucosa with a platelet count of 1 K/uL. His past medical history was significant for splenectomy due to sarcoidosis, pre-existing coronary artery disease, and hypertension. The patient was treated with high dose steroids and IVIG. During the infusion he suddenly developed 10/10 substernal chest pain with difficulty breathing and diaphoresis. Subsequent EKG showed ST depression in anterolateral leads and blood work was significant for elevated troponin of 4.75 ng/mL. Due to his persistently low platelets, the patient did not undergo cardiac cath during his hospitalization. He was continued on high dose steroids and was discharged home after his troponins started to down trend and his platelets stabilized. Further review of his medical records showed that this was the second NSTEMI in the setting of an exacerbation of acute on chronic ITP. His first episode was 5 years ago when he was admitted for an NSTEMI, again in the setting of an ITP exacerbation with a platelet count of 39 K/uL. Cardiac cath at the time showed a chronic occlusion of his RCA with extensive collaterals. PCI of the RCA was attempted but was unsuccessful. Patient had been on 81 mg of aspirin since. A hypercoagulable work up at the time consisting of anticardiolipin antibodies, antithrombin III, prothrombin gene mutation, lupus inhibitor, and protein C and S deficiencies were unremarkable. Serial outpatient platelet counts confirmed his baseline platelets were 200–300 K/uL during the interval (2008 and 2013) between his cardiac events.

DISCUSSION: We hypothesize that in the setting of pre-existing coronary artery disease, acute coronary syndrome may be precipitated via rapid precipitous antibody mediated decreases in platelet count as occurred in our patient and that platelet microparticles generated during the rapid destruction of platelets may help mediate the prothrombotic state. Microparticles are submicron vesicles shed from various cell types that play a role in coagulation, vascular injury, cell signaling, vascular injury, and homeostasis. Platelet microparticles in particular was first described in 1967 by a British Physician, Peter Wolfe who discovered that these particles had pro-coagulant properties. Since then platelet microparticles have been implicated in both arterial and venous thrombotic disease. Our case demonstrates this hypothesis to dramatic effect as our patient's precipitous drop in platelet count has a clear temporal relation to his two episodes of acute coronary syndrome. Management of thrombosis during an exacerbation of ITP is not currently addressed by guidelines. The consensus agreement is that anticoagulation is acceptable at platelet counts 40–50 K/uL and that the underlying ITP should be aggressively treated.

RECURRENT BENIGN LYMPHOCYTIC MENINGITIS (RBLM) IN A PREGNANT WOMAN Delia Lee; Kurt J. Pfeifer; Mark A. Beilke. Medical College of Wisconsin, Milwaukee, WI. (Tracking ID #1895597)

LEARNING OBJECTIVE 1: Diagnose recurrent benign lymphocytic meningitis (RBLM), also known as Mollaret's meningitis

LEARNING OBJECTIVE 2: Tailor treatment of RBLM in pregnant patients

CASE: A 40-year-old African-American woman who was 11-weeks pregnant presented with a 3-day history of throbbing headache associated with photophobia, phonophobia, nausea, vomiting, and nuchal rigidity. She was healthy except for having a history of two episodes of viral meningitis 6 and 17 years prior. She denied association between pregnancy and prior episodes of viral meningitis. Physical exam revealed an alert but mildly distressed woman with tenderness at the temples, mild cervical adenopathy, reproducible nuchal rigidity and positive Kernig's sign but without focal neurological deficits. Complete blood count was normal, and basic metabolic panel was only notable for hypokalemia. Blood cultures were drawn on admission but showed no growth. Cerebrospinal fluid (CSF) studies showed high protein, normal glucose, reactive pleocytosis, and herpes simplex virus (HSV) NAAT positive for HSV-2. Pelvic ultrasound confirmed a single, live intrauterine pregnancy with estimated 11 week gestational age. She completed a 5-day course of intravenous acyclovir and was discharged from the hospital with plans to complete a two-week course of therapeutic-dose of valacyclovir, followed by suppressive valacyclovir at least through the pregnancy. Two days after hospital discharge, her symptoms completely resolved. She completed 5 days of therapeutic valacyclovir but stopped prematurely due to disliking the large pill size. After further discussion, she was agreeable to the suppressive valacyclovir with smaller pills, and subsequently she has had no other documented recurrences.

DISCUSSION: RBLM is postulated to be caused by a reactivation of HSV-2 that may not be concurrent with mucocutaneous manifestations. Incidence is 1–2/100,000, occurring more often in women. Initial treatment is typically intravenous acyclovir, but there are no guidelines regarding treatment and suppression of RBLM, particularly in pregnant women. However, valacyclovir can reduce the number of genital HSV outbreaks during pregnancy. A recent randomized controlled trial demonstrated that with suppression therapy there was no prevention of recurrence. Additionally, there was a possible rebound of recurrence after completion of suppression though a decrease of mucocutaneous outbreaks. However, this study had several exclusion criteria, including pregnancy. In conclusion, we assert that the potential to prevent herpes transmission to the fetus justifies prescribing suppressive therapy for a pregnant woman with RBLM despite the paucity of supportive study data.

However, this study had several exclusion criteria, including pregnancy. In conclusion, we assert that the potential to prevent herpes transmission to the fetus justifies prescribing suppressive therapy for a pregnant woman with RBLM despite the paucity of supportive study data.

RECURRENT CASE OF ASEPTIC MENINGITIS FROM IBUPROFEN Paras Karmacharya¹; Naba R. Mainali¹; Madan R. Aryal¹; Ranjan Pathak¹; Raju Khanal¹; Supriya Shrestha Tamrakar³; Pragya Shrestha²; Benjamin Lloyd¹. ¹Reading Health System, West Reading, PA; ²Nanjing Medical University, Nanjing, China; ³Guangxi Medical University, Guangxi, China. (Tracking ID #1935167)

LEARNING OBJECTIVE 1: Recognize that the clinical course as well as CSF findings of NSAIDs induced aseptic meningitis may be similar to that of acute bacterial meningitis. It should be considered in the differential diagnosis of patients with underlying autoimmune connective tissue disorders and recurrent aseptic meningitis.

LEARNING OBJECTIVE 2: It may be appropriate to screen for autoimmune diseases in healthy subjects developing NSAIDs induced aseptic meningitis. Patients developing this should avoid all types of NSAIDs as these have been described with many NSAIDs and a recurrence can be more severe.

CASE: A 28-year-old female with a history of mixed connective tissue disease on low dose prednisone and Ibuprofen presented with high grade fever, frontal headache, nausea and generalized bodyaches for 1 day. She had been taking ibuprofen 600 mg two to three times a day for the past 2 days for her arthralgia. Physical examination revealed an alert lady with a temperature of 103 °F and hypotension. Neck flexion was slightly limited because of pain. Kernig's and Brudzinski's signs were absent and no focal neurological deficits were elicited on exam. She was started on broad-spectrum antibiotic coverage with cefepime, vancomycin and acyclovir for possible infectious meningitis. Cerebrospinal fluid analysis showed neutrophilic pleocytosis with negative bacterial, viral and fungal cultures. The antibiotics were subsequently discontinued after 3 days. She did not receive any NSAIDs during her hospital course. Her symptoms completely resolved with no neurological sequelae. She was advised not to take NSAIDs and hasn't had a second recurrence as of now.

DISCUSSION: NSAID induced aseptic meningitis is extremely rare, however, the widespread use of ibuprofen, as well as other NSAIDs, particularly for rheumatological diseases makes it an increasing possibility (1). Ibuprofen is the most frequently implicated culprit (2,3). The clinical course as well as CSF findings may be similar to that of acute bacterial meningitis, so it should be considered in the differential, mainly in patients with underlying autoimmune connective tissue disorders and in patients with recurrent meningitis. In fact, NSAID induced meningitis must be considered in any case of recurrent aseptic meningitis, and it may be appropriate to screen for autoimmune diseases in healthy subjects developing this. RECURRENT CONGESTIVE HEART FAILURE, WHEN IT IS NOT ALL ABOUT THE HEART Amornpol Anuwatworn; Imelda A. Cirilo; Viswanathan Iyer; Pramil Cheriyath. Pinnacle Health System - Harrisburg Hospital, Harrisburg, PA. (Tracking ID #1939708)

LEARNING OBJECTIVE 1: Recognize the clinical manifestations of severe pulmonary hypertension caused by high output heart failure due to large atriovenous fistula.

LEARNING OBJECTIVE 2: Investigate and manage severe pulmonary hypertension caused by high output heart failure due to large atriovenous fistula

CASE: A 71 year-old man with a history of ESRD requiring transplantsations in 1998, 2008, non occlusive CAD, hypertension, OSA and COPD presented with 1 year history of progressive exertional dyspnea and recurrent symptoms of congestive heart failure. Brachial cephalic atriovenous (AV) fistula was implanted in 2007 but it was

unused after the successful second transplantation. Examination showed a markedly enlarged right upper extremity AV fistula with thrill and flow murmur. Chest x-ray revealed congestion. Pulmonary function test showed a mild obstructive pattern. Echocardiogram showed normal left ventricular size and function, flattened septum, no aortic stenosis. Right ventricular size was moderately dilated and right ventricular systolic function was moderately reduced. There were moderate tricuspid regurgitation and biatrial enlargement. Pulmonary arterial systolic pressure (PASP) was measured at 71 mmHg. He underwent right heart catheterization and AV fistula was temporary occluded with the use of a blood pressure cuff. The results included PA pressure 64/34 with a mean of 44, PCWP of 24 mmHg. Thermodilution prior to occlusion was 6.7 l/min. Post-occlusion, thermodilution gave a cardiac output of 5.4 l/min. There was reduction in cardiac output with occlusion of the AV fistula, roughly 1.3 l/min. He was diagnosed with severe pulmonary hypertension caused by high output heart failure due to unused large AV fistula. He underwent AV fistula ligation. Repeated echocardiogram at the end of 2 weeks, PASP has already dropped to 50 mmHg and he clinically improved.

DISCUSSION: Etiology of pulmonary hypertension is diverse. We report a rare case of pulmonary hypertension caused by high output heart failure due to AV fistula. As illustrated in this case, the patient had severe pulmonary hypertension with no left-sided valvular heart disease or septal defects. Even though he had COPD, the mild severity of COPD was unlikely a cause of his severe pulmonary hypertension. The right cardiac catheterization revealed high output heart failure. The improvement of his symptoms and PASP after AV fistula ligation confirmed that large AV fistula resulted in high output heart failure leading to severe pulmonary hypertension. In patients with pulmonary hypertension who have ESRD and AV fistula, high output heart failure due to enlarged AV fistula may be a culprit.

RECURRENT PLEURAL EFFUSION AS THE PRESENTING MANIFESTATION OF MULTIPLE MYELOMA Lawrence Giove; Nikhil Kapila; Andrew Hamarich. University of Connecticut, Farmington, CT. (Tracking ID #1937498)

LEARNING OBJECTIVE 1: Recognize that pleural effusion is a rare initial manifestation of multiple myeloma.

CASE: A 70-year-old man presenting to the hospital with recurrent bilateral pleural effusion of unclear etiology. Previously, pleural fluid studies revealed a transudate effusion with negative cytology for malignancy or infection. Upon presentation, he complained of chronic cough and worsening dyspnea. He denied previous cardiac or pulmonary disease, trauma, cancer, or exposures. His social history was significant for 35 pack years of tobacco use, having quit 15 years prior. Physical exam revealed an elderly man, in mild respiratory distress. He was noted to have limited chest excursion with decreased breath sounds at the lung bases. The remainder of his exam was unremarkable. White blood count was 8300 cells/mm³, hemoglobin was 11.9 g/dL, serum creatinine was 3.0 mg/dL and serum calcium was 8.4 mg/dL. A chest x-ray revealed mild cardiomegaly, prominent vascular markings, and bilateral pleural effusions. Echocardiogram showed left ventricular ejection fraction of 65 % without evidence of pulmonary hypertension. Subsequently, the patient underwent a video assisted thoracoscopy, right basilar lung biopsy, pleural biopsy, and talc pleurodesis. Initial pleural studies revealed an exudative effusion with a white blood cell count of 350 cells/mm³, 95 % mononuclear cells, lactate dehydrogenase was 229 IU/L, fluid protein was 2900 mg/dL, and pH 7.5. The fluid and pleural biopsy were negative for infection, plasma cells or other tumor cells. Pathology of the lung biopsy revealed characteristic apple green birefringence compatible with amyloid deposition. The patients serum protein electrophoresis was without the presence of an M protein, however, his urine immunofixation was significant for the presence of lambda free light chains. A bone marrow biopsy revealed 20 % plasma cells, which exhibited lambda light chain monocytia. His hospital course was complicated by an episode of ventricular tachycardia, which was treated with intravenous lidocaine. Cardiac MRI was performed and findings were consistent with amyloid deposition in the myocardium. The patient met the diagnostic criteria for multiple myeloma with >10 % plasma cells on bone marrow biopsy and monoclonal protein in the urine. The etiology of his recurrent pleural effusions was secondary to amyloid deposition in the setting of a light chain restricted plasma cell dyscrasia. He was started on bortezomib, cyclophosphamide, and decadron in the outpatient setting and currently is in remission.

DISCUSSION: Multiple myeloma accounts for 1 % of all cancers and 10 % of all hematologic malignancies. It is primarily a disease of the bone marrow, but can involve other organ-systems. Thoracic manifestations include plasmacytomas, mediastinal lymphadenopathy, bony lesions and pleural effusions. Pleural effusion in myeloma can occur due to several mechanisms. These mechanisms include the involvement of the pleural space from adjacent skeletal or parenchymal tumors, lymphatic obstruction, nephrotic syndrome, chronic renal failure, restrictive cardiomyopathy, and pulmonary amyloidosis. Direct myeloma involvement of the pleural space is extremely rare occurring in less than 1 % of cases. Persistent pleural

effusions develop in 1 to 2 % of patients with systemic amyloidosis and appear to be caused by pleural infiltration with amyloid deposits. In myeloma, these amyloid deposits are a result of deposition of protein from immunoglobulin light chain fragments. Light chain myeloma can be missed on serum electrophoresis and urine electrophoresis should always be done. Pulmonary amyloidosis can be diagnosed by bronchoscopic lung biopsy. Pleural involvement can be diagnosed by presence of plasma cells in pleural fluid or a pleural biopsy. Persistent pleural effusions due to amyloidosis or myelomatous involvement of the pleural space are associated with a poor prognosis and limited response to treatment.

RECURRENT PLEURAL EFFUSION IN A PATIENT WITH NEPHROLITHIASIS: A CASE FOR CAUTION Aderonke Salau-Okeleji; Michael Riveros; Maryam Sattari. University of Florida, Gainesville, FL. (*Tracking ID #1933671*)

LEARNING OBJECTIVE 1: Recognize urinothorax as a rare cause of pleural effusion, especially in patients with recent urinary tract manipulation

LEARNING OBJECTIVE 2: Become familiar with clinical presentation of urinothorax

CASE: A 70-year-old male with a history of hypertension and nephrolithiasis presented with weakness, productive cough, and decrease in oral intake and urine output. The patient had recently undergone percutaneous nephrolithotomy for bilateral staghorn calculi and hydronephrosis, shortly after which he had developed an asymptomatic right-sided pleural effusion. He was initially treated empirically with Augmentin for “parapneumonic effusion.” However, he had presented again with shortness of breath and cough and undergone repeat thoracentesis with removal of 1.7 L and 2.7 L of “exudative” pleural fluid. On presentation, the patient was tachypneic, hypoxemic, and had decreased right-sided breath sounds. The most significant lab abnormality was a serum creatinine of 3.9 mg/dL. Chest x-ray confirmed recurrence of right-sided pleural effusion. Thoracentesis removed 1.5 L of pleural fluid. Since the effusion was recurrent and had appeared in the setting of recent urological manipulation, pleural fluid creatinine was checked in addition to conventional studies. Fluid-to-serum creatinine ratio greater than 1 confirmed the diagnosis of urinothorax. Acute kidney injury was thought to be obstructive in nature and improved with Foley catheter placement. To prevent recurrence of effusion, the patient underwent talc pleurodesis with chest tube placement, followed by repeated doxycycline pleurodesis. Chest tube was eventually removed successfully.

DISCUSSION: Urinothorax, a rare form of pleural effusion, results from accumulation of urine in the pleural space. Reported etiologies include obstructive uropathy, blunt and iatrogenic trauma, urinary tract malignancy, and renal transplantation. The appearance and odor of the pleural fluid is often consistent with urine. The fluid usually fulfills Light's criteria for a transudate with low glucose and pH. However, elevated LDH levels may lead to misclassification as an exudative effusion, as demonstrated by our case. Furthermore, the biochemical characteristics of the pleural fluid may become modified depending on duration of its presence in the pleural space or after repeat thoracentesis. The pleural fluid-to-serum creatinine ratio >1.0 might be the most reliable marker for this condition. Various techniques, including Mercaptoacetyltriglycine (MAG3) renogram, may aid in establishing the diagnosis of urinothorax by demonstrating leakage of the tracer from the urinary tract into the pleural space. While urinothorax may resolve with relief of urinary obstruction, iatrogenic/traumatic cases associated with a direct tract to the pleura may persist or recur, as in our case. As urological procedures become more common, urinothorax will likely increase in incidence. As our case demonstrates, urinothorax can often go undiagnosed. Timely diagnosis requires a high index of clinical suspicion and should be considered whenever a pleural effusion occurs in the setting of urinary tract obstruction or recent urological intervention. The creatinine level of pleural fluid, a biochemical parameter not routinely measured, should be determined. Furthermore, earlier thoracentesis is more likely to reveal the characteristic parameters of urinothorax.

RECURRENT PNEUMONIA OR PULMONARY ALVEOLAR PROTEINOSIS: A CONCEALED DIAGNOSIS Fayruz Araji¹; Omar Mousa²; Daniela Moran³.

¹Universidad Francisco Marroquin, Guatemala, Guatemala; ²SUNY Upstate Medical University, Syracuse, NY; ³Lung and Asthma Clinic, Houston, TX. (*Tracking ID #1934266*)

LEARNING OBJECTIVE 1: Diagnose Pulmonary Alveolar Proteinosis when the presentation is challenging with different mimickers of the disease.

LEARNING OBJECTIVE 2: Recognize that outcomes are worrisome for disease progression with high rates of recurrence and mortality.

CASE: We hereby present a case of a 49-year old Middle Eastern male patient who presented with worsening exertional dyspnea and productive cough with thick secretions for 3 months. In the preceding 6 months, he was evaluated multiple times for abnormal chest X-rays and clubbing and he was treated for recurrent pneumonia with oral antibiotics and glucocorticoids. He noticed weight loss of 20 lb but denied other symptoms. He had a history of recurrent sinusitis with no lung disease or a family history of similar illnesses. He worked as an aircraft maintenance technician and reported exposure to fiberglass and metal dust. He had a 25 pack-year smoking history with no recent travel. Physical examination revealed tachycardia (110 bpm) and hypoxemia (O2 saturation 92 % on 6 L O2). He had clubbing, bilateral diffuse crackles and the exam was otherwise unremarkable. He had bilateral interstitial alveolar infiltrates on the chest X-ray and the CT scan showed diffuse ground glass opacities bilaterally. Bronchoscopy was unremarkable and a single bronchoalveolar lavage culture was positive for nontuberculous mycobacterium. His symptoms worsened despite inpatient care and close monitoring. He required a video-assisted thoracoscopic surgery and anatomic pathology showed filling of the alveolar spaces with eosinophilic acellular finely granular material that stained positive with PAS, consistent with Pulmonary Alveolar Proteinosis. He received high volume bilateral lung lavage, oxygen therapy, GM-CSF 250 mcg SQ daily and anti-mycobacterial treatment with rifampin and ethambutol. The hospital course was complicated by non-sustained ventricular tachycardia. He improved slowly after a prolonged hospital stay.

DISCUSSION: Pulmonary alveolar proteinosis (PAP) is a very rare disease of the lungs with an estimated annual incidence and prevalence as high as 0.49 and 6.2 cases per million, respectively. The natural history of PAP has been studied over the past 6 decades through less than 1000-reported cases. The diagnosis is easily missed and delayed due to the mimickers of its various presentations, including disorders with similar radiographic manifestations. With only 8 % of patients experiencing clinically significant spontaneous improvement, delay in the management increases the mortality risk. Healthcare providers should have a high index of suspicion for PAP in patients with recurrent pneumonia. Raising awareness about the stepwise plan of treatment with whole lung lavage, inhaled GM-CSF then rituximab improves the clinical outcomes and the pulmonary function. Early intervention with such therapeutic modalities remains the standard of care until further immunologic mechanisms are discovered.

RECURRENT RASH WITH FEVER Sadie Trammell Velasquez. ¹University of TX Health Science Center at San Antonio, San Antonio, TX; ²South Texas Veterans Healthcare System, San Antonio, TX. (*Tracking ID #1936647*)

LEARNING OBJECTIVE 1: Identify the differential diagnosis of fever and rash in an adult.

LEARNING OBJECTIVE 2: Recognize the clinical presentation of Adult-Onset Still's Disease and understand the treatment and clinical course of Adult-Onset Still's Disease.

CASE: A 20 year-old woman presented with 3 days of fever, rash and arthralgias. Arthralgias were of elbows, ankles and back. She describes her rash as non-painful and non-pruritic that has progressed to cover her arms, palms and legs. She has also had associated myalgias and a sore throat. Her temperature was 39.4oC; heart rate 145 bpm; blood pressure 127/76 mmHg. She was tachycardic with regular rhythm. Skin exam revealed erythematous, somewhat blanching thin plaques with slight edema scattered on her bilateral arms, bilateral and medial aspects of legs, lateral thighs/hips and lower chin/neck and spared her torso; bilateral palms had macular lesions, slightly raised papules (PICTURE). The remainder of her exam was normal. Her WBC was 8 with 31 % bands; hemoglobin was 13 and platelet count of 253,000. Her liver function tests were normal. Her LDH was elevated at 550 IU/L and ferritin elevated to 1411 ng/mL. Her RPR was negative in addition to ANA, HIV antibody, HIV PCR, respiratory viral PCR, monospot heterophile antibody, CMV and throat culture. Her complements were normal. The patient was admitted and started on high dose ibuprofen with continued fevers yet resolution of her rash. On hospital day four she was initiated on prednisone 20 mg daily with resolution of her fevers. She followed up with Rheumatology 3 weeks after discharge.

DISCUSSION: Fever and rash are common findings that the general internist (hospitalist) encounters. A stepwise approach to determining the etiology of this constellation of symptoms should be taken and careful attention should be taken to assure that a treatable cause is not overlooked. The differential diagnosis with erythematous, slightly edematous rash with fever includes reactive, viral exanthema, autoimmune/connective tissue disease, Adult Onset Still's disease (ASD). Viral etiologies are to be considered given her sore throat, arthralgias and other nonspecific complaints. In our patient with fever and rash, the associated arthralgias clued the diagnosis of ASD. Currently there is no specific test or combination of tests that can be used to establish the diagnosis of ASD. The Yamaguchi criteria have the highest

sensitivity in patients with a definite diagnosis of ASD. This criteria requires five features for diagnosis, two being the major criteria. ASD has been associated with markedly elevated serum ferritin concentrations in as much as seventy percent of patients.

RECURRENT VS. LINGERING LEGIONELLA? A CASE HIGHLIGHTS RISK FACTORS, DIAGNOSTIC CHALLENGES AND KNOWLEDGE GAPS IN THE AFTERMATH OF HURRICANE SANDY Madeline R. Sterling, New York Presbyterian - Weill Cornell, New York, NY. (*Tracking ID #1927313*)

LEARNING OBJECTIVE 1: Review clinical features of Legionella Pneumonia and understand how a clinical test (Urine Antigen) is applied and interpreted.

LEARNING OBJECTIVE 2: Demonstrate how the incidence of Legionnaire's disease is affected by environmental exposures and patient characteristics.

CASE: A 73 year-old man with CLL (stage 3, on immunosuppression) and hospitalization 1 year prior for Legionella pneumonia, presents from home to our hospital with 3 days of intermittent fevers and 1 week of blood-tinged sputum. He reports a maximum oral temperature of 103 F, associated with a productive cough. He notes dyspnea and hemoptysis of blood-tinged sputum for the last week. He denies night sweats, weight loss, lymphadenopathy, rhinorrhea, headache, neck stiffness and chest pain. He is retired and is able to walk 20 city blocks without dyspnea at baseline. He denies recent travel or Tuberculosis exposure. The patient's apartment was victim to flooding from Hurricane Sandy; his apartment sustained extensive water damage. He did not relocate due to finances. He has not been to a primary care provider since his last hospitalization. On presentation he was afebrile and breathing comfortably (O2sat 98 %) on 2 L NC. He was alert and oriented, speaking in full sentences, without blood in his oropharynx. His lung exam was notable for decreased breath sounds on the right, without dullness to percussion. CT was remarkable for diffuse bilateral groundglass opacities, right greater than left, suspicious for diffuse alveolar hemorrhage. Blood cultures, PCR for atypical pneumonias and fungal cultures were negative. Urine Legionella antigen was positive and he was treated with Levaquin for 7 days. The patient was hemodynamically stable and improving; a diagnostic bronchoscopy was deferred.

DISCUSSION: Legionella, which was first discovered in a 1976 Philadelphia outbreak linked to water supply and air conditioning units, is a common cause of community-acquired and nosocomial Pneumonias. When the clinical situation appropriate, a urine antigen test is used to detect *L. pneumophila*. The test, which is relatively cheap and rapid, has a sensitivity of 70 % and specificity of 99 %. Although easy to diagnose, clearance is difficult to pinpoint, particularly in immunocompromised hosts such as this patient. Following treatment, it is not recommended to check urine antigen in the outpatient setting, since false positive tests are likely in the short term. In fact, immunocompromised patients can shed the antigen upwards of 300 days post-treatment. Not only is this patient at risk due to his lymphoma treatment(s), but he remained in his flood-zone apartment during (and after) the largest Atlantic hurricane on record, Sandy. Although Legionella has an incubation of 2 to 14 days after exposure, several hard-hit regions took several months to be restored and cleaned. It is unclear how flooding and stagnant water affected his clinical state and susceptibility for this bacterium. Further research ought to examine the association between hurricane-affected areas and disease incidence. If Legionella incidence is higher in flood zones, then patients with clinical risk factors or prior infections ought to be screened more vigilantly and counseled regarding early evacuation by their primary care providers.

RED, HOT, SWOLLEN, AND TENDER: A CASE OF CELLULITIS? Aderonke Salau-Okeleji^{1,2}; Margaret C. Lo^{2,1}. ¹Univeristy of Florida, Gainesville, FL; ²University of Florida, Gainesville, FL. (*Tracking ID #1939038*)

LEARNING OBJECTIVE 1: Distinguish between the clinical, diagnostic, and therapeutic features of refractory cellulitis vs. drug-induced myositis

LEARNING OBJECTIVE 2: Recognize the adverse health effects of popular energy drinks, the associated risk factors in the development of these adverse effects, and the need for screening for abuse of energy drinks.

CASE: A 30 year-old healthy, athletic Caucasian male was admitted by his PCP for refractory cellulitis after he failed to respond to a 7-day course of oral doxycycline for worsening right arm swelling with pain and redness. He denied any trauma or associated fevers, chills, right arm paresthesia or weakness. Vital signs on admission were all normal including temperature. Physical exam revealed a severely erythematous right upper extremity with increased warmth, dependent +2 pitting edema and taut skin extending from proximal biceps to distal elbow. Rest of the cardiopulmonary, skin, musculoskeletal and neurologic exam was unremarkable. Admission laboratory values including BMP, CBC, CRP, ESR, and

blood cultures were all normal. Upon hospitalization, the patient was started empirically on IV Vancomycin for presumed refractory cellulitis that had failed out patient management. However, when he failed to improve on hospital day 2, investigation for noninfectious causes was initiated in light of no other objective evidence of systemic infections. Right upper extremity Doppler ultrasound was negative for DVT. Further studies including CPK level came back severely elevated at 11640 U/L with corresponding elevated aldolase value of 30.8 U/L. Urine myoglobin and anti-Jo 1 antibody titers were negative; ESR/CRP levels remained normal. Subsequent MRI of the right arm showed nonspecific myositis and swelling of the biceps, brachialis, and pronator teres. Further history from the patient revealed that 1 week prior to presentation he and his friends had vacationed at South Beach for Spring Break week where he had "gone clubbing all night, every night" and had gone weight-lifting during the day. To stay awake, he would drink 3–4 cans/day of Red Bull and 2–3 shots/day of 5-hour Energy. With this history, antibiotics were discontinued and supportive measures including IV fluids, arm elevation, and ice were started. His right arm symptoms resolved and his CPK level normalized 2-weeks later at his PCP follow-up visit.

DISCUSSION: Energy drinks such as Red Bull, Monster, and 5-hour Energy have become quite the craze in young adult culture with self-report surveys of consumption in 30–50 % of adolescents and young adults. Touted for positive effects on physical and mental endurance, growing evidence in the literature has now surfaced that energy drinks are not as harmless as advertised. Multiple studies have revealed adverse health effects such as obesity, seizures, cardiac anomalies (hypertensive urgency, tachyarrhythmias), strokes, rhabdomyolysis, mood disorders (mania, anxiety attacks), and even death. Our case adds to the literature by highlighting the potential for energy drinks to cause myositis. Such clinical presentations can become a diagnostic challenge by mimicking cellulitis. However, unlike cellulitis, clinicians must recognize that drug-induced myositis exhibits no systemic signs of infection (i.e. fevers, leukocytosis, elevated ESR/CRP), often fail to respond to antibiotics, and produces severe CPK and aldolase elevation. Risk factors for incurring the detrimental effects of energy drinks include mixture with alcohol and dehydration. Sleep deprivation and extreme exercise workouts can also be included as risk factors, as revealed in our case. Since there are no current diagnostic guidelines for energy drink abuse, a detailed and targeted social history for energy drink ingestion, either alone or with alcohol, is instrumental in the prompt recognition and management of their adverse effects. Screening by clinicians is particularly important for athletes, young adults with high-risk behaviors, certain health conditions (i.e. seizures, diabetes, obesity, hypertension, cardiac anomalies), and those with unexplained myalgias/myositis, behavioral/mood changes, anorexia, or sleep problems.

REDISCOVERING AN ANCIENT DIAGNOSIS Stephanie Behringer; Gianni Carrozzi. Montefiore Medical Center, Bronx, NY. (*Tracking ID #1939336*)

LEARNING OBJECTIVE 1: Recognize visceral manifestations of tertiary syphilis in a patient with hepatic lesions

CASE: A 32 year-old man with HIV (normal CD4 count, on HAART), high risk sexual behavior and polysubstance abuse presented with 4 weeks of vague abdominal pain. The pain was diffuse and dull in nature, intermittent and would last several days before resolving on its own. He denied fevers, chills or weight loss and was well appearing. Infectious workup was notable for a positive serum RPR test with a titer of 1:256, but was otherwise negative. His primary care doctor and the New York State Department of Health confirmed that he had been diagnosed with syphilis in the past. However, it was unclear whether he had been successfully treated, and he continued to engage in high-risk sexual behavior, exposing himself repeatedly to reinfections and had poor medical follow up. A CT scan of the abdomen revealed scattered ill-defined hypodense lesions within the liver.

DISCUSSION: Syphilis is caused by the spirochete *Treponema pallidum* and is virtually always sexually transmitted. About 6 % of patients with HIV infection have serologic evidence of syphilis. If left untreated, 25–40 % of patients will develop late phase syphilis, also known as tertiary syphilis. Tertiary syphilis can manifest itself anytime from 1 to 30 years after primary infection and has become a forgotten diagnosis in parts of the world where screening and antibiotic treatment have made advanced stages of this disease a rare finding. In the past, however, tertiary syphilis used to be a common diagnosis leading to visceral involvement with space occupying lesions known as syphilitic gummatata (or syphilitic gummata). These lesions are granulomas that contain a central necrosis and are surrounded by inflammatory tissue that can mimic metastatic disease or sarcoidosis. In some cases, they are found in the liver, but can develop in any organ. In cases of hepatic involvement, patients can present with abdominal discomfort, mild hepatitis, jaundice and fatigue. Depending on size and location, syphilitic gummata can cause portal hypertension, variceal bleeding, hepatic vein thrombosis, ascites and liver failure. They are not malignant in nature, but can lead to biliary obstruction. Antibiotic treatment usually results in complete resolution of the lesions. The diagnosis of tertiary syphilis with visceral involvement is confirmed by high serologic markers (serum RPR titer >1:32) and by response to treatment with penicillin. Biopsies of

gummata may be indistinguishable from other granulomatous diseases unless spirochetes are visualized within the tissue samples. Treatment of tertiary syphilis requires a prolonged antibiotic course with penicillin as spirochetes are slowly growing bacteria. Therapeutic levels are achieved with long-acting depot penicillin preparations. The current guidelines recommend Benzathine penicillin G 2.4 million units IM once a week for a total of 3 weeks.

REDUCING POLYPHARMACY IN THE ELDERLY-ROUND AND ROUND WE GO Celeste Newby; Alegra Venditto. Tulane University Health Sciences Center, New Orleans, LA. (*Tracking ID #1924994*)

LEARNING OBJECTIVE 1: Discuss the challenge of managing polypharmacy in the elderly.

LEARNING OBJECTIVE 2: Highlight physician barriers to reducing polypharmacy in the elderly and the need for greater evidence-based strategies to reduce polypharmacy

CASE: A 69-year-old man with multiple medical problems presented to his primary care physician (PCP) for medication review after expressing confusion about his regimen. He also sees four subspecialty physicians who manage his chronic diseases. Review of his medication list via the electronic medical record revealed twenty total medications; all five of his physicians had prescribed medications. As requested, the patient presented to clinic with his home medications in two large duffel bags containing a total of 45 medication bottles. In addition to his currently prescribed regimen, the patient had two expired antibiotics, three duplicate medications, and medications for blood pressure and muscle pain that had been previously discontinued. After review, 25 medication bottles were given to pharmacy for destruction. A complete medication list, including essential and as-needed medications, was reviewed with patient. The electronic medical record was reconciled accordingly, with all extraneous medications eliminated. The patient returned to primary care clinic 1 month later after seeing several specialists. Four new medications had been added to his list. Again, the medication list was reviewed and edited with the patient as it had been the month prior.

DISCUSSION: Polypharmacy is a well-known topic to most internists, and an important consideration in caring for any elderly patient. One in six hospital admissions (one in three for age >75) for older adults can be attributed to an adverse drug effect. Older patients often have multiple chronic diseases, and long medication lists consisting of both essential and as-needed prescriptions. The clinical picture is complicated further by multiple prescribers. Medication lists can easily grow or change when patients have new complaints or are involved in care transitions. Even with electronic medical records, keeping medication lists current and appropriate can be a daunting task. The PCP often feels a responsibility to reduce polypharmacy, as he or she is the main coordinator of a patient's care. While studies have reported that the number of prescribing physicians is an independent risk factor for adverse drug reactions in the elderly, physicians report awkwardness and reluctance to discontinue a medication prescribed by another physician. Additional barriers include difficulty in convincing patients to discontinue long-term medications, and problems distinguishing between new complaints and medication side effects. While there is great interest in improving appropriate medication use in the elderly, how to best accomplish this goal is still unclear. A recent Cochrane review found that while the Beers criteria and Medication Appropriateness Index (MAI) appeared beneficial in reducing medication-related problems and inappropriate prescribing, it was not clear that these interventions translated into clinically significant improvements. More evidence-based strategies are needed to implement meaningful change in the area of polypharmacy to improve safety for older patients.

REFRACTORY HYPOGLYCEMIA IN A TYPE 1 DIABETIC PATIENT - CLUE TO ADDISON'S DISEASE AND AUTOIMMUNE POLYENDOCRINE SYNDROME TYPE 2 Anene Ukaigwe; Adetokunbo Oluwasanjo. The Reading Health System, West Reading, PA. (*Tracking ID #1936684*)

LEARNING OBJECTIVE 1: Recognize features of Autoimmune Polyendocrine Syndrome type 2 (APS-2).

LEARNING OBJECTIVE 2: Manage and appropriately screen APS-2 patients.

CASE: A 47-year-old Caucasian female presented for the third time to the emergency room with hypoglycemia and hypotension. For 3 months, she had recurrent hypotension, hypoglycemia, fatigue, orthostatic dizziness, weight loss and vomiting. She had a 16-year history of T1DM. Glycemic control was stable for 6 years on same dose of insulin. She had hypothyroidism for 5 years, also stable on levothyroxine. She denied recent travel, lifestyle or medication changes. Insulin dose was adjusted several times but hypoglycemic episodes persisted, occurring 2–3 times weekly. For her symptoms, she had seen a Cardiologist, Neurologist, Otorhinolaryngologist,

Primary Care and Emergency Physicians. Work up thus far excluded Multiple Sclerosis, cobalamin deficiency, myasthenia gravis, hemochromatosis, vestibular, cardiac and rheumatologic disease. On examination she was alert and oriented, hypotensive; Blood Pressure = 87/53 mmHg and tachycardic; Heart rate = 124/min. Her skin was diffusely tan. The remaining exam was unrevealing. Labs showed Complete Blood Count, renal, liver and thyroid function tests were within normal range. Blood glucose was 70 mg/dL. Adrenal insufficiency was suspected based on hypoglycemia, hypotension, tachycardia and tan skin. This was confirmed with serum cortisol = 0.8 mcg/ml (normal 8.7–22.4 mcg/dL) and ACTH = 298 pg/ml (normal 10–60 pg/ml). After intravenous hydrocortisone and fluids, symptoms resolved. Given hypothyroidism, adrenal insufficiency and T1DM further antibody tests confirmed APS-2.

DISCUSSION: APS-2 is an autosomal dominant disease affecting HLA genes. APS-2 is characterized by Addison's disease, autoimmune thyroid disease and type I diabetes mellitus. Other associated disorders include Pernicious anemia, celiac disease, Hepatitis, Hypogonadism, Hypophysitis, vitiligo. Unlike APS-2, APS-1 affects only children. APS-2 occurs more in females and is often diagnosed between ages 30s to 40s. Although APS-2 is uncommon (1.4–4.5 per 100,000), its prevalence increases when subclinical cases are included (150 per 100,000) implying it is not as rare as believed. The clinical presentation depends on specific APS-2 component disorders and involved organs. However, conventional treatment for each component disorder is often sufficient. Specialist care is required only as needed. The importance of APS-2 is illustrated in our patient. More than one APS-2 disorder should raise vigilance for associated disorders given that clinical features of these disorders are nonspecific. In addition, the interval between development of one disorder and the next can be as long as 20 years, making screening necessary for early initiation of disease-specific management. Experts recommend that patients with two APS-2 disorders should be screened every 1–2 years until 50 years old. In addition to detailed history and physical examination, screening includes autoantibody testing for T1DM, thyroid disease, Addison's disease, Celiac disease and autoimmune hepatitis. Vitamin B12, sex hormone and blood glucose levels including liver and thyroid function tests are also useful.

RELATED CEREBRAL HEMORRHAGE WITH AN INFECTED ABDOMINAL AORTIC ANEURYSM AND VERTEBRAL OSTEOMYELITIS? Suzue Hirano-Kuwata; Yumiko Kanzaki; Hirokazu Mizohata; Keishi Kuriyama; Kentaro Isoda; Kenichiro Hata; Yukimasa Ooi; Akira Ukimura. Osaka Medical College Hospital, Takatsuki, Osaka, Japan. (*Tracking ID #1934970*)

LEARNING OBJECTIVE 1: Manage the complications of bacteremia.

LEARNING OBJECTIVE 2: Recognize the causes of intracranial hemorrhage.

CASE: A 73-year-old man with hypertension, coronary artery disease, and peripheral artery disease presented with severe lumbago and fever. Despite several different types of intravenous antibiotic treatments at another hospital, his symptoms remained over 2 weeks. He was transferred to our institution for further treatments. On admission, his body temperature was 38.0, his heart rate was 74 beats/min, and respiratory rate was 18 breaths/min. Laboratory studies showed a WBC count of 10160/ μ L (79 % neutrophils, 13 % lymphocytes), and a CRP concentration of 155 mg/L. He was diagnosed as vertebral osteomyelitis (disk-space infection) based on a hyperintense lesion of the spine on MRI. Streptococcus sanguinis was detected in one of three blood cultures. The transthoracic echocardiogram revealed no valvular vegetation, no other evidence of infective endocarditis, nor any regurgitant murmur was heard. His symptoms gradually improved with antibiotic therapy, but a CT scan showed a newly developed abdominal aortic aneurysm with periaortic soft tissue infiltration. The diameter of the abdominal aorta was 35 mm; it had been 20 mm on admission and we recognized it as an infectious aortic aneurysm. The aneurysm was adjacent to the vertebral osteomyelitis and despite sustained antibiotic treatment, the aneurysm enlarged. Eventually he had a graft implantation operation and was discharged 22 days after surgery. Two months after the aortic operation, he presented with left hemiplegia. A CT scan of the head showed a right putamenal hemorrhage, and he had an open craniotomy and an evacuation of the hematoma. He survived but was left with significant disability.

DISCUSSION: We describe a case of vertebral osteomyelitis, an infected abdominal aneurysm, and cerebral hemorrhage, which occurred in a short period of time. One possible cause of all three phenomena is hematogenous spread of infection. Vertebral osteomyelitis most often results from hematogenous seeding. Infected aortic aneurysms are also related to hematogenous spread of infection. Co-existence of an infected aneurysm and vertebral osteomyelitis is occasionally reported, and is thought to be caused by contiguous involvement of the vessel wall from adjacent pyogenic vertebra. Our patient presented with cerebral hemorrhage only 4 months after the initial symptoms. The most common cause of cerebral hemorrhage is hypertension, but intracranial infectious aneurysm is one of the

causes. A minimum of 4 to 6 weeks of antimicrobial therapy is recommended for intracranial infectious aneurysm, but there remains a high risk for rupture even during appropriate medical treatment. It may be beneficial to perform cerebrovascular imaging on patients with a suspected infectious aneurysm. We are not sure whether this cerebral hemorrhage is relevant to an infected cerebral aneurysm, without previous examinations of cerebral arteries. This case involved vertebral osteomyelitis with an adjacent infected aneurysm and subsequent cerebral hemorrhage. Hematogenous spread of infection can explain the sequence of phenomena, though it is not proven. This case provides us an opportunity to consider further therapeutic plans that might lead to a better prognosis.

RESISTANT HYPOGLYCEMIA FROM GLYBURIDE-CIPROFLOXACIN INTERACTION Suzanne J. Supplee; Anthony A. Donato. Reading Health System, West Reading, PA. (*Tracking ID #1939107*)

LEARNING OBJECTIVE 1: Recognize a drug interaction between glyburide and ciprofloxacin may lead to potentially fatal hypoglycemia.

CASE: A 50 year-old male with a history of diabetes mellitus type 2 on long-term combination glyburide/metformin therapy who was recently treated with a 14 day course of ciprofloxacin for venous stasis ulcers presented to the ED after his sister noticed he was disoriented, mumbling, diaphoretic and unarousable, but exam was otherwise non-focal. EMS recorded a finger stick blood glucose at 33 mg/dl. The patient was given one ampule of D50 en route. Upon arrival to the ED, the patient required another 3 ampules of D50 to get serum glucose over 100 mg/dl. A 5% dextrose in half normal saline solution at 150 ml/h was required to stabilize his blood sugars over the next 24 h. The patient denied any recent change in medications except for the ciprofloxacin course completed 10 days prior, and in fact had not taken the oral hypoglycemic in the 24 h leading up to admission. He denied medication misuse, exogenous insulin or alcohol use. He denied any previous episodes of hypoglycemia. Laboratory values included a normal TSH and WBC count. Abdominal CT was negative for pancreatic mass. Abnormal laboratory values at the time of hypoglycemia included a C-peptide of 8.1 ng/ml (normal: 1.1–4.4 ng/ml) and free Insulin of 59 µIU/ml (normal: 1.4–14 µIU/ml).

DISCUSSION: Hypoglycemia is a common medical complication in patients receiving pharmacotherapy for diabetes that may result in permanent neurologic deficits and even death if unrecognized. With over 285 million people diagnosed with diabetes worldwide, many require oral hypoglycemic agents for disease management. A possible interaction between glyburide and ciprofloxacin has been reported, resulting in reduced drug clearance and a prolonged hypoglycemic effect of glyburide. Recognition of potential drug side effects is critical in the management of complex medical patients. Ciprofloxacin causing hypoglycemia in patients taking glyburide may be under-reported as the mechanism of action is poorly understood, therefore a causal relationship overlooked. A thorough medication history in hypoglycemics is essential to uncover potential adverse drug interactions. In patients on sulfonylurea therapy presenting with hypoglycemia of unknown etiology, ciprofloxacin should be considered as a potential cause and prescribed cautiously in patients currently on glyburide therapy.

RETIFORM PURPURA AS A CLUE TO DIAGNOSIS Sarah Apgar. Yale-New Haven Hospital, New Haven, CT. (*Tracking ID #1938728*)

LEARNING OBJECTIVE 1: Recognize the clinical features of retiform purpura

LEARNING OBJECTIVE 2: Understand the differential diagnosis of retiform purpura

CASE: A 50 year-old asplenic man with a history of hypertension presented with 4 days of nausea, vomiting and diarrhea and 1 day of lower extremity burning pain and numbness. Two days prior to admission he noted red spots on his upper thighs which became larger blotches on his feet and ankles followed by bluish discoloration of his third toe. Upon admission, he was afebrile, tachycardic at 125 with a blood pressure of 123/82. Physical examination demonstrated an ill man with a non-blanching purple mottled rash on the legs and feet without neurologic deficit. Blood work revealed a creatinine of 4.8 mg/dl, white blood cell count of 40 with 36 % bands, platelet count of 67, normal coagulation studies and lactic acid of 3.3. He was admitted to the intensive care unit and started on broad spectrum antibiotics and intravenous fluids. Further investigation revealed a D-dimer of >10,000, fibrinogen of 959, negative anti-cardiolipin antibodies and ANA<1:40. A skin biopsy was compatible with disseminated intravascular coagulation and purpura fulminans without evidence of vasculitis. Extensive infectious evaluation did not reveal a specific pathogen as the etiology of his sepsis. The patient subsequently required a transmetatarsal amputation of the left foot, as well as amputation of his third and fifth toes on the right for treatment of gangrene.

DISCUSSION: Purpura is defined as visible hemorrhage into the skin or mucous membranes. It can be classified by size, palpability of the lesions and presence of the livedoid pattern. Retiform purpura results from occlusion in the vessels that cause the livedo reticularis pattern. What is observed clinically is hemorrhage into the skin around occluded dermal vessels resulting in a “puzzle-piece” morphology. Two major causes include vasculitis and microvascular occlusion syndromes which manifest as inflammatory or non-inflammatory retiform purpura respectively. The major distinguishing factor between the two is palpability of the lesion; however, there is significant overlap clinically and often a biopsy is required for diagnosis. Microvascular occlusion syndromes can be caused by thrombotic, embolic or infectious phenomena. Some common etiologies include anti-phospholipid antibody syndrome, calciphylaxis, warfarin necrosis, cholesterol emboli and disseminated intravascular coagulation (DIC). DIC results from massive activation of the clotting cascade and manifests clinically with either bleeding or thrombosis. Purpura fulminans is a severe form of DIC which results in extensive areas of skin necrosis usually over the extremities and buttocks. It is most frequently found in the setting of sepsis, specifically with encapsulated organisms, placing asplenic patients at high risk. Typical laboratory findings in DIC include elevated D-dimer, prolonged clotting times, thrombocytopenia and low fibrinogen; however, the balance between thrombin generation, clotting factor depletion and thrombolysis can lead to variable results. In this case, the diagnosis of DIC was originally questioned given the elevated fibrinogen level, resulting in a delay in starting anticoagulation. Subsequent recognition of the clinical exam finding of purpura fulminans led to initiation of treatment with later pathologic confirmation on skin biopsy. This case highlights the importance of recognizing the clinical exam finding of retiform purpura as this will guide the differential diagnosis of a patient with sepsis and a rash.

RETROPERITONEAL FIBROSIS AND PERIAORTITIS, IS THIS AN IgG4-RELATED DISEASE? Laila Shiekh Sroujeh¹; Alexis C. Haftka¹; Iyer Gayathri².

¹Henry Ford Hospital, Detroit, MI; ²Henry Ford Hospital, Detroit, MI. (*Tracking ID #1935038*)

LEARNING OBJECTIVE 1: Identify IgG4 related systemic disease as a disease of multiorgan involvement that's been newly recognized

LEARNING OBJECTIVE 2: Identify retroperitoneal fibrosis extending to iliac vessels as a cause of compression and venous stasis followed by DVT/PE

CASE: A 50 year old male patient with past history of hypertension, CKD and chronic lymphedema presented to the ED complaining of shortness of breath, chest pain, fever and cough. In the ED he was febrile, tachypnic and tachycardic. His labs revealed a white cell count of 14.7. Physical examination was unremarkable except for chronic edema in bilateral lower extremities. CXR revealed airspace disease that was questionable for pneumonia. He was started on antibiotics and was admitted as a case of CAP. In addition to his respiratory symptoms, he was complaining of severe abdominal pain. Abdomen CT scan was obtained and revealed a large pericardial effusion, retroperitoneal fibrosis and left hydronephrosis. A 2D echo was then obtained and revealed concern for cardiac tamponade in addition to aortic root and ascending aortic dilation. Pericardiocentesis was then performed with removal of 410 ml of serosanguinous fluid, with eventual drainage of an additional 160 ml by pericardial drain post procedure. Chest CT scan was obtained to evaluate the aorta and it confirmed aortic root and ascending aorta dilatation. Chest CT scan also revealed multiple bilateral segmental and subsegmental pulmonary emboli. Heparin drip was started. Bilateral lower extremity dopplers were obtained and were positive for an acute left peroneal DVT. Outside records were obtained showing presence of retroperitoneal fibrosis and history of aortic dissection and aneurysm back in 2010. In light of all these findings diagnosis of IgG4 related disease was a concern. Rheumatology was consulted and they thought that with the retroperitoneal fibrosis and history of aortic dissection and aneurysm back in 2010, IgG4 disease is the likely etiology of extensive fibrosis with peri-/aortic involvement. A biopsy of the retroperitoneal fibrosis was done and was sent for special staining for IgG4. Results of the biopsy are still pending. Patient was started on high dose steroids (1 mg/kg) and was discharged home with a plan to follow up with rheumatology for steroid tapering and repeat CT scan as outpatient pending biopsy results.

DISCUSSION: IgG4 related disease is a newly recognized multisystem disease. It has been described in every organ system: the biliary tree, salivary glands, periorbital tissues, kidneys, lungs, lymph nodes, meninges, aorta, breast, prostate, thyroid, pericardium, and skin. Many medical conditions that have long been viewed as conditions confined to single organs are now acknowledged to fall within the Spectrum of IgG4-Related Disease. For example Mikulicz's syndrome (affecting the salivary and lacrimal glands), Küttner's tumor (affecting the submandibular glands), Riedel's thyroiditis, Retroperitoneal fibrosis (Ormond's disease) Periaortitis and periaorteritis to name a few. These different conditions were previously thought to be unrelated. The pathogenesis of IgG4-related disease (IgG4-

RD) is poorly understood. Diagnosis of IgG4-related disease is defined by both elevated serum IgG4 (>1.35 g/l) and histopathological features, including storiform fibrosis, obliterative phlebitis, and lymphocyte and IgG4+ plasma cell infiltration (IgG4+ plasma cells/IgG+ plasma cells ratio >50 % on a highly magnified slide); tissue eosinophilia may also be present. Glucocorticoids are typically the first line of therapy. They appear to be effective in the majority of patients but disease flares are common. Azathioprine, mycophenolate mofetil, and methotrexate are used frequently as glucocorticoid-sparing agents or remission-maintenance drugs after glucocorticoid induced remissions. For patients with recurrent or refractory disease, B-cell depletion with rituximab appears to be a useful approach. Additionally, there have been case reports and studies about the development of lower extremity DVTs leading to PEs in patients with retroperitoneal fibrosis due to involvement of iliac vessels and in those cases treatment was steroids in addition to anticoagulation.

RETROPERITONEAL HEMORRHAGE ARISING FROM A RENAL MASS: A CASE REPORT Jean Canham. University of North Dakota School of Medicine and Health Sciences, Bismarck, ND. (*Tracking ID #1924635*)

LEARNING OBJECTIVE 1: Recognize the possibility of spontaneous hemorrhage as a complication of anticoagulation in the setting of renal cell carcinoma.

CASE: A 91 year old female with a past medical history significant for stasis dermatitis, lower extremity edema, and a known left renal mass presented to the emergency department with complaints of a swollen and painful right leg of 1 day's duration. The renal mass had been previously detected on a CT scan, but the patient and her family had declined any work-up or treatment for it because of her advanced age. Physical exam revealed 3+ edema and redness to the mid-thigh of the right lower extremity. Initial labs included a CBC demonstrating WBC of 11.6 and a microcytic anemia with a hemoglobin of 10.5. Doppler ultrasound of the right lower extremity revealed a large occlusive thrombus extending from the common femoral to the popliteal vein. She was admitted and started on therapeutic heparin and warfarin. The patient initially improved on anticoagulation therapy, but 36 h after starting heparin she began to experience left flank pain. A drop in her hemoglobin was noted. An abdominal CT was performed which revealed internal hemorrhage of the left renal mass, which appeared to represent likely renal cell carcinoma. A large amount of blood and hematoma were seen in the left retroperitoneum. An extensive tumor thrombus extending from left renal vein to the inferior vena cava was also seen. Heparin was immediately stopped and vitamin K was administered. Despite these measures, her hemoglobin continued to drop and she became hypotensive. Resuscitative efforts were initiated, but her hemodynamics failed to improve and the patient expired.

DISCUSSION: Renal cell carcinoma is known to be highly vascular, posing bleeding complications in surgical settings. However, little is known about the risk of spontaneous hemorrhage in RCC when anticoagulation therapy is initiated. Anticoagulation brings with it the inherent risk of bleeding, but this case forces us to ask if patients with renal cell carcinoma are particularly vulnerable to catastrophic spontaneous hemorrhage when anticoagulated.

REVENGE OF VIRCHOW'S TRIAD: MAY-THURNER SYNDROME Megan Sisk; Paula Wichienkuer; Mark Gibson. PPMC, Portland, OR. (*Tracking ID #1896509*)

LEARNING OBJECTIVE 1: May-Thurner syndrome should be considered in cases of DVT in young patients, unprovoked clot, or extensive proximal clot burden.

LEARNING OBJECTIVE 2: Definitive treatment should be pursued if the patient is symptomatic from complications related to May-Thurner.

CASE: A 59 year old man presented to the ED with acute onset of left lower extremity swelling. His leg was normal at 6 am and by noon he had significant swelling, pain, and was unable to ambulate. On physical exam he had 3+ edema to the thigh, cyanosis, and the dorsal pedis pulse could be found using Doppler only. Ultrasound showed extensive occlusive clot burden extending from the left common femoral, profunda femoris, and proximal femoral veins. Due to concern for limb ischemia, he was taken for catheter directed thrombolysis. CT imaging for preparation of vascular access showed occlusive clot and compression of the left common iliac vein consistent with May-Thurner Syndrome. After 24 h of thrombolysis, the catheter was removed and angioplasty with stent placement of the left common iliac vein was performed. By day 4, the patient was discharged with complete resolution of his symptoms.

DISCUSSION: In 1851, Virchow first proposed the idea that a LLE clot could be caused by this compression of the vein by the artery. In 1957, May and Thurner confirmed this idea and the principles of Virchow's Triad through autopsy studies where they noted effects of endothelial damage and turbulent flow. May-Thurner Syndrome leads to DVT of the left lower extremity due to the narrowed turbulent flow caused by the compression and repetitive

trauma on the left common iliac vein. The vein traverses between the right common iliac artery where it can be compressed against the spine at L5. Additionally, the constant pulsatile force leads to fibrosis of the vein wall. May-Thurner Syndrome is being identified more often due to an increase in catheter directed endovascular treatments. While findings are often found incidentally during CT or ultrasound, venogram remains the gold standard. Treatment typically involves angioplasty with stent placement to support the vein from further compression. The exact length of anticoagulation and recommendations regarding prophylactic stenting remain controversial. This case demonstrates the importance of evaluation for additional causes in an unprovoked DVT. May-Thurner syndrome should be considered in cases of DVT in young patients, unprovoked clot, or extensive proximal clot burden. Definitive treatment should be pursued if the patient is symptomatic from complications related to May-Thurner.

REVERSIBLE ENCEPHALOPATHY IN AN ELDERLY PATIENT WITH END-STAGE RENAL DISEASE Naoki Misumida; Krupa Majmundar. Beth Israel Medical Center, New York, NY. (*Tracking ID #1925564*)

LEARNING OBJECTIVE 1: Recognize cefepime-induced encephalopathy as a cause of altered mental status in patients with chronic kidney disease.

LEARNING OBJECTIVE 2: Review the typical clinical course of cefepime-induced encephalopathy.

CASE: A 93 year-old female with a history of end-stage renal disease on hemodialysis presented from nursing home with a five-day history of shortness of breath and dry cough. Her blood pressure was 131/66 mmHg, heart rate was 65/min and SpO₂ was 92 % on room air. She was afibrile. Her cognitive function was unchanged from her baseline and neurological examination was unremarkable. She had coarse crackles on right lung base. Laboratory data did not show leukocytosis. Chest X-ray showed right lower lobe infiltration. She was admitted for suspected healthcare-associated pneumonia and fluid overload, and treated with cefepime (2 g/day), vancomycin (500 mg, once) and azithromycin (500 mg/day). Hemodialysis was performed on the following day and her dry weight was lowered. After hemodialysis, her respiratory condition improved and the infiltration on chest X-ray resolved. All of the antibiotics were discontinued based on her clinical improvement on the second day. On the third day, she became confused with temporo-spatial disorientation and expressive dysphasia. Extensive work-up including laboratory tests, head CT scan and brain MRI did not reveal the cause of acute mental status change. Metabolic encephalopathy and central nervous system infection were considered and excluded. She started to improve gradually on the fifth day and returned to her baseline level of mental status on the sixth day. Because of the temporal association of the symptom onset and drug administration, as well as complete improvement after drug discontinuation, a final diagnosis of cefepime-induced encephalopathy was made. Patient was discharged without any sequelae.

DISCUSSION: Cefepime is a fourth-generation cephalosporin used to treat severe infection, which is mainly excreted by the kidney. Cefepime-induced encephalopathy has been sporadically reported worldwide over the last decade. The neurotoxic side effects are likely secondary to suppression of inhibitory neurotransmission mediated through gamma-aminobutyric acid-A receptor. A review of 42 cases of cefepime-induced encephalopathy most commonly observed confusion with temporo-spatial disorientation (96 %), myoclonus (33 %) and seizures (13 %) in affected patients. Almost all affected patients have had renal failure and the dose of cefepime was relatively higher for the level of renal failure. In our case, the dosage of cefepime should have been adjusted more precisely according to the creatinine clearance even though it was stopped on the second day. The latency varied between 1 to 10 days. Symptoms usually regress within 2 to 7 days after stopping cefepime. In conclusion, physicians need to be aware of this potential adverse effect although it is uncommon. To avoid this complication, dose adjustment should be undertaken in patients with chronic kidney disease.

REVERSIBLE MYELONEUROPATHY IN A YOUNG WOMAN Ximena A. Levander¹; Traci A. Takahashi^{3,1}; Maxwell Ma². ¹University of Washington, Seattle, WA; ²University of Washington, Seattle, WA; ³VA Puget Sound Healthcare System, Seattle, WA. (*Tracking ID #1928649*)

LEARNING OBJECTIVE 1: Diagnose B12 deficiency and distinguish it from other etiologies of myeloneuropathy.

LEARNING OBJECTIVE 2: Recognize nitric oxide abuse as a potential cause of B12 deficiency.

CASE: A 35-year-old woman presented to clinic with 1 week of bilateral upper and lower extremity numbness. The paraesthesia occurred suddenly and felt like her extremities "fell asleep but never woke up." She also reported difficulty ambulating,

requiring a cane to walk even short distances. Symptoms had neither improved nor worsened since onset. Review of systems was notably negative for vision changes, headaches, new neck or back pain, and urinary or bowel incontinence. She denied any recent infections, sick contacts, travel, injury or immunizations. Medical history was significant for PTSD, depression, chronic pain, and cervical and lumbar surgeries. Her medications included morphine, etodolac, citalopram, lorazepam and a multi-vitamin. Family history was unremarkable. She had a 20-pack-year smoking history but denied any alcohol or illicit drug use. On physical exam she had normal vital signs except for a BMI of 30. Her neurological exam was notable for decreased pinprick sensation in a stocking and glove distribution bilaterally and hyper-reflexia in the lower extremities. Her gait exam demonstrated spasticity and sensory ataxia such that she was unable to ambulate unassisted. The neurology service admitted her and initial laboratory results were notable for normal electrolytes and a slight normocytic anemia. She had normal TSH and copper levels. Her RPR, treponemal antibody and ANA panel were negative. Her B12 level was 253 pg/mL (normal >211 pg/mL). Both her methylmalonic acid and homocysteine were elevated. MRI brain was unremarkable. MRI C and T spine demonstrated non-contiguous bilateral dorsal column lesions with high T2 signal that was non-enhancing with contrast. On further questioning, she revealed almost daily use of inhaled nitrous oxide for the past few weeks. She was started on cobalamin 1,000 mcg IM daily for 6 doses then switched to 1,000 mcg PO daily for 2 months. She was discharged to rehab and advised to stop using nitrous oxide. Within 1 month her ataxia resolved and she only had minor residual sensory deficits. In 2 months her B12 level was 1,092 pg/ml.

DISCUSSION: Nitrous oxide is an inhaled anesthetic used in minor medical and dental procedures. Its recreational use started shortly after its discovery in the eighteenth century, when English chemist Humphry Davy demonstrated its psychogenic effects. Today, nitrous oxide continues to be an inhaled drug of abuse, obtained from medical settings or from whipped cream cartridges, commonly referred to as whippets. The toxicity of nitrous oxide is thought to be caused by irreversible binding of the cobalt ion in cobalamin, rendering it unable to function as a coenzyme with methionine synthase. The enzymatic reactions catalyzed by methionine synthase are critical for DNA synthesis and for regeneration of carbon donor groups. Primary care providers need to be aware of the medical complications of nitrous oxide abuse since patients may present to clinic with its sequelae and may not readily volunteer information regarding abuse on social history screening. The differential diagnosis for our patient's initial presentation was extensive and most worrisome for anatomic injury given her spinal surgical history but also included autoimmune conditions, malignancies, nutritional deficiencies and infections. Her MRI findings were consistent with many conditions on this differential and a lumbar puncture with cerebrospinal fluid analysis was the next step in evaluation. However, the patient later revealed her substance abuse history deeming this diagnostic procedure unnecessary. A high degree of suspicion was required given she denied any substance abuse both in clinic and to the initial inpatient team. Case reports of nitrous oxide toxicity have been described in toxicology, neurology, emergency medicine and anesthesiology texts and highlight patients presenting with myeloneuropathy and/or megaloblastic anemia. Most patients reported prolonged nitrous oxide abuse and had true B12 deficiency, unlike our patient who had a borderline low normal B12 level. Because of this lab value and her well-nourished appearance, the inpatient team tested her methylmalonic acid and homocysteine levels, which came back elevated. Given her presenting symptoms, MRI findings and the lab results, as well as her response to high dose B12 repletion, nitrous oxide had caused an effective B12 deficiency. Fortunately, symptoms of nitrous oxide abuse related cobalamin deficiency often resolve upon stopping nitrous oxide use and aggressively repleting B12.

REVERSIBLE POSTERIOR LEUKOENCEPHALOPATHY SYNDROME: MRI SAYS IT ALL Charu Ramchandani; Waleed Quwatli; Chris Burke. Unity Health System, Rochester, NY. (*Tracking ID #1939239*)

LEARNING OBJECTIVE 1: Recognizing the clinical and radiologic findings in reversible posterior leukoencephalopathy syndrome for the timely initiation of treatment.

CASE: A 28 year old African American female presented to the hospital with a constant headache in the frontal region, 9/10 in severity not responding to over the counter pain medications. The pain was associated with fever, nausea, right sided neck pain, blurred vision and photophobia. She was seen by her primary care doctor a week ago who prescribed her amoxicillin for sore throat. Her past medical history was significant for viral meningitis in 2006 and atopic eczema. There was no significant family history. She denied any recent sick contacts or travel outside the country. On physical examination, vital signs were stable, oral examination revealed mild pharyngeal erythema, and pain on flexion of the neck. There was no associated photophobia, vesicular rash or any focal neurologic

deficits. Laboratory values were remarkable for white blood cell count 17000/cu mm; Cerebro-spinal fluid (CSF) showed - 8/cu mm of red blood cell, 15/cu mm WBC with 26 % segmented cells and no organisms on gram stain. CSF protein and glucose were 17.5 and 54.5 mg/dl respectively. Head Computed tomography (CT) scan with contrast was normal. Patient was seen by the infectious disease concerning for meningitis for which she was started on Vancomycin, Ceftriaxone and Acyclovir with a pending CSF culture and polymerase chain reaction (PCR) for Herpes simplex virus (HSV) 1 and 2. Three days after the admission, patient continued to have persistent headache, nausea, vomiting and her antibiotics were stopped because PCR for HSV and CSF culture came back to be negative. On the 7th day, she experienced two episodes of generalized tonic clonic seizure along with hypertensive urgency/persistently elevated blood pressure readings. Immediately, she was started on Keppra for seizures and Nicardipine drip for her blood pressure control and was taken for a repeat CT scan. Repeat CT head showed decreased attenuation within the right parieto-occipital region which was suspicious for an acute infarct. Magnetic resonance imaging (MRI) showed numerous areas of patchy ill-defined high T2 and flair signal in bilateral supra- and infra-tentorial white matter with effacement of overlying sulci and fissures suggestive of reversible posterior leukoencephalopathy. Over the next few days, Nicardipine was stopped and she was started on oral Labetalol. After controlling for her high blood pressure, her headache and blurry vision resolved, and she was discharged home on a regimen of oral Labetalol. A repeat MRI month after the discharge showed resolution of the high T2 flair signal in bilateral supra- and infra-tentorial white matter along with continued improvement in her symptoms.

DISCUSSION: Reversible posterior leukoencephalopathy syndrome (RPLS) is a clinic-radio-neurologic entity presenting as headache, visual symptoms, seizure with accompanying symmetrical white matter edema in posterior cerebral hemispheres on MRI brain. Hypertensive encephalopathy, eclampsia and use of cytotoxic or immunosuppressive drugs are the most common causes of RPLS. Etiology remains unclear, but some of the proposed mechanisms which could lead to RPLS are: (1) failure of auto-regulation of cerebral blood flow in severe hypertension leading to cerebral hyperperfusion and breakdown of blood brain barrier; (2) damage of vascular endothelium with cytotoxic agents leading to disruption of blood brain barrier and vasogenic edema. Primary involvement of the parieto-occipital region is not well understood. MRI is the best diagnostic modality to support the diagnoses of RPLS. Treatment consists of rapid lowering of blood pressure and discontinuation of any offending agent as mentioned earlier. In this case report, the patient was neither pregnant nor on any immunosuppressive drugs and the most likely underlying etiology/triggering event could be the rapid elevation of blood pressure on an unrecognized essential hypertension. Improvement of her symptoms with control of hypertension and resolution of MRI findings further supports the diagnosis of RPLS. RPLS can be easily confused with a stroke/stroke mimic based on CT scan findings and MRI should be obtained to help differentiate the diagnoses. Differentiating RPLS from stroke is very important for early management strategies in both the conditions. RPLS is a reversible condition if recognized early and treated promptly. It is essential for the internists to recognize this entity early to avoid long term complications in patients presenting in a similar fashion.

RIBBON-SHAPED STOOL IS NOT ALWAYS CANCER Maryam Sattari; Ravneet Bajwa; Robert S. Eggerman. University of Florida, Gainesville, FL. (*Tracking ID #1935612*)

LEARNING OBJECTIVE 1: Recognize signs and symptoms of retroperitoneal fibrosis

LEARNING OBJECTIVE 2: Become familiar with diagnosis, management, and treatment options for retroperitoneal fibrosis
